DISCLAIMER
Care has been taken to confirm the accuracy of the information present and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at **(800) 638-3030** or fax orders to **(301) 223-2320**. International customers should call **(301) 223-2300**.

Visit Lippincott Williams & Wilkins on the Internet: http://www.lww.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6:00 pm, EST.

DEDICATION

We dedicate this book to our wives and families, whose tolerance, love and support sustained us throughout this endeavor; to our colleagues, from whom we have learned so much; to our chapter authors, who have given so much of themselves to produce this new edition; and to students everywhere, upon whose curiosity and energy the future of medical science depends.

This 7th edition is also specially dedicated to the memory of Raphael Rubin, MD, who was associate editor of the 4th edition and who co-edited the 5th and 6th editions. There are no words to express either our happiness that he was part of our lives, or our feelings of loss at his untimely death. We are grateful to him for his courage and grace in the face of terrible disease and for his essential goodness, which permeated everything he did.

PREFACE

Students and instructors have complementary roles and needs as participants in the educational process. This book is intended to help modern medical students learn—and to help instructors teach—pathology as a foundation of clinical medicine.

So much has happened to change what and how medical students are taught. Medicine is rapidly being transformed, in part by the pace of scientific advance, and in part by the world around us. These forces reshape the subject matter and how it is presented. They also require that we consider carefully what we expect students of medicine to master.

Thus, this book's purpose is to teach pathology and disease pathogenesis to medical students. It is not geared to residents or fellows in pathology, nor to bench scientists. ***Our goal is to prepare future medical practitioners—cardiologists, pediatricians, gerontologists and so forth—for their specialties, not for ours.*** We do this by helping them to understand how diseases happen and how they appear. We provide a foundation on which future clinicians of all specialties can build and, we hope, a sense of excitement for medical advances yet to come.

Perhaps the hardest—and at the same time the most important—challenge facing us in preparing this textbook is determining what should not be stressed, that is, what is better left for more specialized texts in biochemistry, molecular biology, pathology subspecialities and so on. Even as we try to avoid such superfluities as unproven hypotheses, abstruse discussions, medical minutiae and details of scientific experiments that fill some other textbooks, the amount of information remains overwhelming. We therefore applied a filter throughout this book, a question we asked both in writing our own chapters (Chapters 1, 5 and 8) and in editing the work of our superb contributors: what do students of medicine *need* to know in order to be good doctors, to prepare them for a lifetime of professional learning and to understand how advances in the medical sciences will affect their patients?

We stress the interrelatedness of the many medical disciplines. Traditional pathology texts have a section of basic principles, followed by a section covering each of the several organs in turn. This is no longer enough. Many processes and diseases affect multiple organ systems and are best understood and taught as such. It does not suffice, for example, only to describe aging as a series of separate effects on cells in culture or on the brain or on the cardiovascular system. As we can attest from personal experience, aging—apart from the very dubious wisdom that some people believe accompanies it—affects almost everything an individual does and can do. Its impact on one organ system is inextricably linked to its effects on others. It, and similar processes that affect multiple organ systems, is thus best approached against the background of the whole person, not just individual organs.

Accordingly, we have added a new section on systemic conditions: processes that affect whole human beings, not just their kidneys, lungs or joints. These include new chapters on aging (Chapter 10), autoimmune diseases (Chapter 11), sepsis (Chapter 12) and pregnancy (Chapter 14), plus amyloidosis (Chapter 15) and obesity, diabetes and metabolic syndrome (Chapter 13), which appeared in past editions. These are among the most important processes that doctors will have to understand in approaching patients. These integrated presentations should greatly facilitate how these topics are taught and, hopefully, understood. Organ-specific chapters still cover respective manifestations of these processes.

Understanding systemic processes is thus fundamental to this book and our approach to presenting pathology. Pathology is not just a compilation of burdensome, isolated facts or abstruse and arcane pathways to be memorized and promptly forgotten. It is the drama of human frailty and mortality, which we present as concepts to understand and principles to apply.

We also include a new chapter, which we feel adds excitement to the study of pathology: pathology in forensic investigation. This addition illustrates the relevance and sophistication of pathology as it interfaces with patient care and relates to the world outside of medicine.

Education in general is changing. Traditional, printed textbooks are being replaced by texts viewed on portable devices such as tablet computers. These versatile devices offer many more opportunities for interactive learning, including self-quizzing, animated illustrations, virtual microscopy, networking and many more. Many such ancillaries are part of the instructional package that begins with this textbook. Because students have become increasingly sophisticated and exacting, our presentations encompass the full range of instructional aids and are based on the principle that pathology and pathogenesis are inseparable and are fundamental to all clinical medicine.

These teaching adjuncts underscore the fact that ***the real challenge is to identify what students should understand, and then decide how best to aid that understanding***—not to apply the maximum number of electronic (or other) embellishments, or to use these tools to add yet more facts to the mountains of information that already burden students. Appreciating what a good doctor must understand, and the limits of students' time and energy, we have not tried to be comprehensive, preferring instead to be useful.

Consequently, this new edition is much different from its predecessors. The reorganization of this textbook, described above, is an attempt to help students learn about complex issues in modern medicine in a more unified way. Many chapters are rewritten or extensively revised. New authors in Chapters 6, 10, 11, 12, 14, 19, 20, 26, 28 and 34 join the outstanding authors whose continuing contributions are so valuable, and exemplify this goal. The diligent and selfless work of all these authors is the backbone of this textbook.

We emphasize what is understood but also describe the limits of our current knowledge. Hopefully, inquisitive minds will find in this textbook a springboard to further exploration, and students and colleagues will share the excitement of discovery that we have been privileged to experience in our education and careers.

What is the role of a textbook in an era when most medical school courses prepare their own syllabi, when online information and other resources are abundantly available to students and when many faculty may feel their time and energy are more profitably invested in other pursuits? This volume was designed to gather experts from around the world, to have them present to students a thorough but digestible understanding of how diseases occur and to provide for faculty an educational program that facilitates instruction. *Rubin's Pathology* is characterized by its stylistic uniformity and readability, its strikingly visual presentation, its focus on clinical relevance in all material presented, the dedication of its authors to maintaining the currency of the material and the desire of the entire production team to providing textual material and instructional ancillaries that help students to learn and that help teachers to teach. The determination to achieve these goals is, we believe, an important contribution to medical education that can only be provided in this format.

This is the 25th anniversary of the first edition of this textbook, and the occasion lends itself to recounting one of the most amusing anecdotes from editions past. Thus, we recall that one chapter author for the first edition had prepared elaborate hand-drawn figures ready to be sent for rendering by the illustrator. One night, he fell asleep on the couch, with his precious illustrations scattered on the surrounding floor. It just so happened that he was paper-training a new puppy at the time. Unaware of the significance of the papers, and not appreciating their contents, the puppy dutifully used the papers as it had been trained. The author, when he awoke, wiped the results of the dog's training from the sheets of paper and sent them to us. Picture our perplexity when we received a sheath of papers decorated with brown smears of some unknown type!! We only found out the reason later.

Finally, we remember with humility and deep enduring affection Raphael Rubin, a previous coeditor of *Rubin's Pathology*. His death in September 2011, at age 55, was an incalculable professional and personal loss for us both. We have tried to memorialize Raph in our dedication of this 7th edition. He is with us in our hearts, and we trust that this new edition would have made him proud.

David S. Strayer, MD, PhD
Emanuel Rubin, MD
Philadelphia, 2014

ACKNOWLEDGMENTS

Many dedicated people, too numerous to list, provided insight that made this 7th edition of *Rubin's Pathology* possible. The editors would like especially to thank the managing and editorial staff at Lippincott Williams & Wilkins and in particular Sirkka Howes and Stacey Sebring whose encouragement and support throughout all phases of this endeavor have not only touched us greatly personally but also been a key to the successful publication of this text and its ancillaries.

The editors also acknowledge contributions made by our colleagues who participated in writing previous editions and those who offered suggestions and ideas for the current edition.

Pathology ***is the study of structural and functional abnormalities that manifest as diseases of organs and systems.*** Classic theories attributed disease to imbalances or noxious effects of "humors." In the 19th century, Rudolf Virchow, often called the father of modern pathology, proposed that injury to cells, the smallest living units in the body, is the basis of all disease. To this day, this concept underlies all of pathology.

To understand cell injury, it is useful to consider how cells sustain themselves in a hostile environment.[1] To remain viable, the cell must generate energy. This process requires it to establish a structural and functional barrier between its internal milieu and the outside. The **plasma membrane** does this in several ways:

- It maintains a constant internal ionic composition against very large chemical gradients between interior and exterior compartments.
- It selectively admits some molecules while excluding or extruding others.
- It provides a structural envelope to contain the cell's informational, synthetic and catabolic constituents. Thus, it creates an environment to house signal transduction molecules that communicate between each other and between the external and internal milieus.

Cells must also be able to adapt to fluctuating environmental conditions, such as changes in temperature, solute concentrations, oxygen supply, noxious agents and so on. The evolution of multicellular organisms eased the precarious lot of individual cells by establishing a controlled extracellular environment, in which temperature, oxygen availability, ionic content and nutrient supply remain

[1]Facts can only be established by observation (i.e., without imposing an external logical framework suggesting that certain functions or abilities evolved in order to achieve a particular goal). However, teleology—the study of design or purpose in nature—can be a useful tool to help in framing questions, even though it is not accepted as a legitimate part of scientific investigation.

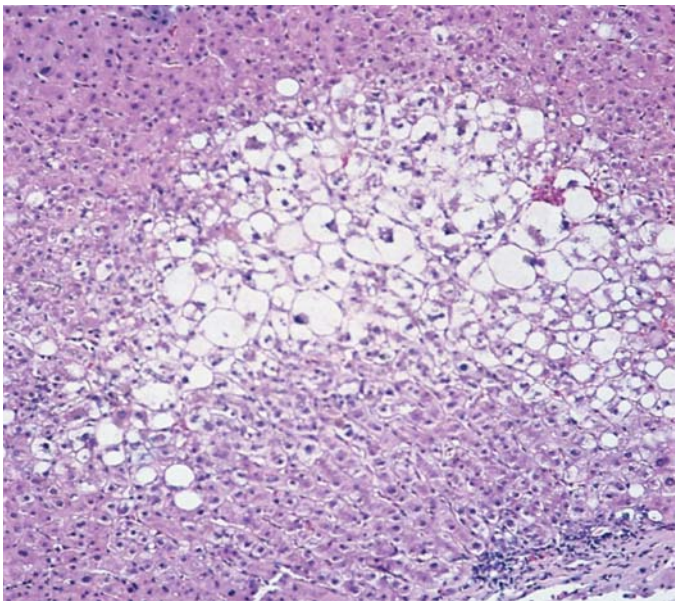

FIGURE 1-1. Hydropic swelling. The liver of a patient with toxic hepatic injury shows severe hydropic swelling in the centrilobular zone. Affected hepatocytes exhibit central nuclei and cytoplasm distended by excess fluid.

relatively constant. It also permitted the luxury of cell differentiation for such diverse functions as energy storage (glycogen in hepatocytes, lipids in adipocytes), communication (neurons), contractile activity (heart muscle), protein synthesis for export (pancreas, endocrine cells), absorption (intestine) and defenses from foreign invaders (immune system).

These adaptations notwithstanding, changes in an organism's internal and external environments strain the tranquility of its constituent cells. ***Patterns of response to such stresses make up the cellular basis of disease.*** If an injury exceeds a cell's adaptive capacity, that cell dies. A cell exposed to persistent sublethal injury has limited available responses, expression of which we interpret as cell injury. ***Thus, pathology is the study of injury to cells and organs and of their capacity to adapt to such injury.*** The science of disease (pathology) is thus an application of normal biological principles.

Mechanisms and Morphology of Cell Injury

All cells have efficient mechanisms to deal with shifts in environmental conditions. Thus, ion channels open or close, harmful chemicals are detoxified, metabolic stores such as fat or glycogen may be mobilized and catabolic processes lead to the segregation of internal particulate materials. When environmental changes exceed the cell's capacity to maintain normal homeostasis, we recognize acute cell injury. If the stress is removed in time or if the cell can withstand the assault, the damage is reversible, and complete structural and functional integrity is restored. For example, when circulation to the heart is interrupted for less than 30 minutes, all structural and functional alterations prove to be reversible. The cell can also be exposed to persistent sublethal stress, as in mechanical irritation of the skin or exposure of the bronchial mucosa to tobacco smoke. Cells have time to adapt to reversible injury in a number of ways, each of which has a morphologic counterpart. On the other hand, if the stress is sufficiently severe, irreversible injury leads to cell death. The moment when reversible injury becomes irreversible injury, the "point of no return," is not known at present.

Hydropic Swelling Is a Reversible Increase in Cell Volume

Hydropic swelling is characterized by a large, pale cytoplasm and a normally located nucleus (Fig. 1-1). The greater volume is caused by increased water content and reflects acute, reversible cell injury. It may result from such varied causes as chemical and biological toxins, viral or bacterial infections, ischemia, excessive heat or cold and so on.

By electron microscopy, the number of organelles is unchanged, although they appear dispersed in a larger volume. The excess fluid accumulates preferentially in cisternae of the endoplasmic reticulum, which are conspicuously dilated, presumably because of ionic shifts into this compartment (Fig. 1-2).

Hydropic swelling results from impairment of cellular volume regulation, a process that controls ionic concentrations in the cytoplasm. This regulation, particularly for sodium, involves three components: (1) the plasma

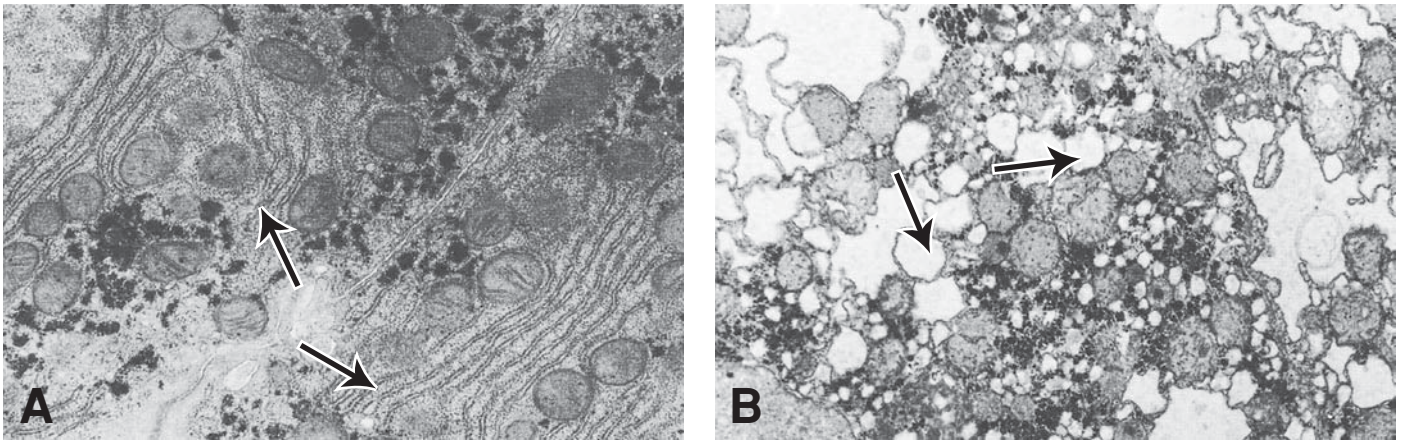

FIGURE 1-2. Ultrastructure of hydropic swelling. A. Two apposed normal hepatocytes contain tightly organized, parallel arrays of rough endoplasmic reticulum (*arrows*). **B.** Swollen hepatocytes show dilations of the cisternae of the endoplasmic reticulum by excess fluid (*arrows*).

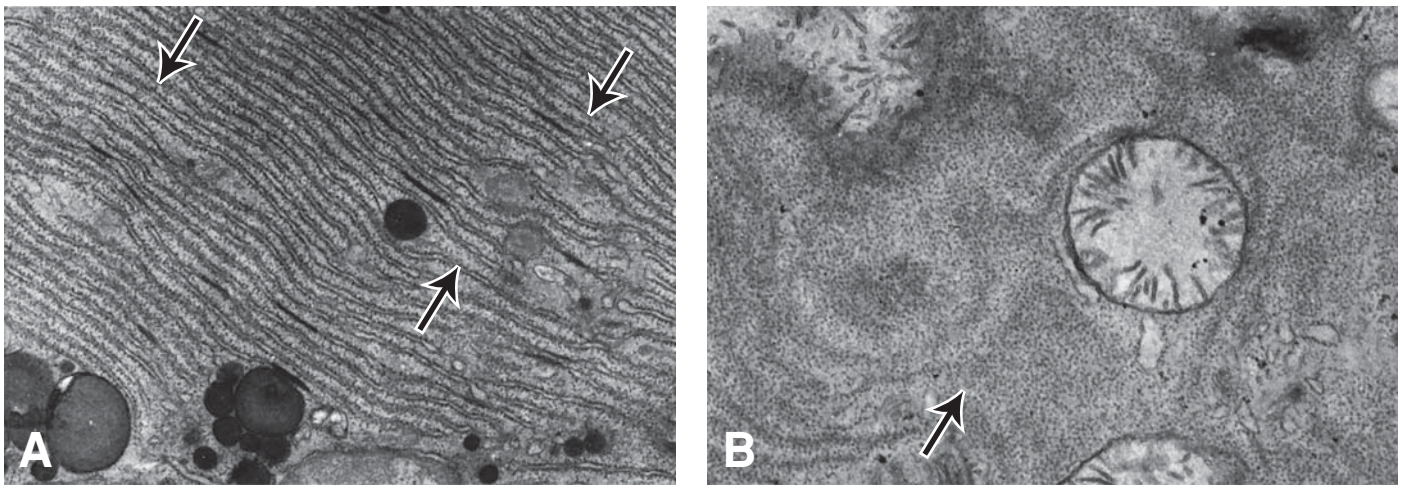

FIGURE 1-3. Disaggregation of membrane-bound ribosomes in acute, reversible liver injury. A. The profiles of endoplasmic reticulum (*arrows*) in a normal hepatocyte are studded with ribosomes. **B.** An injured hepatocyte shows detachment of ribosomes from the membranes of the endoplasmic reticulum and accumulation of free ribosomes in the cytoplasm (*arrow*).

membrane, (2) the plasma membrane sodium (Na^+) pump and (3) adenosine triphosphate (ATP). The plasma membrane prevents two gradient-driven ion flows: the flow of Na^+ from the extracellular fluid into the cell, and the flow of potassium (K^+) out of the cell. The barrier to sodium is imperfect and its relative leakiness permits some passive entry of sodium into the cell. To compensate for this intrusion, the energy-dependent, plasma membrane sodium pump (Na^+/K^+-ATPase), which is fueled by ATP, extrudes sodium from the cell. Noxious agents may interfere with this membrane-regulated process by (1) increasing plasma membrane permeability to Na^+, thereby exceeding the capacity of the pump to extrude the ion; (2) damaging the pump directly; or (3) interfering with ATP synthesis, and so depriving the pump of its fuel. In any event, accumulation of sodium in the cell leads to increased intracellular water to maintain isosmotic conditions. The cell then swells.

Subcellular Changes in Reversibly Injured Cells

- **Endoplasmic reticulum (ER):** The cisternae of the ER are distended by fluid in hydropic swelling (Fig. 1-2). Membrane-bound polysomes may disaggregate and detach from the surface of the rough endoplasmic reticulum (Fig. 1-3).
- **Mitochondria:** In some forms of acute injury, particularly ischemia (lack of adequate blood flow; see below), mitochondria swell (Fig. 1-4). This enlargement is due to dissipation of the mitochondrial energy gradient (membrane potential), impairing volume control.

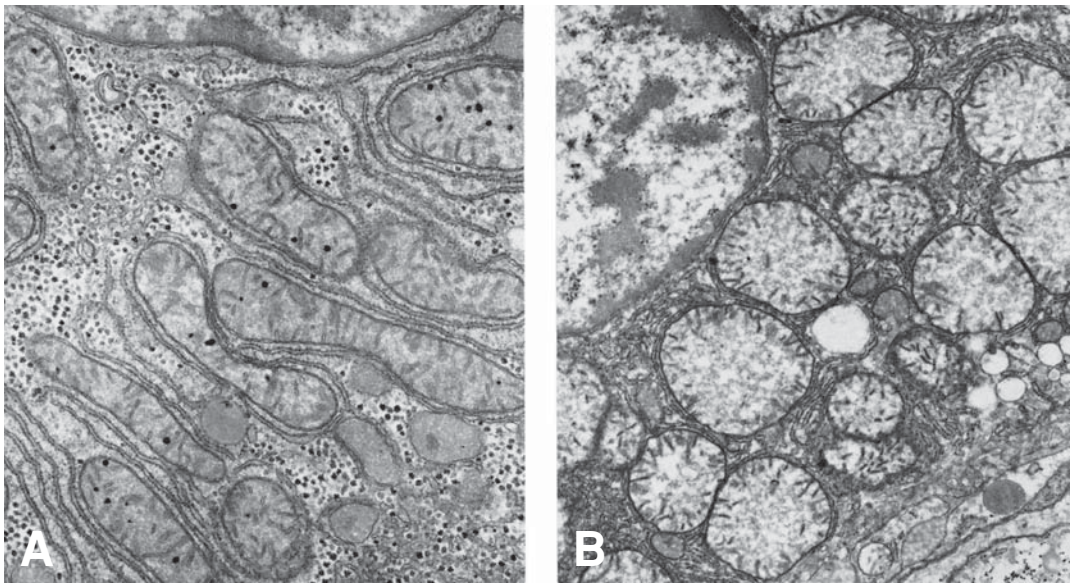

FIGURE 1-4. Mitochondrial swelling in acute ischemic cell injury. A. Normal hepatocyte mitochondria are elongated and display prominent cristae, which traverse the mitochondrial matrix. **B.** Mitochondria from an ischemic cell are swollen and round and exhibit a decreased matrix density. The cristae are less prominent than in the normal organelle.

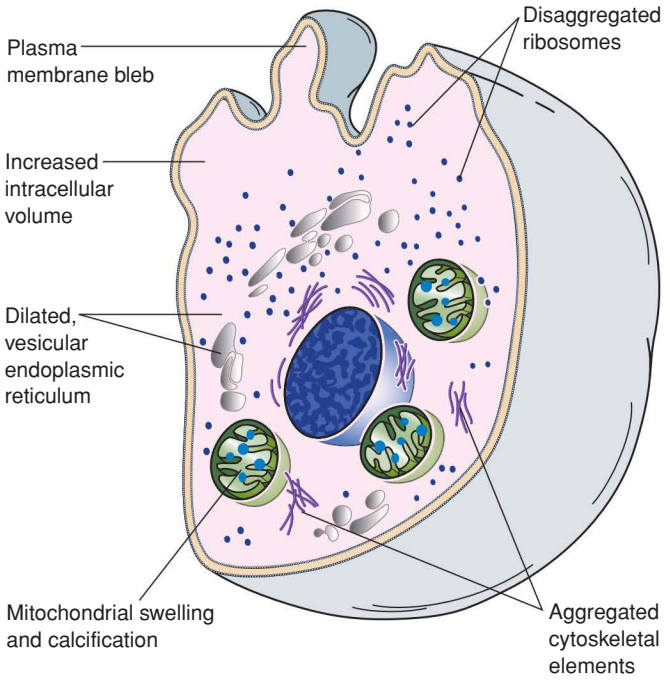

FIGURE 1-5. Ultrastructural features of reversible cell injury.

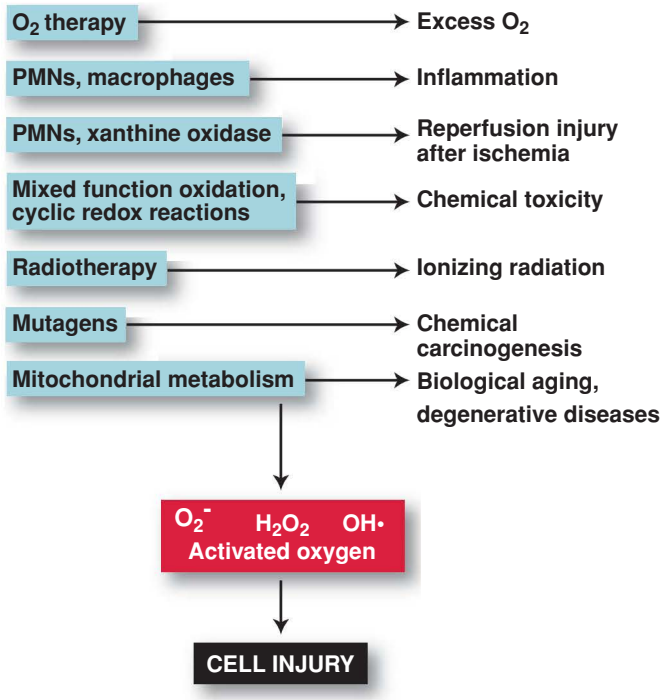

FIGURE 1-6. The role of activated oxygen species in cell injury. H_2O_2 = hydrogen peroxide; O_2 = oxygen; O_2^- = superoxide; $OH\bullet$ = hydroxyl radical; *PMNs* = polymorphonuclear neutrophils.

Amorphous densities rich in phospholipid may appear in the mitochondria, but these effects are fully reversible on recovery.

- **Plasma membrane:** Blebs of plasma membrane—that is, focal extrusions of the cytoplasm—are occasionally noted. These can detach from the membrane into the external environment without loss of cell viability.
- **Nucleus:** Reversible injury of the nucleus is reflected mainly by segregation of the fibrillar and granular components of the nucleolus. Alternatively, the granular component may be diminished, leaving only a fibrillar core.

These changes in cell organelles (Fig. 1-5) are reflected in functional derangements (e.g., reduced protein synthesis, impaired energy production). ***After withdrawal of the stress that caused the reversible cell injury, by definition, the cell returns to its normal state.***

Ischemic Cell Injury Results from Obstruction to the Flow of Blood

When tissues are deprived of oxygen, ATP cannot be produced by aerobic metabolism and is instead made inefficiently by anaerobic metabolism. Ischemia initiates a series of chemical and pH imbalances, which are accompanied by increased generation of injurious free radical species. The damage produced by short periods of ischemia tends to be reversible if circulation is restored. However, long periods of ischemia lead to irreversible cell injury and death. The mechanisms of cell damage are discussed below.

Oxidative Stress Is a Key Trigger for Cell and Tissue Injury and Adaptive Responses

For human life, oxygen is both a blessing and a curse. Without it, life is impossible, but some of its derivatives are partially reduced oxygen species that can react with, and damage, virtually any molecule they reach.

Reactive Oxygen Species

Reactive oxygen species (ROS) are the likely causes of cell and tissue injury in many settings (Fig. 1-6). Oxygen (O_2) has a major role as the terminal electron acceptor in mitochondria. It is reduced from O_2 to H_2O, and resultant energy is harnessed as an electrochemical potential across the mitochondrial inner membrane.

Conversion of O_2 to H_2O entails transfer of four electrons. Three partially reduced species, representing transfers of varying numbers of electrons, are intermediate between O_2 and H_2O (Fig. 1-7). These are O_2^-, superoxide (one electron); H_2O_2, hydrogen peroxide (two electrons); and $OH\bullet$, the hydroxyl radical (three electrons). Under physiologic conditions these ROS come from several sources, including leaks in mitochondrial electron transport and mixed-function oxygenases (P450). In addition, ROS are important cellular signaling intermediates. The major forms of ROS are listed in Table 1-1. Importantly, excessive ROS levels both cause and aggravate many disorders (Fig. 1-6).

Superoxide

The superoxide anion (O_2^-) is produced mainly by leaks in mitochondrial electron transport or as part of inflammatory responses. In the first case, the promiscuity of coenzyme Q (CoQ) and other imperfections in the electron transport chain allow transfer of electrons to O_2 to yield O_2^-. In phagocytic inflammatory cells, activation of a plasma membrane oxidase produces O_2^-, which is then converted to H_2O_2 and eventually to other ROS (Fig. 1-8). These ROS

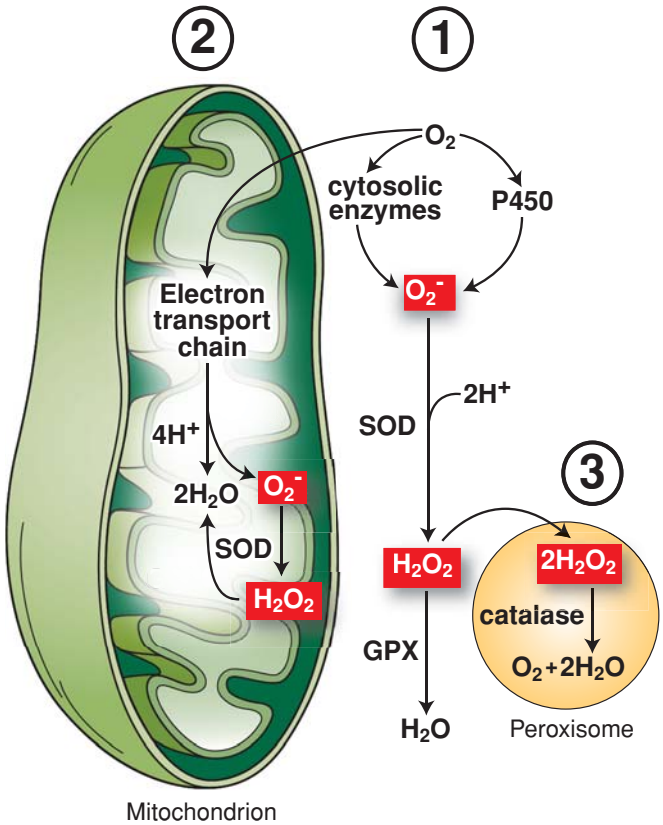

FIGURE 1-7. Mechanisms by which reactive oxygen radicals are generated from molecular oxygen and then detoxified by cellular enzymes. Circulating oxygen delivered to the cell may follow one of three paths: **1.** Molecular O_2 is converted to O_2^- in the cytosol. O_2^- is reduced to H_2O_2 by cytosolic superoxide dismutase (Cu/Zn SOD), and finally to water. **2.** O_2 enters the mitochondria, where inefficiencies in electron transport result in conversion of O_2 to O_2^-. This superoxide is rendered less reactive by further reduction to H_2O_2, via mitochondrial SOD (MnSOD). This H_2O_2 is then converted to H_2O by GPX. **3.** Cytosolic H_2O_2 enters peroxisomes where it is detoxified to H_2O by catalase. *CoQ* = coenzyme Q; *GPX* = glutathione peroxidase; H^+ = hydrogen ion; H_2O = water; H_2O_2 = hydrogen peroxide; O_2 = oxygen; O_2^- = superoxide; *SOD* = superoxide dismutase.

have generally been viewed as key effectors of cellular defenses that destroy pathogens, fragments of necrotic cells or other phagocytosed material (see Chapter 2). ROS acting as signaling intermediates elicit the release of proteolytic and other degradative enzymes, which are critical effectors of neutrophil-mediated destruction of bacteria and other foreign materials.

Hydrogen Peroxide

O_2^- anions are converted by superoxide dismutase (SOD) to H_2O_2. Hydrogen peroxide is also produced directly by a number of oxidases in cytoplasmic peroxisomes (Fig. 1-7). By itself, H_2O_2 is not particularly injurious, and it is largely metabolized to H_2O by catalase. However, when produced in excess, it is converted to highly reactive OH•. In neutrophils, myeloperoxidase transforms H_2O_2 to a potent radical, hypochlorite (OCl^-), which is lethal for microorganisms and, if released extracellularly, can kill cells.

Most cells have efficient mechanisms for removing H_2O_2. Two different enzymes reduce H_2O_2 to water: (1) catalase within peroxisomes and (2) glutathione peroxidase (GPX) in both the cytosol and mitochondria (Fig. 1-7). GPX uses reduced glutathione (GSH) as a cofactor in a reaction yielding oxidized glutathione (GSSG). Because it is membrane permeable, H_2O_2 generated in mitochondria affects the oxidant balance, not only in mitochondria but also in other cellular compartments.

TABLE 1-1
REACTIVE OXYGEN SPECIES (ROS)

Molecule	Attributes
Hydrogen peroxide (H_2O_2)	Forms free radicals via Fe^{2+}-catalyzed Fenton reaction Diffuses widely within the cell
Superoxide anion (O_2^-)	Generated by leaks in the electron transport chain and some cytosolic reactions Produces other ROS Does not readily diffuse far from its origin
Hydroxyl radical (OH•)	Generated from H_2O_2 by Fe^{2+}-catalyzed Fenton reaction The intracellular radical most responsible for attack on macromolecules
Peroxynitrite (ONOO•)	Formed from the reaction of nitric oxide (NO) with O_2^- Damages macromolecules
Lipid peroxide radicals (RCOO•)	Organic radicals produced during lipid peroxidation
Hypochlorous acid (HOCl)	Produced by macrophages and neutrophils during respiratory burst that accompanies phagocytosis Dissociates to yield hypochlorite radical (OCl^-)

Fe^{2+} = ferrous iron.

Hydroxyl Radical

Hydroxyl radicals (OH•) are formed by (1) radiolysis of water, (2) reaction of H_2O_2 with ferrous iron (Fe^{2+}) or cuprous copper (Cu^{1+}) (Fenton reaction) and (3) conversion of O_2^- with H_2O_2 (Haber-Weiss reaction) (Fig. 1-9). *The hydroxyl radical is the most reactive ROS*, and there are several mechanisms by which it can damage macromolecules.

Iron is often an active participant in oxidative damage to cells (see below) by virtue of the Fenton reaction. In a number of different cell types, H_2O_2 stimulates iron uptake and so increases production of hydroxyl radicals.

- **Lipid peroxidation:** The hydroxyl radical removes a hydrogen atom from unsaturated fatty acids in membrane phospholipids, a process that forms a free lipid radical (Fig. 1-10). The lipid radical then reacts with molecular oxygen to generate a lipid peroxide radical. Subsequently, lipid peroxides act as initiators, removing a hydrogen atom from a second unsaturated fatty acid, to yield a lipid peroxide and a new lipid radical, initiating

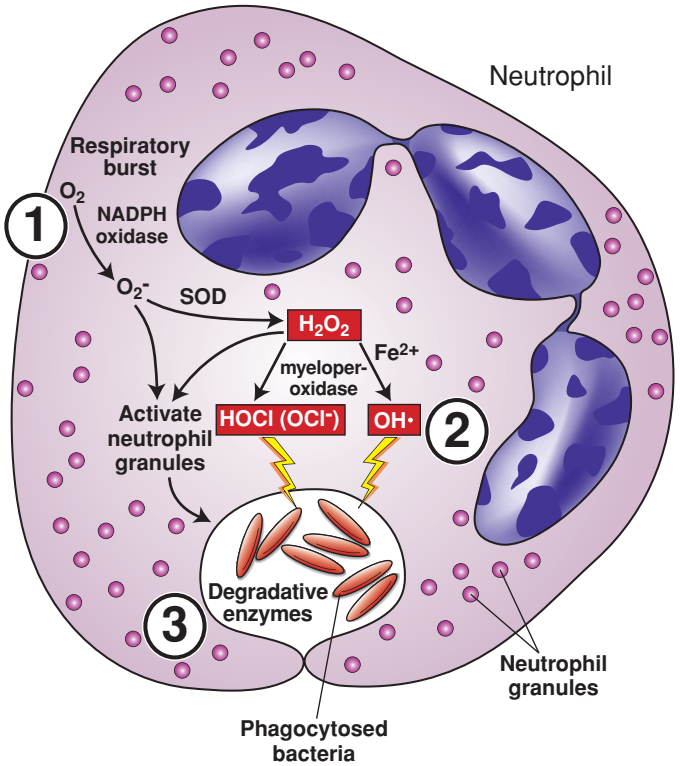

FIGURE 1-8. Generation of reactive oxygen species in neutrophils as a result of phagocytosis of bacteria. 1. The respiratory burst in neutrophils begins with reduction of O_2 to O_2^- by NADPH oxidase. In turn, O_2^- is converted to H_2O_2 by SOD. **2.** Reactive oxygen species (ROS) (HOCl, OH•) are produced from H_2O_2 by myeloperoxidase. Concurrently, O_2^- and H_2O_2 activate neutrophil granules to release degradative enzymes. **3.** Bacteria are engulfed by neutrophils, where they are destroyed by ROS and degradative enzymes. *Fe^{2+}* = ferrous iron; *H_2O_2* = hydrogen peroxide; *HOCl* = hypochlorous acid; *NADPH* = reduced nicotinamide adenine dinucleotide phosphate; *OCl^-* = hypochlorite radical; *OH•* = hydroxyl radical; *SOD* = superoxide dismutase.

a chain reaction. Lipid peroxides are unstable and break down into smaller molecules. Destruction of unsaturated fatty acids of phospholipids results in a loss of membrane integrity.

- **Protein interactions:** Hydroxyl radicals may also attack proteins. The sulfur-containing amino acids cysteine and methionine, as well as the nitrogen-containing moieties arginine, histidine and proline, are especially vulnerable to attack by OH•. As a result of oxidative damage, proteins undergo fragmentation, cross-linking, aggregation and eventually degradation (see below).
- **Sugars:** OH• can attack a variety of sugars and other carbohydrates to generate reactive intermediates that modify proteins to form injurious compounds, called advanced glycation end-products (AGEs).
- **DNA damage:** The hydroxyl radical causes diverse structural alterations in DNA, including strand breaks, modified bases and cross-links between strands. The integrity of the genome can usually be reconstituted by the various DNA repair pathways. However, if oxidative damage to DNA is sufficiently extensive, permanent DNA mutations or cell death may result.

Fig. 1-11 summarizes the mechanisms of cell injury by ROS.

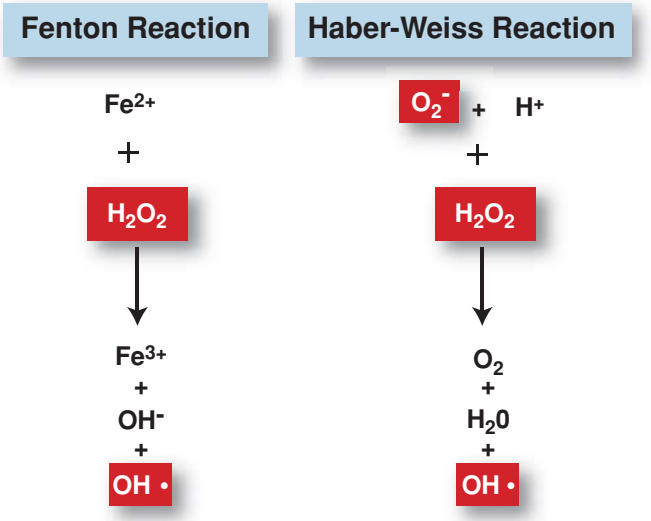

FIGURE 1-9. Fenton and Haber-Weiss reactions generate the highly reactive hydroxyl radical. Reactive species are in red. *Fe^{2+}* = ferrous iron; *Fe^{3+}* = ferric iron; *H^+* = hydrogen ion; *H_2O_2* = hydrogen peroxide; *OH^-* = hydroxide; *OH•* = hydroxyl radical.

Nitric Oxide and Peroxynitrite

Nitric oxide (NO) is a reactive nitrogen molecule that is found in many cells and has a half-life measured in seconds. It is the product of nitric oxide synthase (NOS), a ubiquitous enzyme that comes in two flavors: inducible NOS (iNOS) and constitutive NOSs that are found in several tissues. NO has diverse signaling properties and may be harmful or protective to cells, depending on the circumstances. As a free radical, NO reacts with many molecular targets and activates or inhibits numerous cell functions.

When NO and oxygen interact, production of other free radicals results. These secondary radicals may nitrosate amines or modify other available groups, such as sulfurs on some amino acids. In addition, NO can react with

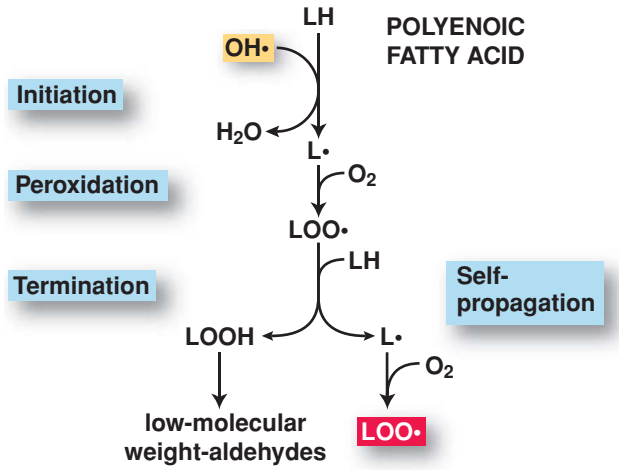

FIGURE 1-10. Lipid peroxidation initiated by the hydroxyl radical (OH•). Unsaturated fatty acids are converted to lipid radicals by OH•, which in turn reacts with molecular oxygen to form lipid peroxides. *H_2O* = water; *O_2* = oxygen; *L•* = lipid radical; *LOO•* = lipid peroxy radical; *LOOH* = lipid peroxide.

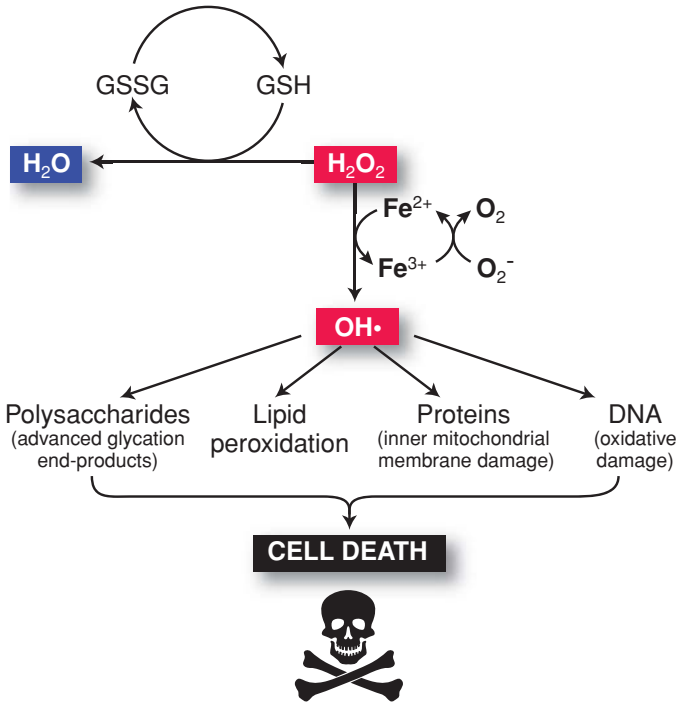

FIGURE 1-11. Mechanisms of cell injury by activated oxygen species. Fe^{2+} = ferrous iron; Fe^{3+} = ferric iron; *GSH* = glutathione; *GSSG* = oxidized glutathione; H_2O_2 = hydrogen peroxide; O_2 = oxygen; O_2^- = superoxide anion; *OH•* = hydroxyl radical.

superoxide to form another free radical, namely, peroxynitrite ($ONOO^-$):

$$NO\bullet + O_2^- \rightarrow ONOO^-.$$

Peroxynitrite attacks many important cellular molecules, including lipids, proteins and DNA. Its actions may be beneficial or harmful, depending on the context.

Miscellaneous ROS

Recent data suggest that other ROS, particularly singlet oxygen (O•) and carbonyl radical ($CO_3^-\bullet$), may play important roles in oxidative stress.

The Effectiveness of Cellular Defenses May Determine the Outcome of ROS-Mediated Injury

Cells possess potent antioxidant defenses, including detoxifying enzymes and exogenous free radical scavengers (e.g., vitamins). The major enzymes that convert ROS to less reactive molecules are SOD, catalase and GPX.

Detoxifying Enzymes

- **SOD** is the first line of defense against O_2^-, converting it to H_2O_2 and O_2 ($2O_2^- + 2H^+O_2 + H_2O_2$).
- **Catalase,** mainly located in peroxisomes, is one of two enzymes that complete the detoxification of O_2^- by converting H_2O_2 to water, thereby, preventing its conversion to OH• ($2H_2O_2 \rightarrow 2H_2O + O_2$).
- **GPX** catalyzes the reduction of H_2O_2 and lipid peroxides in mitochondria and the cytosol ($H_2O_2 + 2GSH \rightarrow 2H_2O +$ GSSG).

Scavengers of ROS

- **Vitamin E (α-tocopherol)** is a terminal electron acceptor that aborts free radical chain reactions. As it is fat soluble, α-tocopherol protects membranes from lipid peroxidation.
- **Vitamin C (ascorbate)** is water soluble and reacts directly with O_2, OH• and some products of lipid peroxidation. It also serves to regenerate the reduced form of vitamin E.
- **Retinoids,** the precursors of vitamin A, are lipid soluble and act as chain-breaking antioxidants.
- **NO•** may scavenge ROS, principally by chelation of iron and combination with other free radicals.

Extracellular Oxidants and Antioxidants

Many intracellular processes generate ROS that diffuse or are transported outside cells, where they then may act as precursors of further oxidants. Such molecules include H_2O_2, lipid hydroperoxides, halogenated species such as hypochlorous acid (HOCl) derived from myeloperoxidase and related enzymes, as well as other compounds. Extracellular molecules that act as antioxidants include albumin, glutathione, ascorbate (vitamin C), α-tocopherol (vitamin E) and an extracellular form of SOD.

Although the consequences of oxidative stress in the extracellular matrix (ECM) are not well understood, matrix proteins such as collagen, elastin, fibronectin and laminin are damaged. Nonprotein ECM constituents (glycosaminoglycans, chondroitin sulfate, hyaluronan, etc.) may also be altered. Damage to these ECM molecules may lead to functional impairments in skin, bone and cartilage. Basement membranes throughout the body are also affected, particularly in the kidney and lungs.

p53 May Enhance or Inhibit Oxidative Damage

p53 is a versatile actor that plays diverse roles in the drama of cell survival and death (see later and Chapter 5). On the one hand, p53 helps to prevent and repair DNA damage, thereby rescuing cells from injury due to many endogenous and exogenous sources. On the other hand, if DNA damage is irreparable, p53 activates cell death programs (see below). In addition to these activities, p53 orchestrates cellular metabolic activity in response to levels of oxidative stress.

Under normal conditions with low oxidant stress and normal levels of metabolic activity, this protein maintains expression of many antioxidant genes, thus promoting cell survival. In the face of severe oxidant stress, p53 performs an about-face and activates a different suite of target genes that impair oxidant defenses, allow cellular damage to accumulate and eventuate in cell death. In addition to these effects on gene transcription, p53 directs metabolic pathways that reinforce its transcriptional activity.

Intracellular Storage Is Retention of Materials within the Cell

Substances that accumulate within cells may be normal or abnormal, endogenous or exogenous, harmful or innocuous.

- **Nutrients,** such as fat, glycogen, vitamins and minerals, are stored for later use.
- **Degraded phospholipids,** from the turnover of endogenous membranes, are engulfed in lysosomes and may be recycled.

- **Substances that are not metabolized** accumulate in cells. These include (1) endogenous substrates that are not further processed because a key enzyme is missing (hereditary storage diseases), (2) insoluble endogenous pigments (e.g., lipofuscin, melanin), (3) aggregates of normal or abnormal proteins and (4) foreign particulates, such as inhaled silica or carbon or injected tattoo pigments.
- **Overload of normal body constituents,** including iron, copper and cholesterol, injures a variety of cells.
- **Abnormal forms of proteins** may be toxic if they are retained within cells (e.g., Lewy bodies in Parkinson disease and mutant α_1-antitrypsin; see below).

Fat

Bacteria and other unicellular organisms continuously ingest nutrients. By contrast, mammals do not need to eat continuously. They eat periodically and can survive a prolonged fast because they store nutrients in specialized cells for later use—fat in adipocytes and glycogen in the liver, heart and muscle.

Abnormal accumulation of fat is most conspicuous in the liver (see Chapter 20). Briefly, hepatocytes always contain some fat, because they take up free fatty acids released from adipose tissue and convert them to triglycerides. Most such newly synthesized triglycerides are secreted by the liver as lipoproteins. If delivery of free fatty acids to the liver increases, as in diabetes, or intrahepatic lipid metabolism is disturbed, as in alcoholism, triglycerides accumulate in liver cells. Fatty liver is visualized as lipid globules in the cytoplasm. Other organs, including the heart, kidney and skeletal muscle, also store fat. ***Fat storage is always reversible and there is no evidence that excess fat in the cytoplasm per se interferes with cell function.***

Glycogen

Glycogen is a long-chain polymer of glucose, formed and largely stored in the liver and to a lesser extent in muscles. It is depolymerized to glucose and liberated as needed. Glycogen is degraded in steps by a series of enzymes, each of which may be deficient because of an inborn error of metabolism. Regardless of the specific enzyme deficiency, the result is a glycogen storage disease (see Chapter 6). These inherited disorders affect the liver, heart and skeletal muscle and range from mild and asymptomatic conditions to inexorably progressive and fatal diseases (see Chapters 11, 20 and 31).

Glycogen storage in cells is normally regulated by blood glucose concentration, and hyperglycemic states are associated with increased glycogen stores. Thus, in uncontrolled diabetes, hepatocytes and epithelial cells of the renal proximal tubules are enlarged by excess glycogen.

Inherited Lysosomal Storage Diseases

As with glycogen, catabolism of certain complex lipids and mucopolysaccharides (glycosaminoglycans) takes place by a sequence of enzymatic steps. Since these enzymes are located in the lysosomes, their absence results in lysosomal storage of incompletely degraded lipids, such as cerebrosides (Gaucher disease) and gangliosides (Tay-Sachs disease) or products of mucopolysaccharide catabolism (Hurler and Hunter syndromes). Although these disorders are all progressive, their manifestations vary from asymptomatic organomegaly to rapidly fatal brain disease (see Chapter 6 for the metabolic bases of these disorders and Chapters 30 and 32 for specific organ pathology).

Cholesterol

The human body has a love–hate relationship with cholesterol. On the one hand, it is a critical component of all plasma membranes. On the other hand, when stored in excess, it is closely associated with atherosclerosis and cardiovascular disease, which is the leading cause of death in the Western world (see Chapter 16).

Briefly, the initial lesion of atherosclerosis (fatty streak) reflects accumulation of cholesterol and cholesterol esters in macrophages within the arterial intima. As the disease progresses, smooth muscle cells also store cholesterol. Advanced lesions of atherosclerosis are characterized by extracellular deposition of cholesterol (Fig. 1-12A).

In some disorders characterized by elevated blood levels of cholesterol (e.g., familial hypercholesterolemia), macrophages store cholesterol. If clusters of these cells in subcutaneous tissues are grossly visible, they are called **xanthomas** (Fig. 1-12B).

Lipofuscin

Lipofuscin is a mixture of lipids and proteins that appears as a golden-brown pigment and has been termed "wear and tear" pigment. **It tends to accumulate by accretion of peroxidized unsaturated lipids and oxidized, cross-linked proteins. It is indigestible** and has been compared to production of linoleum by oxidation of linseed oil. This process causes the unsaturated lipids in the oil progressively to solidify, turn brown and become less soluble. Lipofuscin accumulates mainly in postmitotic cells (e.g., neurons, cardiac myocytes) or in cells that cycle infrequently (e.g., hepatocytes) (Fig. 1-12C) and increases with age. In fact, measurement of lipofuscin in optic neurons has been used by fisheries to estimate age in lobsters and other crustaceans. It is often more conspicuous in conditions associated with atrophy of an organ.

Although it was previously thought to be benign, there is increasing evidence that lipofuscin may be both a result and a cause of increasing oxidant stress in cells. It may impair both proteasomal function and lysosomal degradation of senescent or poorly functioning organelles, and so promote cellular oxidant injury. Inefficient or misfunctioning mitochondria may accumulate, make more ROS and continue the cycle.

Melanin

Melanin is an insoluble, brown-black pigment found principally in epidermal cells of the skin, but also in the eye and other organs (Fig. 1-12D). It is located in intracellular organelles known as melanosomes and results from polymerization of certain oxidation products of tyrosine. The amount of melanin is responsible for the differences in skin color among the various races, as well as the color of the eyes. It serves a protective function owing to its ability to absorb ultraviolet light. In white persons, exposure to sunlight increases melanin formation (tanning). The hereditary inability to produce melanin is known as **albinism**. The presence of melanin is also a marker of cancers that arise from melanocytes (melanoma). Melanin is discussed in detail in Chapter 28.

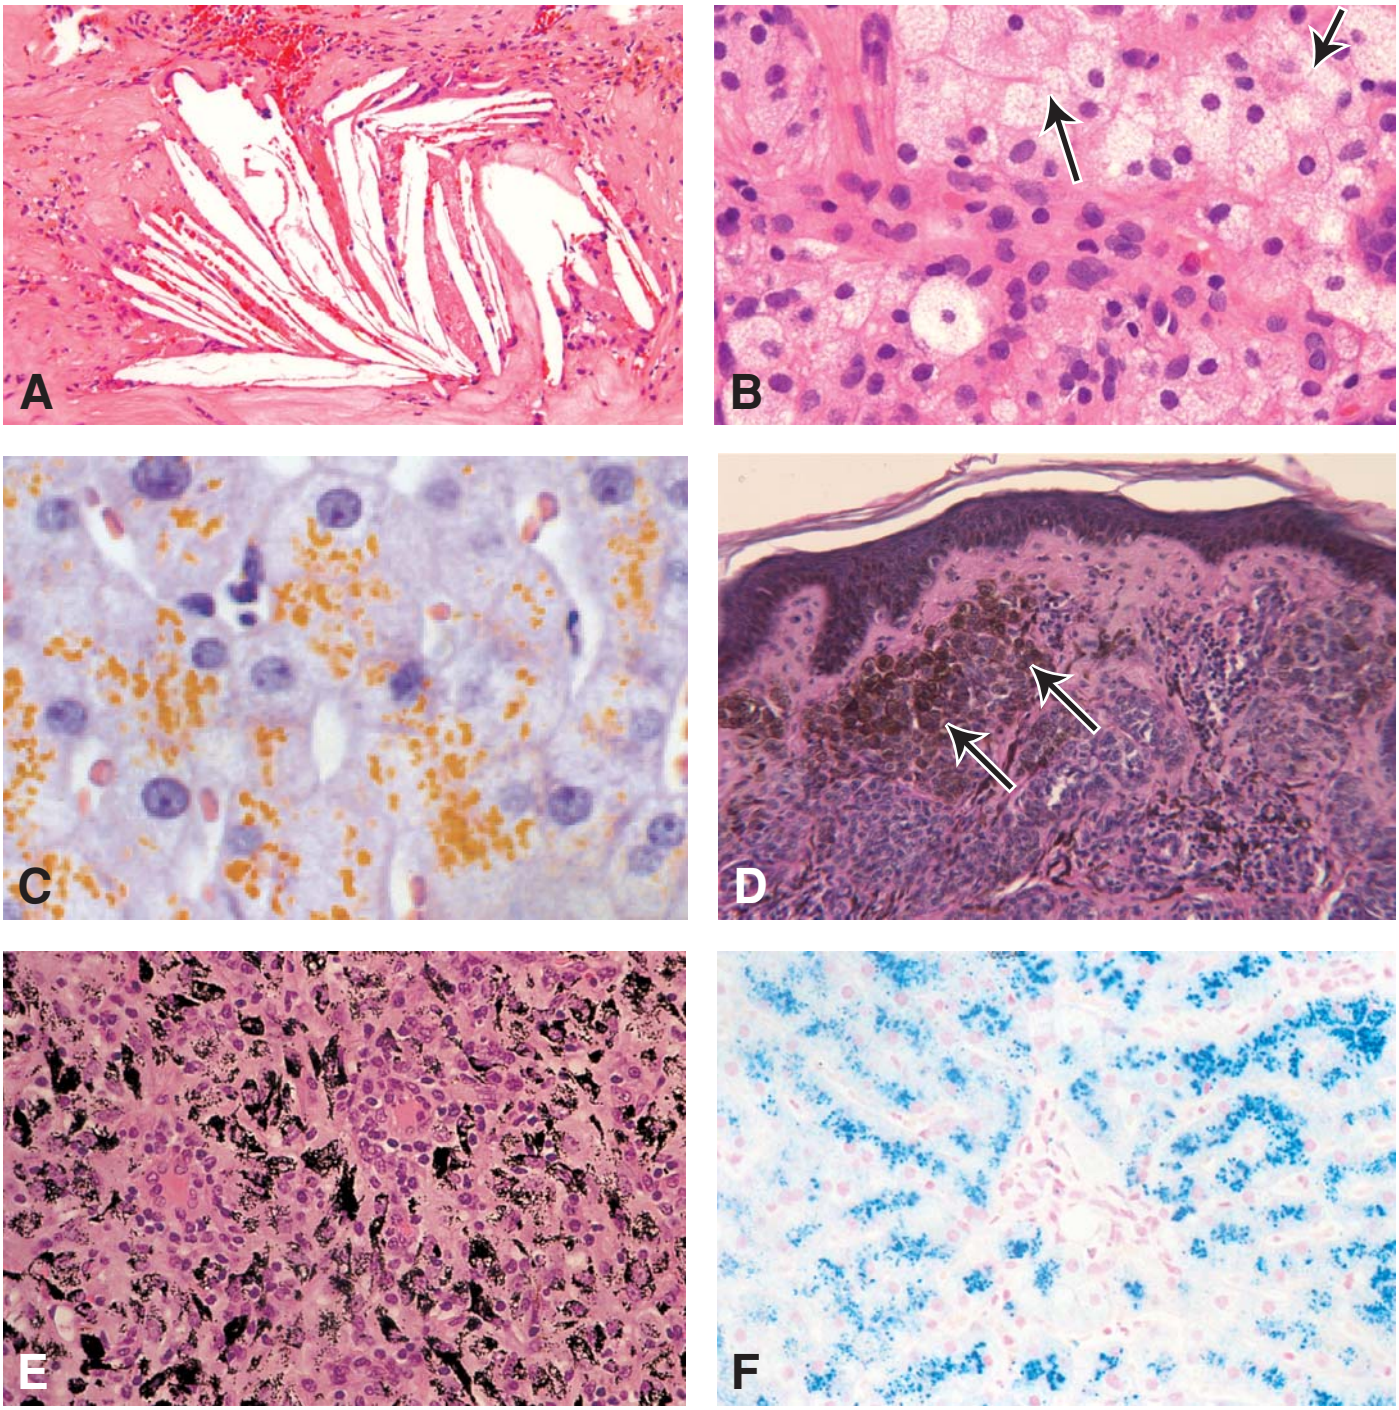

FIGURE 1-12. Abnormal intracellular storage. A. Abnormal cholesterol accumulation is characterized by transparent clefts, shown here in an atherosclerotic plaque. **B.** Lipid is stored in macrophages (*arrows*) in a cutaneous xanthoma. **C.** Lipofuscin in the liver from an 80-year-old man appears as golden cytoplasmic granules in lysosomes. **D.** Melanin (*arrows*) is stored in the cells of an intradermal nevus. **E.** Carbon pigment storage. A mediastinal lymph node, which drains the lungs, exhibits numerous macrophages that contain black anthracotic (carbon) pigment. This material was inhaled and originally deposited in the lungs. **F.** Iron storage in hereditary hemochromatosis. Prussian blue stain of the liver reveals large deposits of iron within hepatocellular lysosomes.

Exogenous Pigments

Anthracosis refers to storage of carbon particles in the lung and regional lymph nodes (Fig. 1-12E). Virtually all urban dwellers inhale particulates of organic carbon generated by the burning of fossil fuels. These particles accumulate in alveolar macrophages and are also transported to hilar and mediastinal lymph nodes, where the indigestible material is stored indefinitely within macrophages. Although the gross appearance of the lungs of persons with anthracosis may be alarming, the condition is innocuous.

Tattoos (from the Samoan, "tatou") reflect the introduction of insoluble metallic and vegetable pigments into the skin,

where they are principally engulfed by dermal macrophages and persist for a lifetime.

Iron and Other Metals

Iron

About 25% of the body's total iron content is in an intracellular storage pool composed of the iron-storage proteins **ferritin** and **hemosiderin**. The liver and bone marrow are particularly rich in ferritin, although it is present in virtually all cells. Hemosiderin is a partially denatured form of ferritin that aggregates easily and is recognized microscopically as yellow-brown granules in the cytoplasm. Normally, hemosiderin is found mainly in the spleen, bone marrow and Kupffer cells of the liver.

Total body iron may be increased by enhanced intestinal iron absorption, as in some anemias, or by repeated blood transfusions, which include iron-containing erythrocytes. In either case, the excess iron is stored intracellularly as ferritin and hemosiderin. Increasing the body's total iron content leads to progressive accumulation of hemosiderin, which is called **hemosiderosis**. In this case, iron is present throughout the body, including the skin, pancreas, heart, kidneys and endocrine organs. However, by definition, intracellular accumulation of iron in hemosiderosis does not injure cells.

If, contrariwise, the increase in total body iron is extreme, it damages vital organs—the heart, liver, testes and pancreas. Iron overload can result from a genetic abnormality in iron absorption, namely, **hereditary hemochromatosis (HH)** (Fig. 1-12F). Tissue injury in HH most likely reflects iron-generated oxidative stress, as described above. In HH, mutations occur in one of the several genes responsible for iron transport and regulation of iron absorption.

Excessive iron storage in some organs is also associated with an increased risk of cancer. Metal polishers with pulmonary siderosis developed lung cancer with greater than normal frequency. Hemochromatosis increases the risk of liver cancer.

Other Metals

Excess accumulation of lead, particularly in children, causes mental retardation and anemia (see Chapter 8). The storage of other metals also presents dangers. In Wilson disease (Chapter 20), a hereditary disorder of copper metabolism, storage of excess copper in the liver and brain leads to severe chronic disease of those organs.

Calcification May Reflect Normal Development or an Abnormal Process

The deposition of mineral salts of calcium is, of course, a normal part of the formation of bone from cartilage. Calcium enters dead or dying cells because such cells cannot maintain a steep calcium gradient (see below). This cellular calcification is not ordinarily visible except as inclusions within mitochondria.

In "dystrophic" calcification macroscopic calcium salt deposits occur in injured tissues. This process does not simply represent accumulation of calcium derived from the bodies of dead cells but rather is caused by extracellular deposition of calcium from the circulation or interstitial fluid. Dystrophic calcification apparently requires the persistence of necrotic tissue; it is often visible to the naked eye and ranges from gritty, sand-like grains to firm, rock-hard material. Often, as in the lung or lymph nodes with tuberculous caseous necrosis, calcification has no functional consequences. However, dystrophic calcification that occurs in crucial locations, such as the mitral or aortic valves (Fig. 1-13), leads to obstruction of blood flow by making valve leaflets rigid and narrowing valve orifices (mitral and aortic stenosis). Dystrophic calcification in atherosclerotic coronary arteries contributes to narrowing of those vessels. Although molecules that participate in physiologic calcium deposition in bone (e.g., osteopontin, osteonectin and osteocalcin) are reported in association with dystrophic calcification, the mechanisms underlying this process remain obscure.

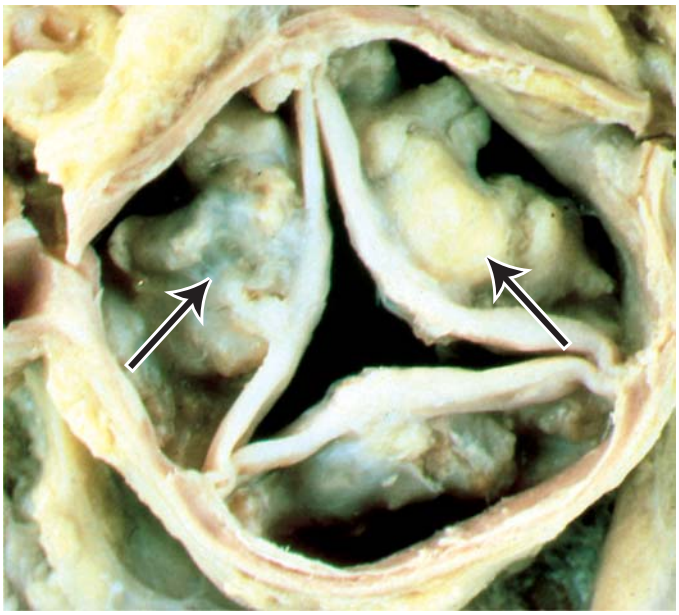

FIGURE 1-13. Calcific aortic stenosis. Deposits of solid calcium salts (*arrows*) are seen in the cusps and the free margins of the thickened aortic valve, viewed from above.

Dystrophic calcification also plays a role in diagnostic radiography. For example, mammography is based largely on the detection of small calcifications in breast cancers; congenital toxoplasmosis, an infection involving the central nervous system, is suggested when calcification is visualized in an infant's brain.

Unlike dystrophic calcification, which has its origin in cell injury, "metastatic" calcification reflects deranged calcium metabolism and is associated with increased serum calcium concentrations **(hypercalcemia)**. In general, almost any disorder that increases blood calcium levels can lead to calcification in such inappropriate locations as pulmonary alveolar septa, renal tubules and blood vessels. Metastatic calcification is seen in various disorders, including chronic renal failure, vitamin D intoxication and hyperparathyroidism.

The formation of calcium-containing stones in sites such as the gallbladder, renal pelvis, bladder and pancreatic duct is another form of pathologic calcification. Under certain circumstances, the mineral salts precipitate from solution and crystallize about foci of organic material. Those who have suffered the agony of gallbladder or renal colic will attest to the unpleasant consequences of this type of calcification.

Hyaline Refers to Any Reddish, Homogeneous Material That Stains with Eosin

The term **hyaline** was used in classic descriptions of diverse and unrelated lesions, such as hyaline arteriolosclerosis, alcoholic hyaline in the liver, hyaline membranes in the lung and hyaline droplets in various cells. The various lesions called hyaline have nothing in common. Alcoholic hyaline is composed of cytoskeletal filaments; the hyaline found in arterioles of the kidney is derived from basement membranes; and hyaline membranes in the lung consist of plasma proteins deposited in alveoli. The term is anachronistic but is still used as a morphologic descriptor.

Hyperplasia Is an Increase in Cell Numbers in an Organ or Tissue

Stimuli that induce hyperplasia and the mechanisms by which they act vary greatly from one tissue and cell type to the next. An agent that elicits hyperplastic responses in one tissue either may not do so in another or may do so via mechanisms that are totally distinct. In response to such stimuli, cells divide to generate an organ or tissue that contains more than its usual complement of those cells (hypercellular). The dividing cells may derive from cells that are already cycling or from resting progenitors. This process may occur as a response to an altered endocrine milieu, increased functional demand or chronic injury. Hypertrophy (an increase in organ and/or cell size; see below) may occur simultaneously with hyperplasia.

Hormonal Stimulation

Changes in hormone concentrations can elicit proliferation of responsive cells. These changes may reflect developmental, pharmacologic or pathologic influences. For example, the normal increase in estrogens at puberty or early in the menstrual cycle leads to increased numbers of endometrial and uterine stromal cells. Estrogen administration to postmenopausal women has the same effect. Enlargement of the male breast, called gynecomastia, may occur in men with excess estrogens (e.g., following estrogen therapy for prostate cancer or when the liver's inability to metabolize endogenous estrogens leads to their accumulation, as in liver failure). Ectopic hormone production may be a tumor's first presenting symptom (e.g., erythropoietin secretion by renal tumors leads to hyperplasia of erythrocytes in the bone marrow).

Increased Functional Demand

Increased physiologic requirements may result in hyperplasia. For example, at high altitudes, low atmospheric oxygen tension causes compensatory hyperplasia of erythroid precursors in the bone marrow and increased blood erythrocytes (secondary polycythemia) (Fig. 1-14). In this fashion, increased numbers of cells compensate for the decreased oxygen carried by each erythrocyte. The number of red blood cells promptly falls to normal on return to sea level. Similarly, chronic blood loss, as in excessive menstrual bleeding, also causes hyperplasia of erythrocytic elements.

Immune responsiveness to many antigens may lead to lymphoid hyperplasia (e.g., the enlarged tonsils and swollen lymph nodes that occur with streptococcal pharyngitis). The hypocalcemia that occurs in chronic renal failure produces increased demand for parathyroid hormone in order to augment blood calcium. The result is hyperplasia of the parathyroid glands.

Chronic Injury

Persistent injury may result in hyperplasia. Long-standing inflammation or chronic physical or chemical injury is often accompanied by a hyperplastic response. For instance, pressure from ill-fitting shoes causes hyperplasia of the skin of the foot, so-called corns or calluses. Resultant thickening of the skin protects it from the continued pressure. Chronic inflammation of the bladder (chronic cystitis) often causes hyperplasia of the bladder epithelium, visible as white plaques on the bladder lining.

Inappropriate hyperplasia can itself be harmful—witness the unpleasant consequences of psoriasis, which is characterized by conspicuous hyperplasia of the skin (Fig. 1-14D). Excessive estrogen stimulation, whether from endogenous sources or from medication, may eventuate in endometrial hyperplasia.

The variety of cellular and molecular mechanisms responsible for the increased mitotic activity that characterizes hyperplastic responses clearly relates to altered control of cell proliferation. These topics are discussed in Chapters 3 and 5.

Metaplasia Is Conversion of One Differentiated Cell Type to Another

Metaplasia is usually an adaptive response to persistent injury. That is, a tissue will assume a phenotype that protects it best from the insult. Most often, glandular epithelium is replaced by squamous epithelium. Columnar or cuboidal lining cells that are committed to mucus production may not be adequately resistant to the effects of chronic irritation or a pernicious chemical. For example, prolonged exposure of bronchial epithelium to tobacco smoke leads to squamous metaplasia. A similar response is associated with chronic infection in the endocervix (Fig. 1-15). Whether metaplasia results from altered differentiation of maturing cells or a change in the commitment of tissue stem cells to one lineage rather than another remains unknown.

The process is not restricted to squamous differentiation. When highly acidic gastric contents reflux chronically into the lower esophagus, the squamous epithelium of the esophagus may be replaced by glandular mucosa **(Barrett esophagus)**. This effect can be thought of as an adaptation to protect the esophagus from injury by gastric acid and pepsin, to which the glandular mucosa is more resistant.

Metaplasia may also consist of replacement of one glandular epithelium by another. In chronic gastritis, chronic inflammation causes atrophic stomach glands to be replaced by cells resembling those of the small intestine. The adaptive value of such intestinal metaplasia is not clear. Metaplasia of transitional epithelium to glandular epithelium occurs when the bladder is chronically inflamed (cystitis glandularis).

Although metaplasia may be thought of as adaptive, it is not necessarily innocuous. For example, squamous metaplasia may protect a bronchus from tobacco smoke, but it also impairs mucus production and ciliary clearance. Cancers

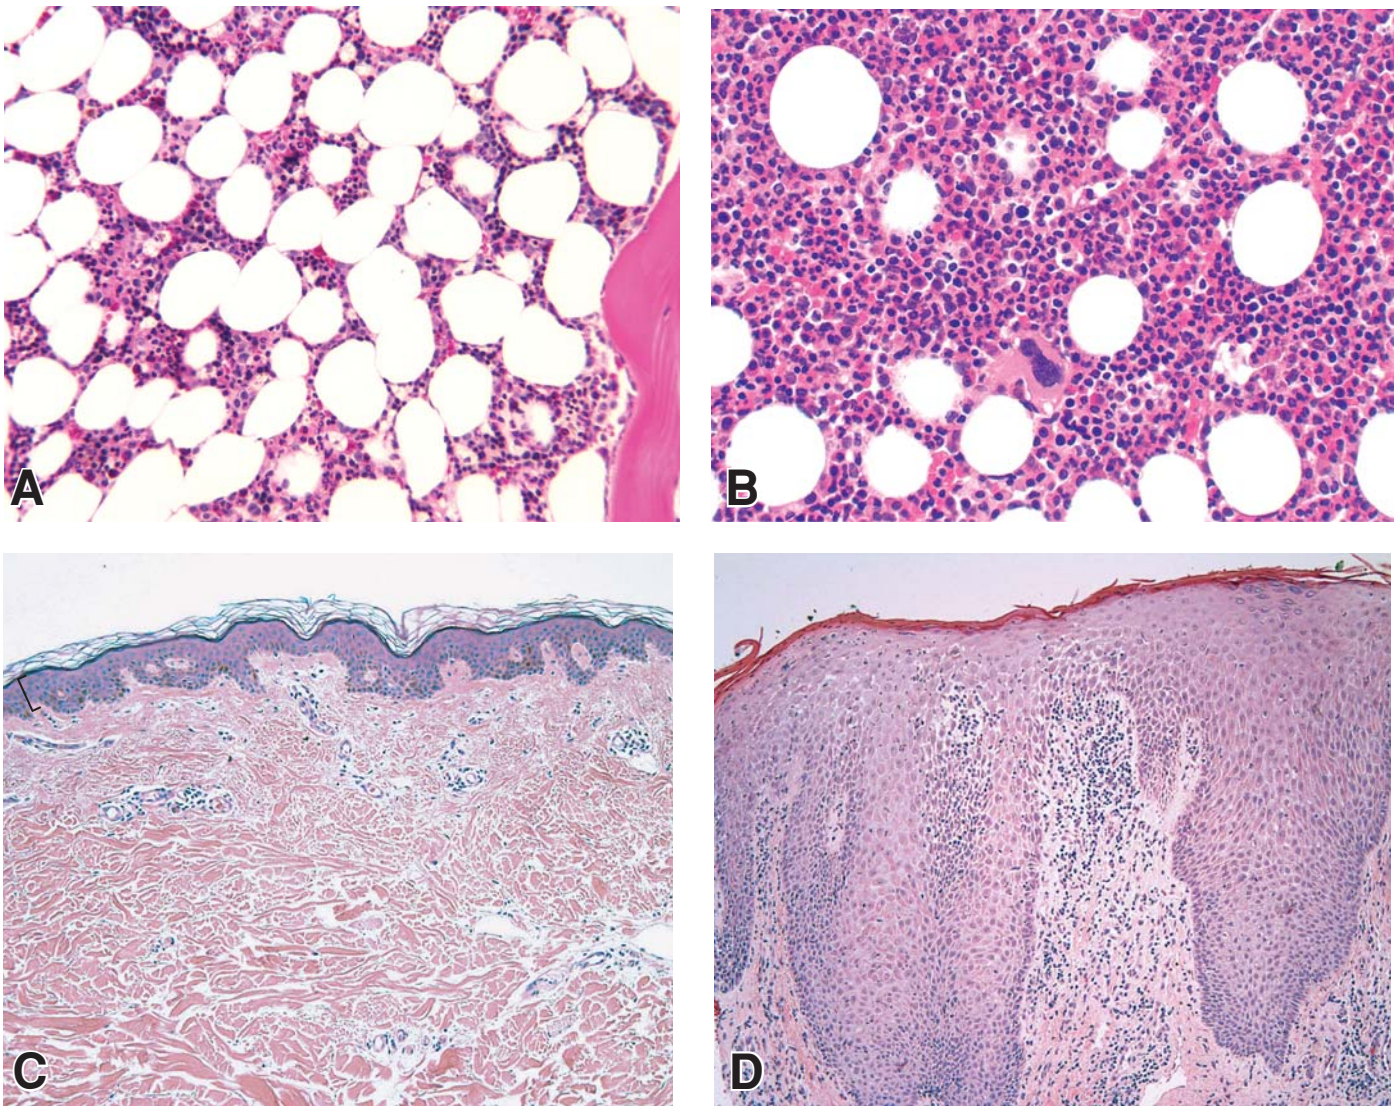

FIGURE 1-14. Hyperplasia. A. Normal adult bone marrow. Normocellular bone marrow shows the usual ratio of fat to hematopoietic cells. **B. Hyperplasia** of the bone marrow. Cellularity is increased; fat is relatively decreased. **C. Normal epidermis.** Epidermal thickness is modest (*bracket*) compared to the dermis (below). **D. Epidermal hyperplasia** in psoriasis is shown at the same magnification as in C. The epidermis is thickened owing to an increase in the number of squamous cells.

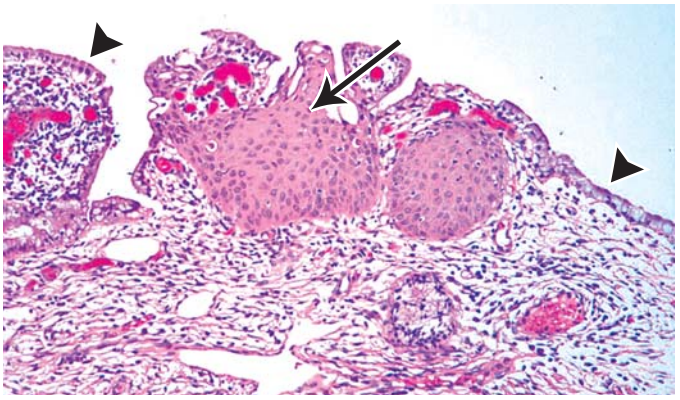

FIGURE 1-15. Squamous metaplasia. A section of endocervix shows the normal columnar epithelium at both margins (*arrowheads*) and a focus of squamous metaplasia in the center (*arrow*).

may develop in metaplastic epithelium; malignancies of the lung, cervix, stomach and bladder often arise in such areas. However, if the chronic injury ceases, there is little stimulus for cells to proliferate, and the epithelium does not become cancerous.

Metaplasia is usually fully reversible. If the noxious stimulus is removed (e.g., when one stops smoking), the metaplastic epithelium eventually returns to normal.

Dysplasia Is Disordered Cellular Growth and Maturation

The cells that compose an epithelium normally exhibit uniformity of size, shape and nuclei. Moreover, they are arranged in a regular fashion; for example, a squamous epithelium progresses from plump basal cells to flat superficial cells. In dysplasia, this pattern is disturbed by (1) variation

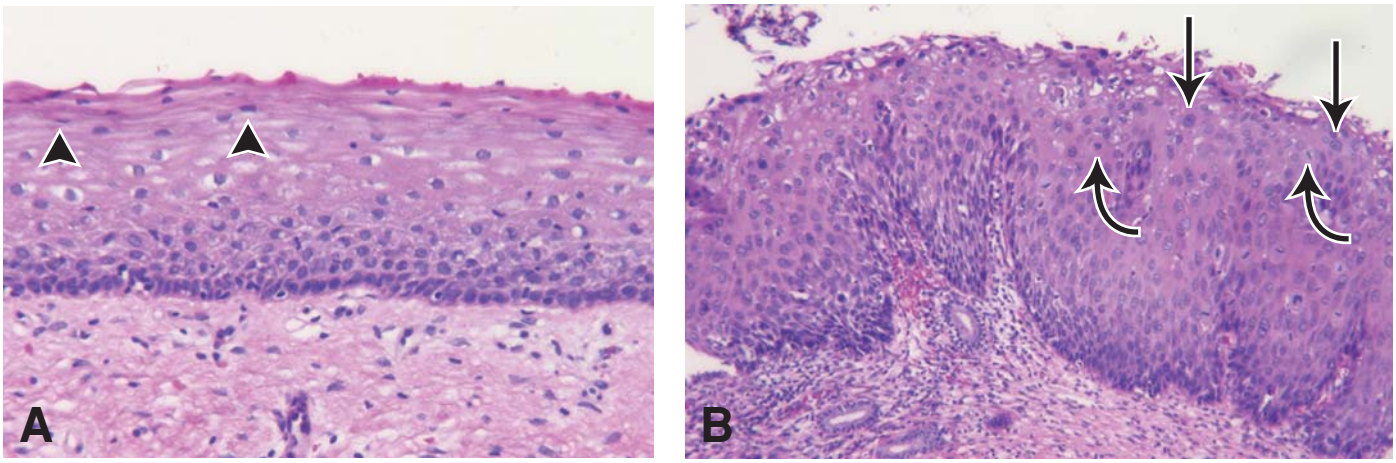

FIGURE 1-16. Dysplasia. A. Nondysplastic cervical epithelium. Normal cervix shows no mitotic activity above the most basal layers, but rather shows epithelial maturation, with flattening of the cells and progressive diminution of nuclei (*arrowheads*). **B.** At the same magnification, dysplastic epithelium of the uterine cervix lacks normal polarity, and individual cells show hyperchromatic nuclei and a greater than normal nucleus-to-cytoplasm ratio. Compare, for example, the size and hyperchromaticity of nuclei in the dysplastic cells (*straight arrows*) with the characteristics of normal counterparts at comparable height in the normal cervix. In contrast to normal cervix, cellular arrangement in dysplastic epithelium is disorderly, largely lacking appropriate histologic maturation, from the basal layers to the surface. Mitotic figures far above the basal layers (*curved arrows*) are common.

in cell size and shape; (2) nuclear enlargement, irregularity and hyperchromatism; and (3) disorderly arrangement of cells in the epithelium (Fig. 1-16). Dysplasia occurs most often in hyperplastic squamous epithelium, as in epidermal actinic keratosis (caused by sunlight), and in areas of squamous metaplasia, such as in the bronchus or the cervix. It is not, however, exclusive to squamous epithelium. For example, dysplastic changes occur in the columnar mucosal cells of the colon in ulcerative colitis, in metaplastic epithelium of Barrett esophagus (see Chapter 19), in prostate glands of prostatic intraepithelial neoplasia and in the urothelium of the bladder (see Chapter 23).

Like metaplasia, dysplasia is a response to persistent injury and will usually regress, for example, if smoking ceases or if human papilloma virus disappears from the cervix. However, dysplasia shares many cytologic features with cancer, and the line between the two may be very fine indeed. It may be difficult to distinguish severe dysplasia from early cancer of the cervix by appearance. ***Dysplasia is a preneoplastic lesion, in that it is a necessary stage in the multistep cellular evolution to cancer.*** In fact, dysplasia is included in morphologic classifications of the stages of intraepithelial neoplasia in several organs (e.g., cervix, prostate, bladder). Severe dysplasia is considered an indication for aggressive preventive therapy to (1) cure the underlying cause, (2) eliminate a noxious agent or (3) surgically remove the offending tissue.

As in the development of cancer (see Chapter 5), dysplasia results from sequential mutations in a proliferating cell population. The fidelity of DNA replication is imperfect, and occasional mutations are inevitable. When a particular mutation confers a growth or survival advantage, the progeny of the mutant cell will tend to predominate. In turn, their continued proliferation provides a greater opportunity for additional mutations. Accumulation of such mutations progressively distances the cell from normal regulatory constraints. ***Dysplasia is the morphologic expression of a disturbance in growth regulation.*** However, unlike cancer cells, dysplastic cells are not entirely autonomous, and with intervention, the tissue may still revert to normal.

REACTIONS TO PERSISTENT STRESS AND CELL INJURY

Persistent stress often requires that a cell either die or adapt. At the *cellular level,* then, it is more appropriate to speak of chronic adaptation than of chronic injury. The major adaptive responses are atrophy, hypertrophy, hyperplasia, metaplasia, dysplasia and intracellular storage. In some settings, as noted, neoplasia may follow adaptive responses.

Atrophy and Hypertrophy Are Two Sides of the Same Coin

Atrophy

Atrophy is the decreased size or function of cells or organs and occurs in both pathologic and physiologic settings. Thus, for example, atrophy may result from disuse of skeletal muscle or from loss of hormonal signals following menopause. It may also be an adaptive response whereby a cell accommodates changes in its environment, all the while remaining viable. However, most commonly atrophy reflects harmful processes, like those involved in some chronic diseases and biological aging (see below).

Atrophy of an organ differs from cellular atrophy. Reduction in an organ's size may be caused either by reversible cell shrinkage or by irreversible loss of cells. For example, renewing physical activity of a disused limb may cause atrophic muscle cells to resume their usual size and function. By contrast, atrophy of the brain in Alzheimer disease[2] is due to

[2]A note about eponymous diseases (i.e., diseases named after a person). In common usage, diseases bearing the names of Alzheimer, Parkinson, Cushing and so forth are cited as possessives (e.g., Alzheimer's disease, Parkinson's disease), but medical convention requires these diseases to be identified *without the possessive proper noun* ("Classification and nomenclature of morphological defects", *Lancet* 1975;1:513). Like many other journals and texts, we honor this convention.

FIGURE 1-17. Atrophy of the brain. Marked atrophy of the frontal lobe is characterized by thinned gyri and widened sulci.

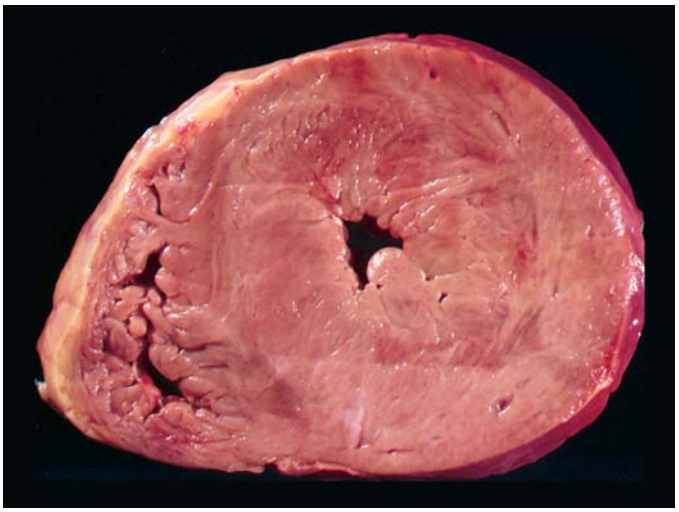

FIGURE 1-18. Myocardial hypertrophy. Cross-section of the heart of a patient with long-standing hypertension shows pronounced, concentric left ventricular hypertrophy.

extensive cell death; the size of the organ cannot be restored (Fig. 1-17). Atrophy occurs under a variety of conditions as outlined in Table 1-2.

Hypertrophy

Hypertrophy is an increase in cell or organ size and functional capacity. When trophic signals or functional demands increase, adaptive changes to satisfy these needs lead to larger cells (hypertrophy) and, in some cases, increased cell number (hyperplasia; see above). In several organs (e.g., heart, skeletal muscle), such adaptive responses are achieved mainly by increased cell size, which leads to increased organ mass (Fig. 1-18). In other organs (e.g., kidney), cell numbers and cell size may both increase.

TABLE 1-2
CONDITIONS ASSOCIATED WITH ATROPHY

Disease or Condition	Examples of Conditions in Which Atrophy Occurs
Aging	Most organs that do not continuously turn over; most common setting for atrophy to occur
Chronic disease	Prototype for atrophy occurring in chronic disease is cancer; also seen in congestive heart failure, chronic obstructive pulmonary disease, cirrhosis of the liver and AIDS
Ischemia	Hypoxia, decreased nutrient availability, renal artery stenosis
Malnutrition	Generalized atrophy
Decreased functional demand	Limb immobilization, as in a fracture
Interruption of trophic signals	Denervation atrophy following nerve injury; menopause effect on the endometrium and other organs
Increased pressure	Decubitus ulcers, passive congestion of the liver

Normal Homeostasis Determines Individual Cell Mass

Cell size reflects an equilibrium between anabolic and catabolic forces. Although many different cell types are capable of atrophy and hypertrophy, skeletal muscle is the tissue most extensively studied, and it will be used as the paradigm of these mechanisms. In this organ, myocytes can adapt to increased functional demand by increasing synthesis of muscle proteins and downregulating their degradation. Conversely, muscle atrophy (wasting) may have many causes and leads to reduced synthesis and increased degradation of contractile proteins. Within a cell, the signaling pathways that control hypertrophy and atrophy are closely interconnected.

Conditions That Cause Atrophy Are Often the Inverse of Those That Stimulate Hypertrophy

Conditions Leading to Atrophy

Reduced Functional Demand

A common form of atrophy follows reduced functional demand. For example, after immobilization of a limb in a cast as treatment for a bone fracture, the limb's muscle cells lose mass, and strength is correspondingly reduced.

Inadequate Supply of Oxygen

***Interference with blood supply to tissues, called* ischemia,** causes oxygen deprivation. If the ischemia is not sufficient to kill cells, affected cells may be viable but functionally impaired. In such settings, cell atrophy is common. It is frequently seen around the inadequately perfused margins of areas of ischemic necrosis (infarcts) in the heart, brain and kidneys after a vascular occlusion affecting these organs.

Insufficient Nutrients

Starvation or malnutrition leads to wasting (decreased mass) of skeletal muscle and adipose tissue. Microscopically this

appears as cell atrophy. Decreased size is prominent in cells (e.g., myocytes and adipocytes) that are not vital to the survival of the organism.

Interruption of Trophic Signals

The activities of many cells depend on signals triggered by chemical mediators (e.g., hormonal or neuromuscular transmission), which place functional demands on them. If the source of the signal is removed (e.g., via ablation of an endocrine gland or denervation), cells dependent on that stimulus will atrophy. If the anterior pituitary is surgically resected or lost to ischemia (e.g., Sheehan syndrome; see Chapter 14), deficiency of thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH, also called corticotropin) and follicle-stimulating hormone (FSH) results in atrophy of the thyroid, adrenal cortex and ovaries, respectively.

Atrophy due to changes in hormone levels is not restricted to pathologic conditions; the endometrium atrophies when estrogen levels decrease after menopause (Fig. 1-19). Even certain cancer cells may undergo atrophy, at least to some extent, following hormonal deprivation. Androgen-dependent prostatic cancers and estrogen receptor–expressing breast cancers regress partially after administration of hormone antagonists. If neurologic damage (e.g., from traumatic spinal cord injury) leads to denervation of muscle, the affected muscles atrophy.

Persistent Cell Injury

Persistent cell injury may occur in prolonged viral or bacterial infections or via inflammation in immunologic and granulomatous disorders. Thus, atrophy of the gastric mucosa occurs during chronic gastritis, and small intestinal villous atrophy accompanies the chronic inflammation of celiac disease (see Chapter 19).

Increased Pressure

Even physical injury, such as prolonged pressure in inappropriate locations, produces atrophy. Prolonged bed rest may create sustained pressure on the skin, causing atrophy of the skin and consequent decubitus ulcers (bed sores). Also, the cells in the center of the liver lobule atrophy when poor venous return from the liver in congestive heart failure increases the pressure within hepatic sinusoids.

Aging

In addition to conspicuous loss of skeletal muscle and adipose tissue, one of the hallmarks of aging (see Chapter 10) is decreased size and/or number of nonreplicating cells, such as those of the brain and heart. The mass of all parenchymal organs decreases with age. Brain size is invariably diminished, and in the very aged the heart may be so small that the term **senile atrophy** has been used.

Chronic Disease

People afflicted with wasting chronic diseases (see below), such as cancer, congestive heart failure or AIDS, often show generalized atrophy of many tissues. Tissue loss exceeds what can be attributed to decreased caloric intake and reflects alterations in cytokines and other mediators.

Conditions Leading to Hypertrophy

The situations that are associated with increased cell and organ mass are in many, but not all, cases the converse of those that lead to atrophy. Thus, increased functional demand or increased trophic signaling (see below) results in adaptive increases in cell or organ size. Unfortunately for many of us, even though nutrient deprivation may lead to atrophy of both muscle and fat, excess nutrient intake only causes increased fat.

Increased Functional Demand

Human skeletal muscle is composed of a mixture of slow-twitch (type I) and fast-twitch (type II) fibers. Each responds to different types of increased functional demand. A marathon runner undergoing endurance training with light loads will increase the strength of type I fibers. This is not usually associated with increased muscle mass (see below). For proper function, type I fibers depend principally on aerobic metabolism, mediated by mitochondria.

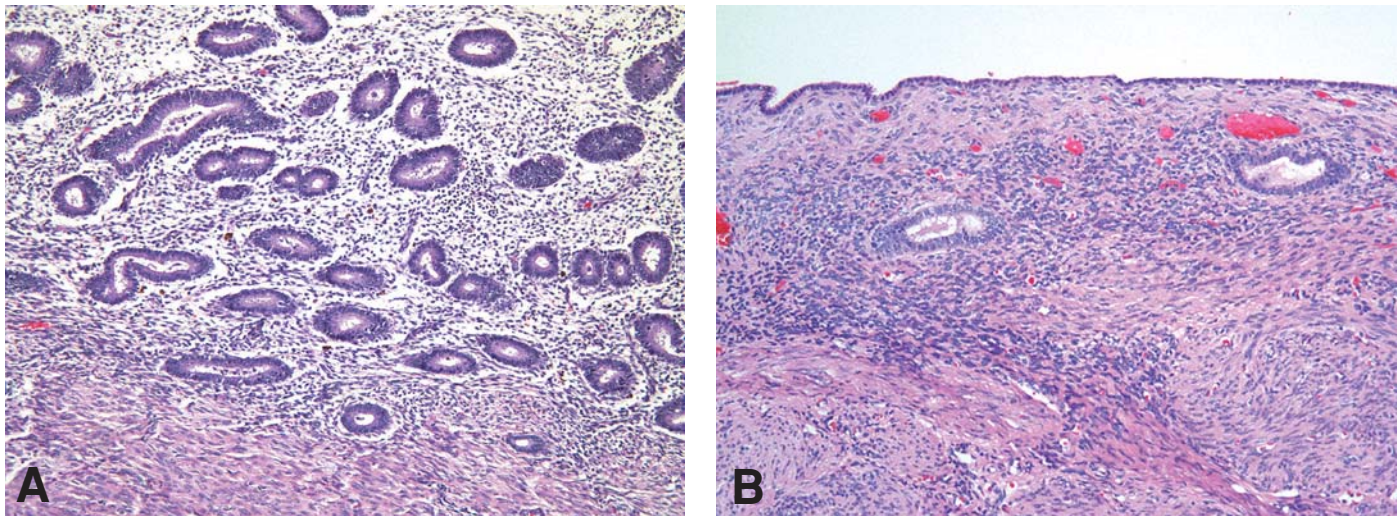

FIGURE 1-19. Atrophy of the endometrium. A. A section of the normal uterus from a woman of reproductive age reveals a thick endometrium composed of proliferative glands in an abundant stroma. **B.** The endometrium of a 75-year-old woman (shown at the same magnification) is thin and contains only a few atrophic and cystic glands.

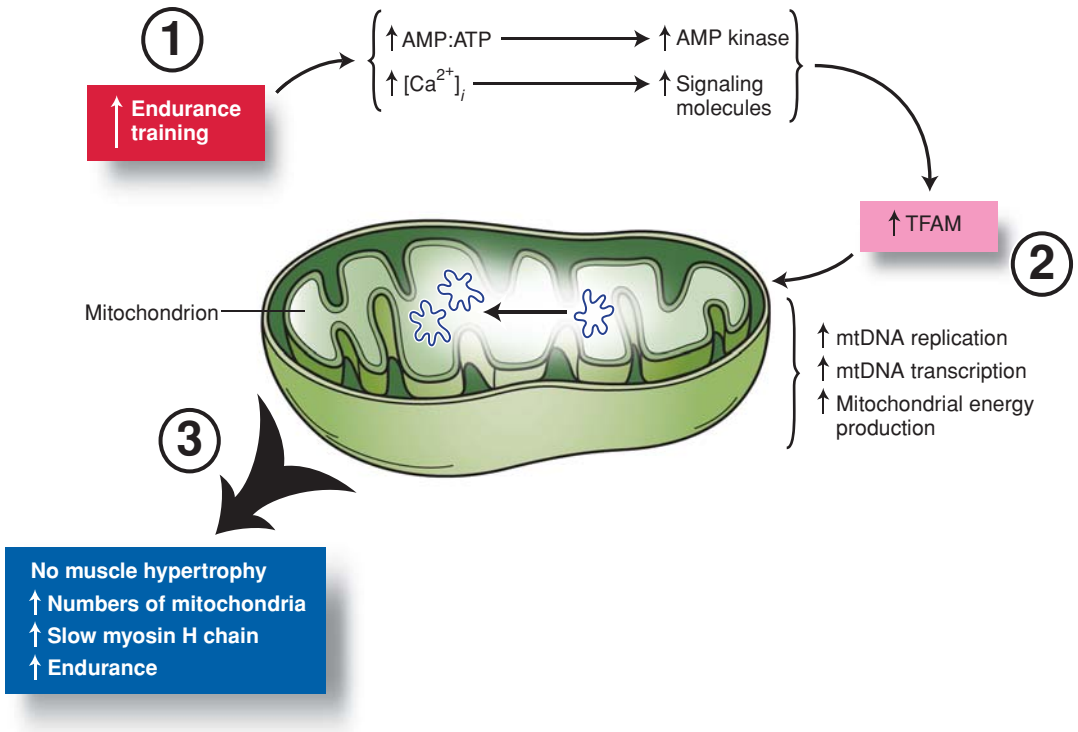

FIGURE 1-20. Mechanisms involved in muscle hypertrophy: Endurance training. 1. Muscle strengthening for endurance entails repeated or prolonged exercise with small loads and raises the adenosine monophosphate–to–adenosine triphosphate (AMP:ATP) ratio, stimulating AMP kinase activity. Such training also increases cytosolic calcium concentration ($[Ca^{2+}]_i$), which triggers a number of cellular signaling intermediates. **2.** Consequent peroxisome activation triggers TFAM (transcription factor–activating mitochondrial transcription), which in turn leads to both replication and transcription of mitochondrial DNA. **3.** The consequence is augmentation of muscle content of slow myosin H chains, increased numbers of mitochondria and improved endurance without muscle cell hypertrophy.

Thus, endurance training increases aerobic activity of type I fibers and, therefore, oxygen consumption (Fig. 1-20). Endurance training augments ATP consumption and Ca^{2+} release from the sarcoplasmic reticulum, both leading to activation of adenosine monophosphate (AMP) kinase and resulting phosphorylation of AMP. Consequent activation of transcription factor-A, mitochondrial (TFAM) increases replication and transcription of mitochondrial DNA (Fig. 1-20).

By contrast, weightlifting with large weight loads leads to hypertrophy of type II fibers and increases muscle mass. These fibers favor anaerobic glycolysis. Mechanisms that mediate type II fiber hypertrophy are more complex than for type I fibers and bear directly on the equilibrium between hypertrophy and atrophy (see Fig. 1-21, below).

Increased Trophic Signals

Cells and organs that respond to soluble mediators, such as the thyroid (TSH) or the breast (estrogens and progestins), undergo hypertrophy when levels of trophic hormones increase.

Puberty

Just as aging is associated with muscle atrophy, the onset of puberty, especially in boys, leads to greater muscle mass. The surge in androgens and growth hormone (GH) raises levels of downstream mediators (see below) and consequently increases the mass of muscle and other tissues.

Mechanisms of Cellular Hypertrophy

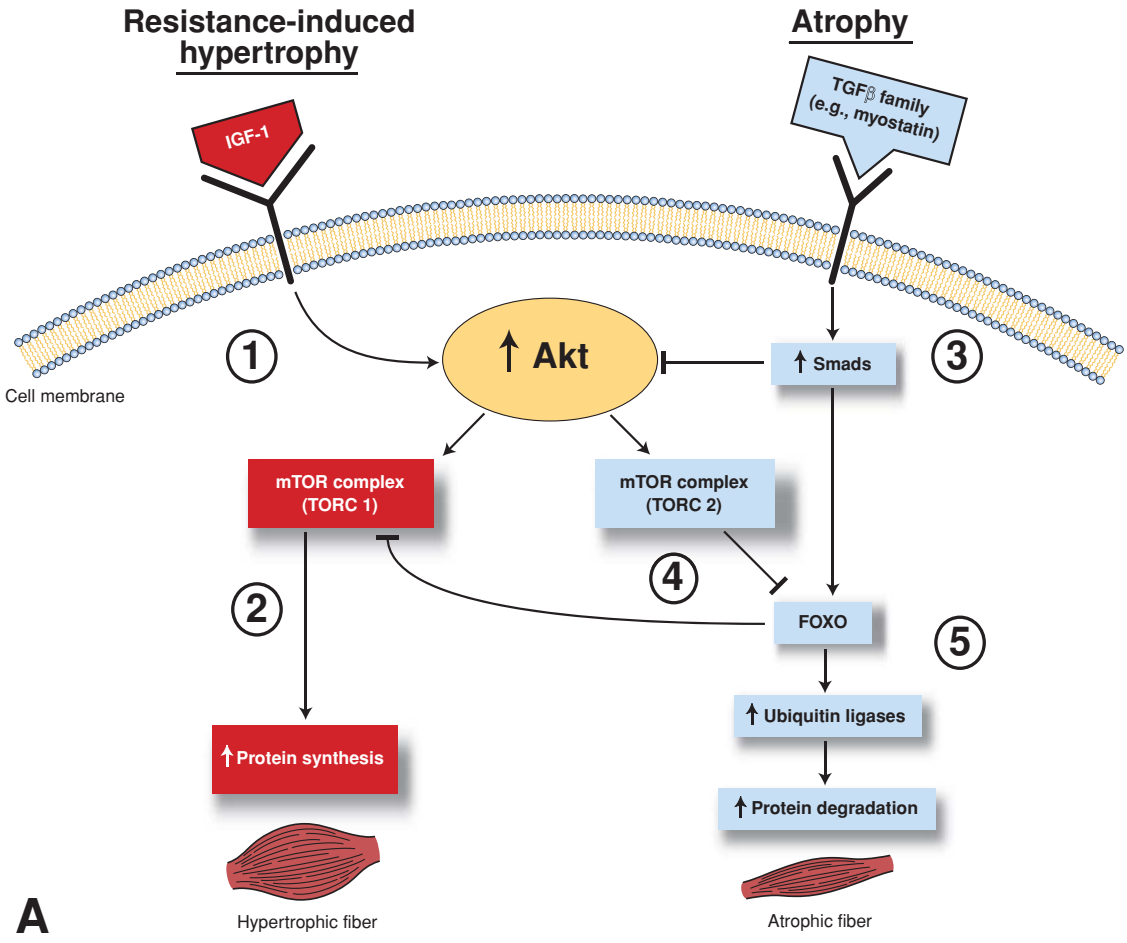
Whether the stimulus to enlarge is increased workload or response to endocrine or neuroendocrine mediators, there are certain processes that usually contribute to generating cellular hypertrophy.

When cells are stimulated to enlarge, one of the first responses is accelerated degradation of selected cellular proteins (see proteasomes, below). Specifically, proteins that do not contribute to the need for hypertrophy are removed, even as production of proteins that promote hypertrophy tends to increase.

Signaling Mechanisms in Hypertrophy

Although signals that elicit hypertrophic responses vary depending on cell type and circumstances, the example of skeletal muscle hypertrophy illustrates some critical general principles that apply to many cell types:

- **Growth factor stimulation:** Each tissue responds to different signals. As previously noted, certain growth factors are key initiators of hypertrophy (e.g., insulin-like growth factor-I [IGF-I] in muscle; see below).
- **Neuroendocrine stimulation:** In some tissues, especially the heart, adrenergic signaling may be important in initiating or facilitating hypertrophy.
- **Ion channels:** Ion fluxes may activate adaptation to increased demand. Calcium channel activity, in particular, may stimulate a host of downstream enzymes



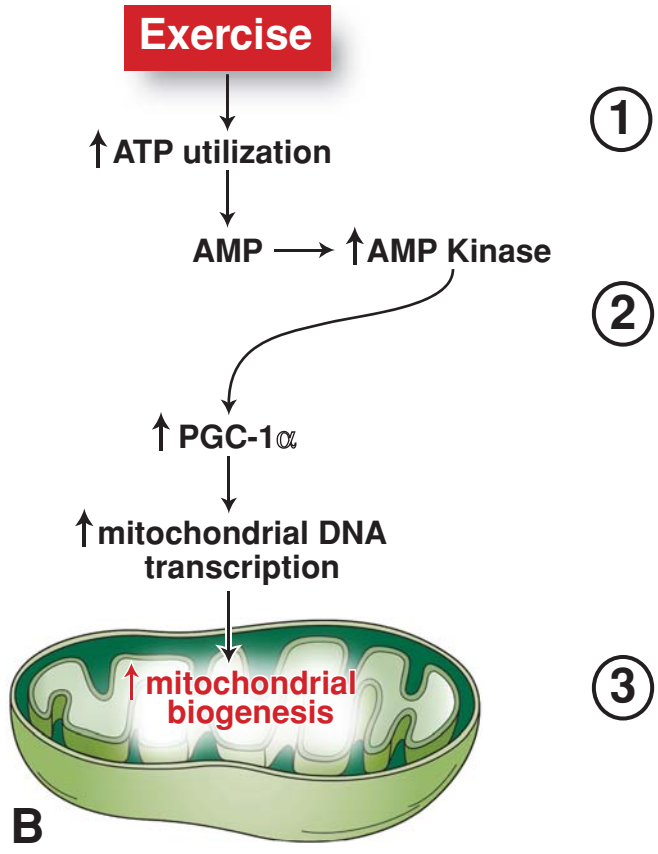


FIGURE 1-21. Interrelationship between muscle atrophy and hypertrophy. A. Centrality of Akt to both atrophy and hypertrophy. 1. In resistance-induced hypertrophy, binding of insulin-like growth factor-I (IGF-I) to its receptor stimulates Akt activity, which leads to **2,** activation of the mTOR complex and consequent increases in protein synthesis. **3.** Conversely, in atrophy, transforming growth factor-β (TGF-β) binding by its receptor triggers Smad activity, which in turn inhibits Akt. **4.** Smads also stimulate a transcription factor (FOXO). FOXO is also inhibited by the Akt-activated mTOR complex, TORC2. Blocking of FOXO relieves its inhibition of the mTORC complex, TORC1, thereby leading to greater protein production during hypertrophy. **5.** Concurrently, FOXO increases protein degradation, which is characteristic of atrophy. **B. Akt-independent mechanism of muscle hypertrophy and prevention of atrophy. 1.** Exercise requires adenosine triphosphate (ATP), which is then converted to adenosine monophosphate (AMP), in turn stimulating AMP kinase. **2.** AMP kinase activates PGC-1α (a transcription factor coactivator that upregulates energy production), leading to increased transcription of mitochondrial DNA. **3.** The final result is an increased number of mitochondria.

(e.g., calcineurin) to produce hypertrophy, again in the heart.

- **Other chemical mediators:** Such factors as nitric oxide, angiotensin II and bradykinin tend to support hypertrophic responses in some tissues.
- **Oxygen supply:** Clearly increased functional demand requires increased energy supply. If a tissue oxygen deficit is sensed, angiogenesis is stimulated, and with it oxygen delivery. Angiogenesis is a key component in adaptive hypertrophy.
- **Hypertrophy antagonists:** Just as some mechanisms foster cellular hypertrophy, others inhibit it. Atrial natriuretic factors and high concentrations of NO• and other molecules either brake or prevent cell adaptation by hypertrophy.

Effector Pathways in Hypertrophy

Whatever mechanisms initiate signaling to stimulate hypertrophy, there are a limited number of downstream pathways that mediate the effects of such signaling:

- **Increased protein degradation:** Several proteolytic pathways contribute to hypertrophy, including the ubiquitin–proteasome system (UPS), activation of intracellular proteases and autophagy (see below).
- **Increased protein translation:** Shortly after a prohypertrophic signal is received, production of certain proteins increases. This occurs very quickly via increased translational efficiency, and without changes in RNA levels. Activities of translational initiators and elongation factors are often stimulated early in hypertrophy and quickly raise levels of specific proteins needed to meet the increased functional demand.
- **Increased gene expression:** Concentrations of key proteins are also elevated by transcriptional upregulation of their genes. Many signaling pathways activated by cytokines, neurotransmitters and so forth in turn activate an array of transcription factors. Thus, for example, the phosphatase calcineurin dephosphorylates transcription factor NFAT (*n*uclear *f*actor of *a*ctivated *T* cells), thereby facilitating its movement to the nucleus to stimulate transcription of target genes. Hypertrophy may also involve increased transcription of genes encoding growth-promoting transcription factors, such as Fos and Myc.
- **Survival:** During hypertrophy, cell death is inhibited. Stimulation of specific receptors activates several enzymes (e.g., Akt, PI3K; see below) that promote cell survival, largely by inhibiting programmed cell death (see below).
- **Extracellular matrix:** In some situations hypertrophy involves changes in a cell's environment, such as remodeling extracellular matrix.
- **Recruitment of satellite cells:** Skeletal muscle hypertrophy includes recruiting perimuscular satellite cells that fuse with myocyte syncytia to provide additional nuclei that support the expanded protein synthetic needs of the enlarging muscle.

Atrophy and Hypertrophy Impact on Similar Signaling Pathways

Molecular Mechanisms in Atrophy

The size of cells and organs reflects an equilibrium between anabolic and catabolic processes and involves changes in both production and destruction of cellular constituents. In its most basic sense, atrophy is a cell's reversible restructuring of its activities to facilitate its own survival and adapt to conditions of diminished use.

Atrophy has been most extensively studied in adipose tissue and skeletal muscle, which respond rapidly to changes in demand for energy storage and contractile force, respectively. In skeletal muscle, when a muscle is immobilized, the need for contraction decreases ("unloading") and myocytes activate adaptive mechanisms:

- **Signaling:** The protein kinase Akt is central to atrophy. (1) Muscle disuse increases extracellular myostatin, a protein in the transforming growth factor-β (TGF-β) family. (2) Myostatin binding activates its receptor, which inhibits Akt. (3) A transcription factor, FOXO, which is normally curbed by Akt, is thereby released from that suppression. (4) FOXO activation increases production of ubiquitin ligases (E3), which mediate the degradation of muscle proteins by proteasomes (Fig. 1-21A, right side). In this context, inactivating mutations of the myostatin gene in cattle are characterized by massively increased muscle mass (double muscling), underscoring the interplay of atrophy and hypertrophy.
- **Protein synthesis:** Shortly after a muscle is relieved of its obligation to contract (unloading), synthesis of certain proteins declines; at the same time, production of other proteins that mediate this adaptation may increase.
- **Protein degradation:** Ubiquitin-related specific protein degradation pathways (see below) are activated as part of atrophic responses. Proteasomal degradation of muscle actomyosin is greatly enhanced by prior actomyosin cleavage by caspase-3 or calpain, both of which also participate in apoptosis (see below). These enzymes cause decreases in certain contractile proteins and in the specific transcription factors that drive expression of contractile protein genes. If the atrophic state is maintained, cells reach a new equilibrium in which mass remains decreased and rates of protein synthesis and degradation realign.
- **Energy utilization:** A selective decrease in use of free fatty acids (as opposed to glucose) as an energy source for muscle occurs during response to unloading.

Atrophy is thus an active, specific adaptive response rather than a passive shutdown of cellular processes. It is also reversible; if the environment that existed before atrophy developed is restored, myocytes reassume their prior size and function.

Molecular Mechanisms in Hypertrophy

At the fulcrum of the balance between atrophy and hypertrophy sits the protein kinase Akt. With resistance training, synthesis of extracellular IGF-I is increased. When IGF-I binds to its cell membrane receptor on type II muscle fibers, it initiates a signaling cascade that leads to Akt activation. This event stimulates mTOR (mammalian target of rapamycin), which upregulates protein synthesis (Fig. 1-21, left side; also see below).

In addition to Akt-related hypertrophy/atrophy mechanisms, an Akt-independent system involves PGC-1α. This molecule is a regulator of transcription factors and a master integrator of exogenous signals that elicit mitochondrial biogenesis. Exercise upregulates PGC-1α, which then induces factors that stimulate production of mitochondrial DNA, thereby increasing mitochondrial biogenesis (Fig. 1-21B). In

the delicate equilibrium between atrophy and hypertrophy, this anabolic response also serves as a countermeasure to prevent development of atrophy.

In this way, atrophy and hypertrophy, although phenotypically presenting as polar opposites, affect the same molecular intermediates.

Loss of Muscle Mass Commonly Results from Disease

Loss of 40% of body mass is usually fatal, but even a decrease of 5% in lean body mass can impair function. A number of conditions are characterized by such loss, and the pathways that are implicated in that result differ among various settings.

Cancer-Related Weight Loss and Cross-Talk between Adipose Tissue and Muscle

Over 80% of patients with gastric and pancreatic cancers lose weight, as do half of those with lung and colorectal cancers. Loss of adipose tissue and muscle is seen in cachexia (wasting), such as occurs in patients with advanced cancers. Tumor-induced lipolysis and energy utilization from adipose tissue release cytokines that initiate muscle atrophy. If such lipolysis is prevented experimentally, muscle mass is preserved.

Other Diseases Characterized by Weight Loss

Other chronic conditions in which weight loss occurs include:

- **Congestive heart failure (CHF):** In cardiac cachexia, type I (mitochondria-rich) muscle fibers are most affected. This unique susceptibility of type I fibers in CHF occurs because impaired oxygen delivery results in the sacrifice of those muscle fibers that use the most oxygen.
- **Chronic obstructive pulmonary disease (COPD).**
- **AIDS:** Before the introduction of effective antiretroviral therapy, wasting was the initial defining presentation in AIDS in 1/3 of patients. This association may reflect the energy expenditure needed to mount continuous acute phase inflammatory responses (see Chapter 2), including ongoing production of inflammatory mediators and decreased hepatic IGF-I production.
- **Rheumatoid arthritis (RA):** RA, the most common adult autoimmune disease (see Chapter 11), is associated with increased production of many catabolic cytokines (e.g., tumor necrosis factor-α [TNF-α], interleukin-1β [IL-1β], IL-6; see Chapters 2 and 4).
- **Aging:** Loss of muscle mass in aging, or **sarcopenia,** is universal and distinct from disease-related cachexia. Unlike the predominant loss of type I fibers in CHF, aging-related sarcopenia affects type II (fast-twitch) muscle fibers. The pathogenesis of sarcopenia is poorly understood, but includes (1) reduced protein synthesis, (2) loss of spinal cord motor units and (3) altered production of and response to anabolic hormones and cytokines. Interestingly, treating elderly patients with inhibitors of angiotensin-converting enzyme (see Chapters 2 and 8)—but not other types of antihypertensive agents—tends to preserve muscle strength, suggesting that the angiotensin system may play a role in sarcopenia.

Postmitotic Cells May Turn Over

Historically, neurons, cardiac myocytes and skeletal muscle cells were considered to be incapable of mitosis and essentially static throughout their life span. This view was generally interpreted to imply that such cells cannot be replaced, and therefore that their respective tissues cannot respond to cell loss or increased demand by adding cells. This conclusion is now considered only partially correct.

The Concept of Postmitotic Cells and Terminal Differentiation

Neurons and cardiac myocytes may not undergo mitosis, but committed progenitor cells in the brain and heart can proliferate and differentiate in response to cell loss and injury or, in the case of striated muscle, increased functional demand. Thus, there is a natural, albeit low, rate of cell loss and replacement among cells that were once considered irreplaceable. If the kinetics of such replacement favor cell loss, organ atrophy results, as in the heart, muscle and brain of the very aged. If progenitor cell activity predominates (e.g., in the skeletal muscle), hypertrophy may result.

UBIQUITIN AND THE UBIQUITIN–PROTEASOME SYSTEM

Ubiquitin and Ubiquitination Initiate Protein Degradation

Ubiquitin (Ub) is an evolutionarily conserved 76-amino-acid protein that is central to multiple cellular functions. These activities are accomplished via reversible Ub conjugation with target proteins and can be divided into proteolytic and nonproteolytic (trafficking) pathways. The Ub molecule contains seven lysine residues, and functional selectivity is provided by diverse patterns of protein linkage to these amino acids. Linkage to some lysines leads to passage of the tagged protein to the proteasome for degradation. However, other patterns of Ub linkage direct proteins to numerous other functions (Fig. 1-22). The fate of Ub-conjugated proteins among the several pathways is determined by the number of Ub moieties conjugated and the site of the conjugation linkages on the Ub molecule. Among the diverse functions of Ub-directed protein sorting are the following:

- Endocytosis
- Intracellular trafficking
- Regulation of histones and transcription
- Cell cycle control
- Autophagy (see below)
- Repair of DNA damage
- Cellular signaling

Further elucidation of these Ub-related mechanisms is beyond the scope of this discussion. We focus here on the proteolysis-related Ub pathway, which involves targeting proteins to degradative proteasomes (Fig. 1-23).

Mechanisms of Ub Conjugation to Proteins

Ub attachment to proteins occurs via a sequence of enzymatic reactions. A Ub-activating enzyme, E1, binds to Ub and then transfers it to one of dozens of Ub-conjugating enzymes (E2). These act together with one of about 800 different Ub-ligating enzymes (E3) to add Ub to a lysine on

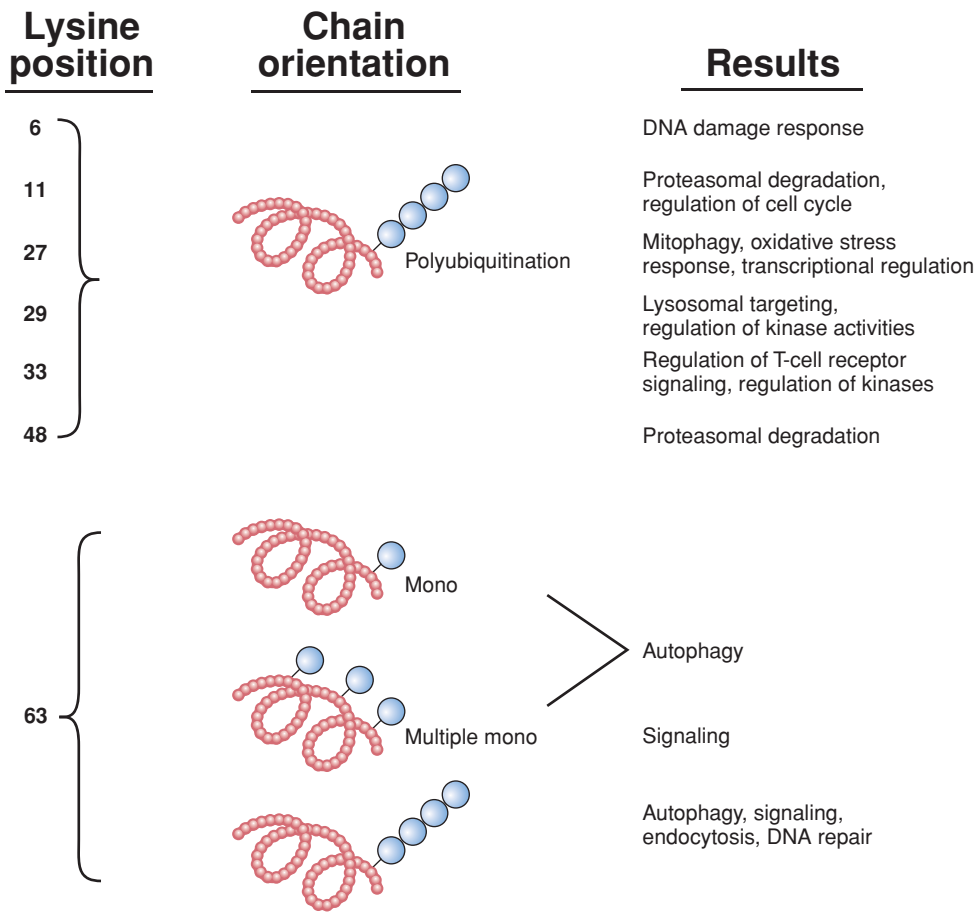

FIGURE 1-22. The diversity of ubiquitination and its consequences. The several lysines of the Ub (ubiquitin) molecule can be used either to form poly-Ub chains or for mono- or oligoubiquitination. Ubiquitination of different lysine residues (represented here by *K*) imparts different functions to the target protein.

the doomed protein (Fig. 1-23). Additional Ub moieties are added to the original Ub, forming a polyubiquitin chain (at least four Ubs). The specificity of the process for the targeted protein resides in the combinations of E2 and E3 enzymes. E3 Ub ligases control many cellular processes, including cell cycle, transcription, life and death, as well as normal cellular homeostasis (see below and Chapter 5).

Proteasomes Are Key Participants in Cell Homeostasis

Cellular responses to altered environments were once studied exclusively by analyzing changes in gene expression and protein production. Protein degradation was either ignored or relegated to the nonspecific proteolytic activities of lysosomes. However, it is now clear that cellular homeostasis requires mechanisms that allow the cell to destroy proteins selectively. Although more than one such pathway exists, the best-understood setting in which specific proteins are eliminated is the proteasomal apparatus.

Proteasomes

Proteasomes are highly conserved organelles in the cytoplasm and possibly the nucleus. They are barrel-shaped complexes whose main (but not only) function is to digest polyubiquitinated proteins. There are two types of proteasomes: 20S and 26S. The degradative unit of both is a 20S destruction chamber, to which, in the 26S proteasome, two 19S "caps" are attached, as shown in Fig. 1-23. The caps at the entrance to the proteolytic core regulate entry. The 20S proteasomes lack these caps.

Proteins targeted for destruction are modified as described below and recognized by one 19S cap. They are then degraded in the proteolytic core. This process produces peptides of 3 to 25 amino acids, which are released through the lower 19S subunit. These peptides may then be further degraded by cytosolic proteases.

The importance of proteasomes is underscored by the fact that they make up 1–2% of the total mass of the cell. ***Mutations that interfere with normal proteasomal function are lethal.*** The 20S proteasomes are important in degradation of **oxidized proteins** (see below). In 26S proteasomes, **polyubiquitinated proteins** are degraded. A type of proteasome, the immunoproteasome, is formed when cells produce interferon-γ (IFN-γ) and is important in processing protein antigens into peptides that attach to major histocompatibility complex (MHC) type I for presentation to the immune system (see Chapter 4).

Proteasomes are charged with eliminating proteins that have been incorrectly folded, damaged, reached the end of their usefulness or need to be destroyed for some other reason. They are, then, key to regulating cell cycle transit, in that they degrade progrowth proteins after they accomplish

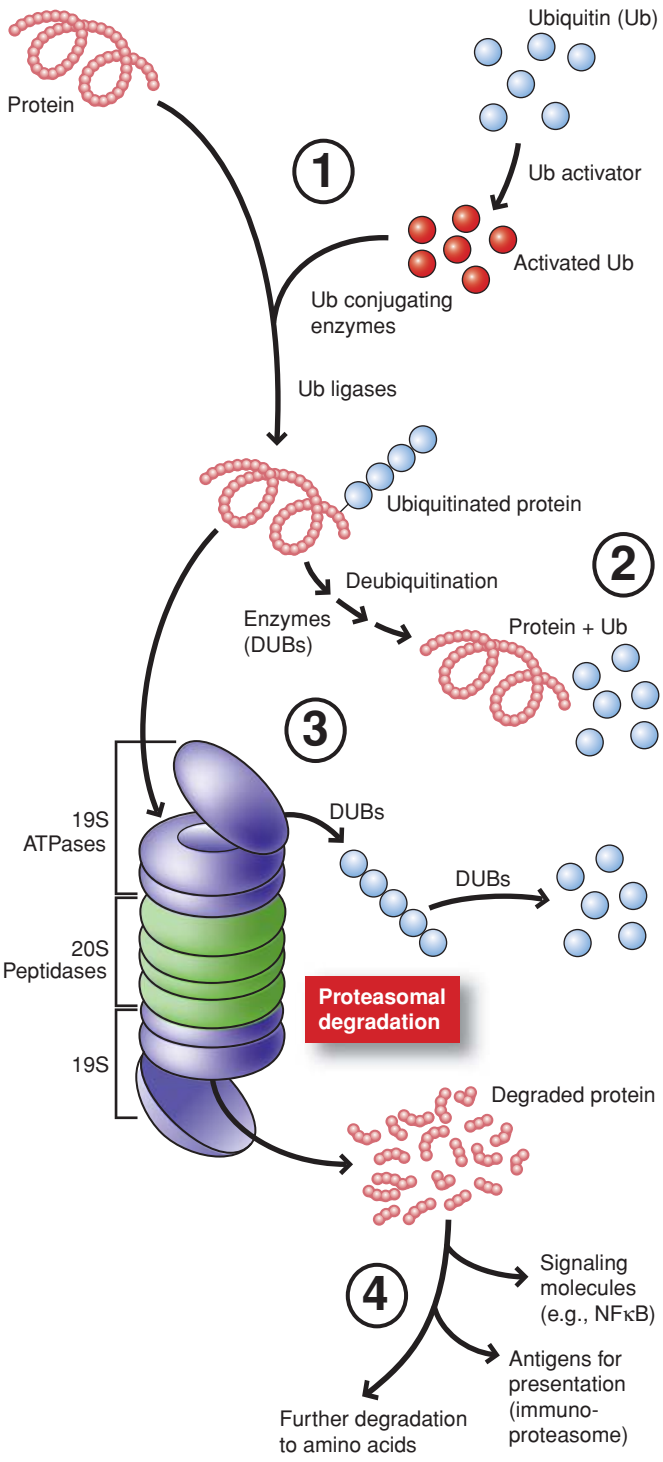

FIGURE 1-23. Ubiquitin–proteasome pathways. Ub (ubiquitin) targets proteins for specific elimination in proteasomes. **1.** Ub is activated by E1 ubiquitin-activating enzyme, after which it is transferred to an E2 ubiquitin-conjugating enzyme. The E2–Ub complex interacts with an E3 ubiquitin ligase to bind a particular protein. The process may be repeated multiple times to append a chain of Ub moieties. There follows a choice: **2.** These complexes may be deubiquitinated by deubiquitinating enzymes (DUBs). **3.** If degradation is to proceed, 26S proteasomes recognize the poly-Ub-conjugated protein via their 19S subunit and degrade it into oligopeptides. In the process, Ub moieties are returned to the cell pool of Ub monomers by DUBs. **4.** After release from the proteasome, partially degraded proteins may follow alternative fates.

their objectives. Proteasomes also maintain the balance of life and death in favor of cell survival by specifically eliminating proapoptotic molecules (such as p53; see below). On balance, these structures maintain and protect cellular viability. Thus, a proteasome inhibitor (bortezomib) is now used in routine clinical practice to treat patients with certain malignancies.

Deubiquitinating Enzymes

Deubiquitinating enzymes (DUBs) are proteases that remove Ubs from poly-Ub chains and their partner proteins. Once a protein's doom is sealed for degradation in a proteasome or lysosome (see below), recycling of the Ub that determines this fate is economically advantageous. However, deubiquitination can also commute a protein's death sentence and enhance its stability. DUBs are critical to the function of Ub-regulated cellular switches in that they counteract the ubiquitination of specific protein targets. As many as 100 DUBs are known that reverse the effects of ubiquitination on many cellular processes, including (1) protein degradation, (2) cell cycle regulation, (3) gene expression, (4) signaling pathways and (5) DNA repair.

Some Pathogens Can Manipulate the Ubiquitin System

Some pathogens can control Ub/DUB pathways at multiple points. Certain bacterial proteins, called effectors, resemble E3 Ub ligases and activate ubiquitination, allowing exquisite exploitation of host cells to facilitate invasion and pathogenicity. Other bacteria (e.g., *Salmonella typhimurium, Chlamydia trachomatis*) and viruses (e.g., herpes simplex virus) encode proteins that act as DUBs, suggesting that interference with cellular ubiquitination may confer a selective advantage to these pathogens.

Some modifications of proteins may protect them from ubiquitination. For example, when the tumor suppressor protein p53 is phosphorylated in response to DNA damage, it is protected from Ub-mediated degradation.

There are a number of proteins that resemble Ub but are structurally and functionally distinct from it, and that subserve somewhat different functions. Such proteins (e.g., SUMO and NEDD8) may participate in forming some E3 complexes. Their polymeric chains may direct protein localization and diverse protein activities.

Ubiquitination and Deubiquitination Are Key to Many Diseases

Ubiquitination and specific protein elimination not only are important for normal cellular homeostasis but also are critical to cellular adaptation to stress and injury. Mutations in Ub pathway constituents can cause specific diseases, and in many cases altered UPS activity is important in disease pathogenesis (Table 1-3). For example, defective ubiquitination is involved in several important neurodegenerative diseases. Mutation in parkin, a ubiquitin ligase, is implicated in the pathogenesis of some hereditary forms of Parkinson disease, in which undegraded parkin accumulates as Lewy bodies (see Chapter 32).

Regulation of ubiquitination may be important in tumor development. Thus, human papillomavirus strains that are associated with human cervical cancer (see Chapters 5 and 24)

TABLE 1-3
INVOLVEMENT OF THE UBIQUITIN–PROTEASOME SYSTEM IN DISEASE

Disease	Ubiquitin–Proteasome System Activity	Anatomic Effect
Neurologic Diseases (Diseases Associated with Neuron Loss)		
Parkinson disease	Decreased	Lewy bodies
Alzheimer disease	Decreased	Amyloid plaques, neurofibrillary tangles
Amyotrophic lateral sclerosis	Decreased	Superoxide dismutase aggregates in motor neurons
Huntington disease	Decreased	Polyglutamine inclusions
Autoimmune Diseases		
Sjögren syndrome	Decreased	Chronic inflammation
Metabolic Diseases		
Type 2 diabetes mellitus	Increased	Insulin insensitivity
Cataract formation	Decreased	Aggregated oxidized proteins
Muscle Wasting		
Aging	Increased	Atrophy
Cancer and other chronic disease	Increased	Atrophy
Cardiovascular		
Ischemia/reperfusion	Decreased	Myocyte apoptosis
Pressure overload	Decreased	Myocyte apoptosis

produce E6 protein, which inactivates the p53 tumor suppressor. E6 accomplishes this by binding an E3 (ubiquitin ligase) and facilitating its association with p53. Such increased ubiquitination of p53 accelerates its degradation, and the loss of its activity is implicated in the genesis of cervical cancer. Impaired ubiquitination may also contribute to cellular degenerative changes in aging and to a variety of storage diseases.

Ubiquitination also plays a role in gene expression. Nuclear factor-κB (NFκB) is an important transcriptional activator that is activated in two different ways by the UPS. The active form of NFκB is a heterodimer (i.e., it is composed of two different protein subunits). Inactive precursor forms of the two NFκB subunits are ubiquitinated and cleaved to their active forms in proteasomes. *This is an example of incomplete protein degradation by the UPS.* Also, the inhibitor of NFκB, called IκB, is degraded by ubiquitination. This step releases active NFκB, which mediates expression of genes that promote cell survival. Proteasome inhibition permits persistence of the IκB–NFκB complex and so decreases NFκB-induced transcriptional activation. In the case of cancer cells, inhibiting proteasome function would impair tumor cell survival and is consequently a target for pharmaceutical manipulation.

Virtually anything that ubiquitination can do, deubiquitination can undo or prevent. DUBs are critical to gene expression and influence a wide variety of distinct mechanisms. They have been shown to activate tumor suppressor proteins and are likely to be important in tumorigenesis. In this way, DUBs are thought to participate in diverse protein interaction networks. Their involvement in major disease pathways may offer attractive targets for pharmacological intervention.

Autophagy Is a Form of Controlled Cellular Cannibalism That Is Crucial to the Balance Between Cell Survival, Death and Adaptation

Autophagy (Greek: "auto," *self;* "phagy," *eating*) is a highly conserved catabolic process by which cytoplasmic targets are recognized and delivered to lysosomes for digestion. Autophagic degradation is generally divided into three categories, based on both the cargoes involved and how they arrive at lysosomes. **Macroautophagy** is responsible for handling bulk portions of cytoplasm, and both macroautophagy and **microautophagy** target damaged cellular organelles, aggregated proteins and other potentially injurious materials. In addition, some defective proteins require interaction with molecular chaperones (see below) and enter the autophagic system via **chaperone-mediated autophagy** (**CMA**) (Fig. 1-24).

It is important to appreciate that autophagy systems operate continuously and are obligatory for cell homeostasis and survival. Bulk autophagy, the most primitive form of the process, protects cells when nutrients are lacking, as in starvation or compromised blood supply. Other forms of autophagy maintain functional homeostasis among cellular

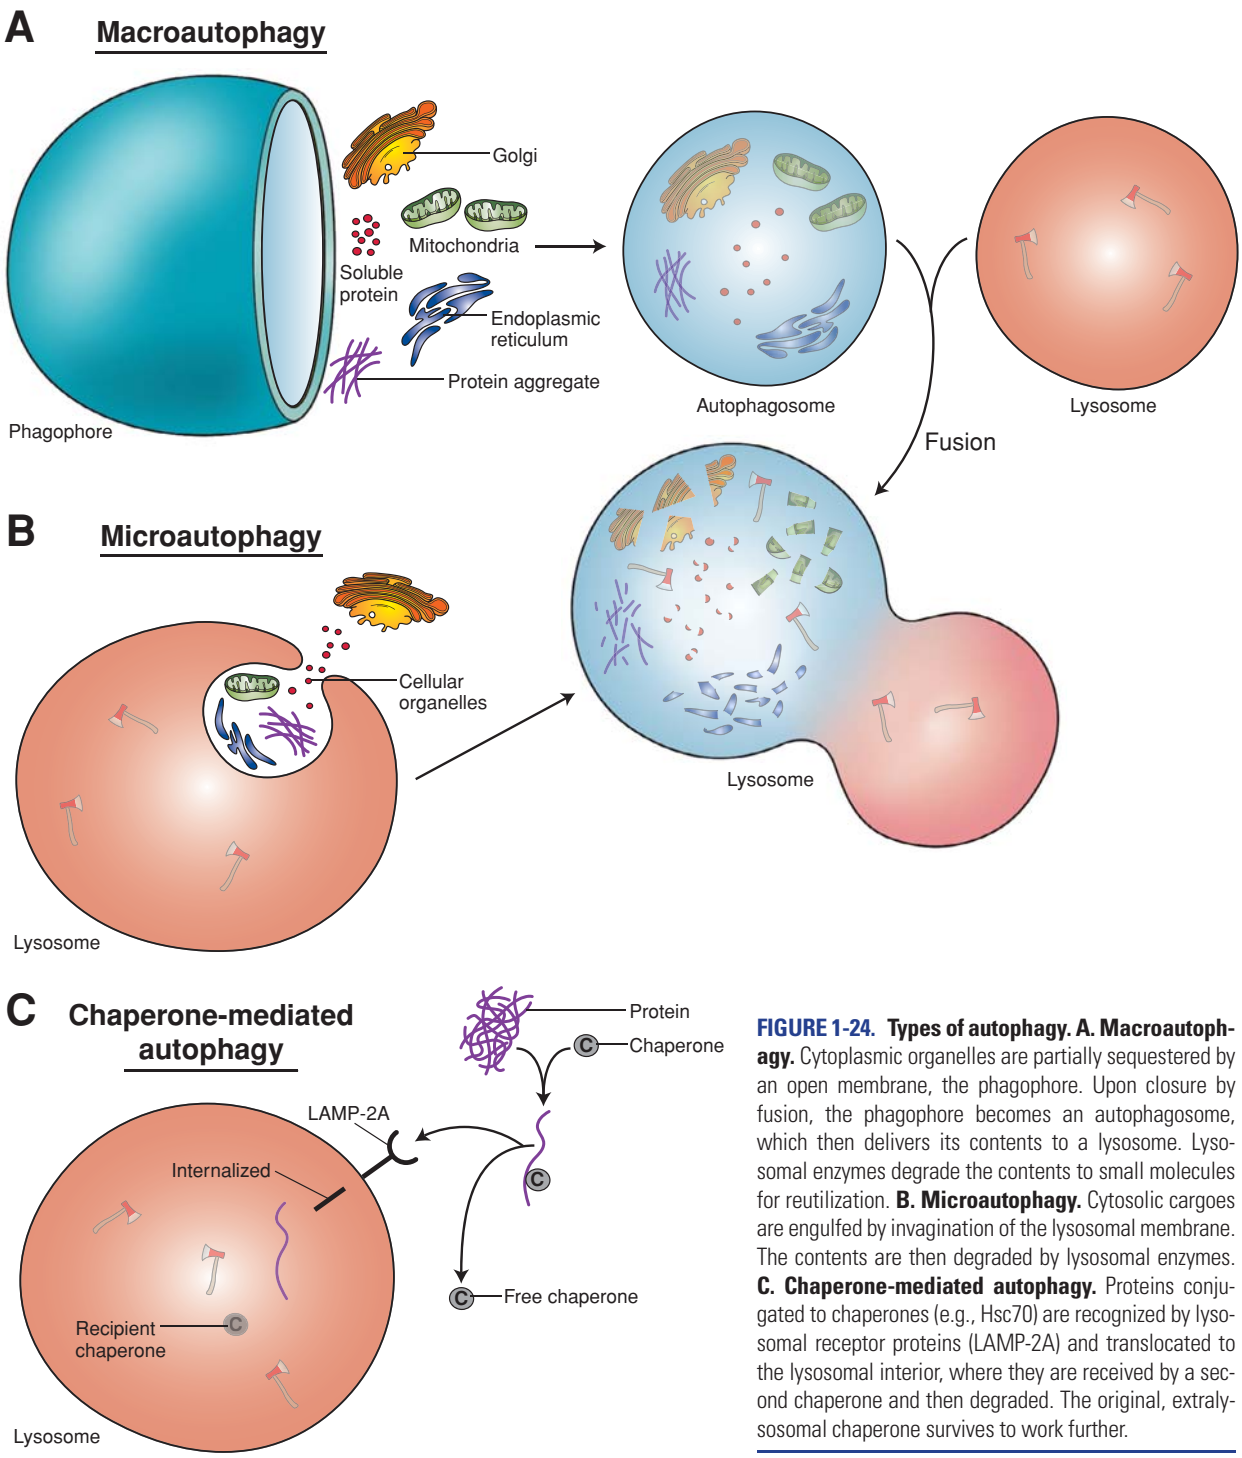

FIGURE 1-24. Types of autophagy. A. Macroautophagy. Cytoplasmic organelles are partially sequestered by an open membrane, the phagophore. Upon closure by fusion, the phagophore becomes an autophagosome, which then delivers its contents to a lysosome. Lysosomal enzymes degrade the contents to small molecules for reutilization. **B. Microautophagy.** Cytosolic cargoes are engulfed by invagination of the lysosomal membrane. The contents are then degraded by lysosomal enzymes. **C. Chaperone-mediated autophagy.** Proteins conjugated to chaperones (e.g., Hsc70) are recognized by lysosomal receptor proteins (LAMP-2A) and translocated to the lysosomal interior, where they are received by a second chaperone and then degraded. The original, extralysosomal chaperone survives to work further.

proteins and organelles in normal settings and in times of stress. Autophagic pathways act as ongoing physiologic quality control mechanisms protecting from, for example, excess production of ROS by inefficient or damaged mitochondria. Autophagy in its various forms is thus essential both for basal cellular physiology and for adaptation to adversity, as illustrated by this abbreviated list of its functions and of circumstances in which it protects the cell:

- Starvation
- Ischemia
- Recycling nutrients from cellular organelles and macromolecules
- Clearance of misfolded or damaged proteins and organelles
- Antigen presentation
- Protection from tumorigenesis
- Protection from neurodegeneration

The following sections illustrate the mechanisms of autophagy, their interrelationships with other systems, their role in maintaining health and their involvement in disease. Since continuous maintenance of intracellular components is necessary for cell survival, impairment of any form of autophagy may lead to accumulation of abnormal proteins and defective organelles. The result may be cell death or disease.

Autophagy is basically a series of processes that are obligatory for normal cell function and that make it possible for a cell to remain viable in hostile environments. It is thus a form of "programmed cell survival." Under some circumstances, however, it may give rise to self-cannibalism as a form of cell death (see below).

The principal pathways of autophagy—macroautophagy, microautophagy and CMA—all lead to the final common pathway of destruction of cell components in lysosomes. However, these processes differ in (1) regulation, (2) types of cargo involved, (3) recognition of the substrate to be degraded and (4) delivery to lysosomes. The fine distinctions between the various forms of autophagy remain somewhat blurred, and some overlap probably exists.

Macroautophagy

Macroautophagy entails bulk sequestration of cytoplasmic contents, including soluble and aggregated proteins and cellular organelles. As they do in the balance between atrophy and hypertrophy (see above), the enzymes **Akt** and **mTOR** play central roles in the autophagic process. Growth factors such as insulin and IGF-I activate Akt. In turn, Akt activates mTOR, which in turn inhibits autophagy (Fig. 1-25).

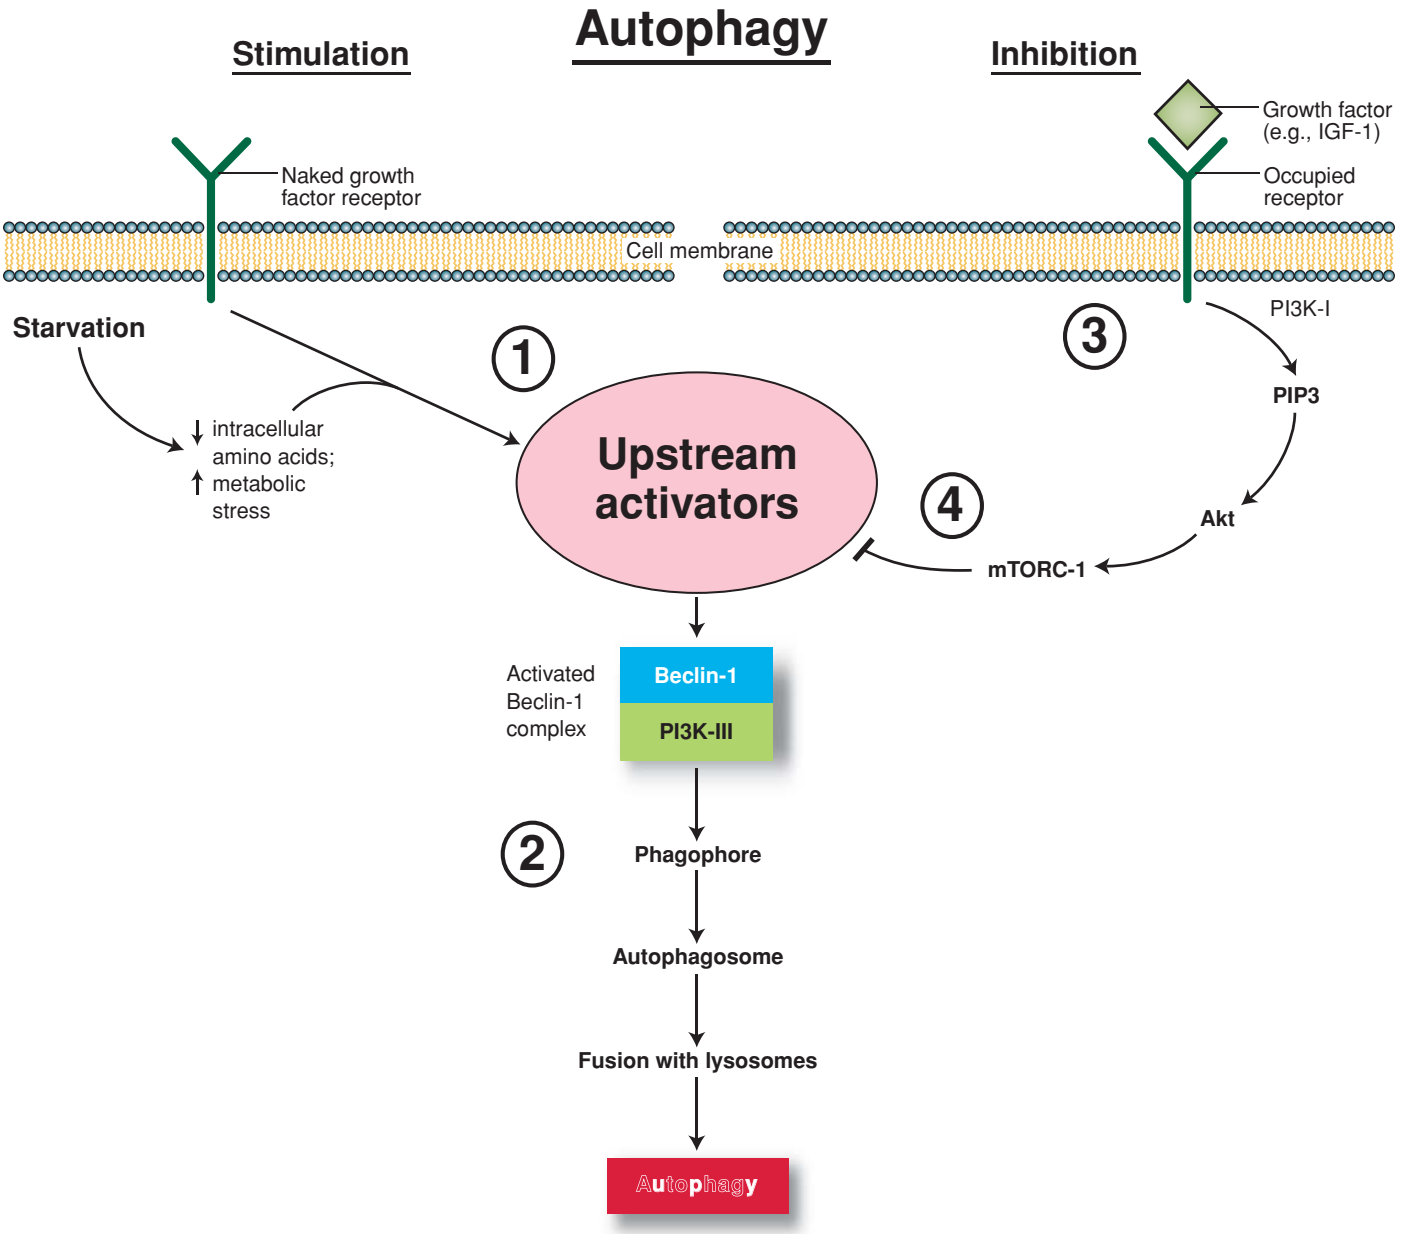

FIGURE 1-25. Triggering and inhibiting autophagy. Stimulation (left). 1. In the setting of starvation or other initiators of autophagy, lack of growth factors leads to depletion of nutrients and hence metabolic stress. A consortium of upstream molecules is triggered. **2.** As a result, an autophagy-activating complex containing Beclin-1 and class III phosphatidylinositol-3-kinase (PI3K-III) is formed. This complex triggers autophagy, from the phagophore to the fusion of the phagosome with the lysosome. **Inhibition (right). 3.** Autophagy is inhibited when nutrients or other stimuli elicit growth factors (e.g., insulin-like growth factor-I [IGF-I], insulin), which bind to their cell membrane receptors. This process activates class I PI3K (PI3K-I), which produces phosphatidylinositol-tris-phosphate (PIP3). **4.** PIP3 then recruits Akt to the cell membrane, where it is activated and in turn stimulates the mTOR-related complex, mTORC1. The latter directly blocks the autophagy cascade, including Beclin-1, to prevent autophagy.

However, in a situation such as starvation, cellular sensors detect a scarcity of amino acid reserves, and production of endocrine and paracrine growth factors declines. This removes mTOR-mediated inhibition and stimulates autophagy. In the process, Beclin-1 and PI3K (phosphatidylinositol-3-kinase) form a complex, which is then activated and sets the autophagic pathway in motion (Fig. 1-25). Thereafter, bulk cytoplasm, containing cytoplasmic organelles and including proteins, lipids and other constituents, is partially sequestered by a membrane (the **phagophore**). The latter fuses at its ends to enclose a structure, the **autophagosome**. Autophagosome membranes may derive from several cytoplasmic sources, including the outer mitochondrial membrane, endoplasmic reticulum, plasma membrane or Golgi apparatus. The autophagosome then fuses with lysosomes, whose enzymes reduce autophagosome contents to small molecules for reutilization by the cell (Fig. 1-25).

Identifying Targets in Macroautophagy

Starvation-related autophagy is mostly nonselective for soluble cytoplasmic constituents and organelles, although even in this setting, recycling of cell contents is not totally random. Macroautophagy also handles damaged cytoplasmic organelles and aggregated proteins, for both of which specific recognition is needed.

In such circumstances, target identification depends on the nature of the dysfunction. For example, a damaged mitochondrion that produces excess reactive oxygen species from dysfunctional electron transport suffers altered membrane potential, thereby causing a cytosolic protein, Nix, to bind to the outer mitochondrial membrane. This complex recruits a protein called **parkin** (for its likely involvement in Parkinson disease). In turn, parkin binds to several members of a series of Ub-like (**UBL;** see below) recognition proteins, which are termed autophagy-related proteins, or **Atgs**. A bridge protein, **p62**, recognizes these UBLs and attaches the damaged mitochondrion to the interior of the developing phagophore (Fig. 1-26).

Protein aggregates are usually concretions of misfolded proteins and are handled by a parallel, but different, pathway. Misfolding may occur at the time of translation or from acquired (e.g., oxidative) damage. Resultant exposure of hydrophobic residues that are normally hidden in the interior of proteins leads to both their recognition by the Ub system and attachment of poly-Ub chains by E3 Ub ligases. In some cases Atgs are also conjugated to these masses of proteins. However, these aggregates are too large to pass through proteasomes, and so Ubs and UBLs are recognized by the same p62 bridge protein and incorporated into autophagosomes (Fig. 1-26).

Macroautophagy was at first considered to be a nonspecific response to stress, especially starvation. It is now recognized that the continuous quality control exerted by this process is of great importance in maintaining cellular integrity.

Microautophagy

Microautophagy (Fig. 1-24) is a process by which cytosolic cargoes are directly engulfed by invagination of lysosomal membranes, then transferred into the interior of lysosomes for degradation. This process is largely constitutive and is important for continuous turnover of membranes and organelles and for maintaining organelle size and composition.

Chaperone-Mediated Autophagy

CMA (Fig. 1-24) is characterized by the fact that all of its targets are recognized selectively by chaperone proteins. Targets are translocated via receptor recognition across lysosomal membranes, without phagosome intermediates. Like an adult chaperone at a teenage dance, who is responsible for maintaining decorum in conduct and for removing incorrigible violators, cytosolic molecular chaperones preside over correct folding of nascent proteins and destruction of misfolded or damaged proteins via CMA. There is a modest level of constitutive CMA, but this pathway can be further activated when the cell is stressed (e.g., starvation, oxidant stress, toxic exposures, etc.).

Crosstalk Among Degradative Pathways

Some branches of the autophagic pathway are regulated by sequential enzymatic activation of Ub and UBLs, the latter resembling the activation cascade of the UPS (see above). Short-lived proteins are generally specifically digested by the UPS, whereas autophagy tends to remove longer-lived proteins selectively. This division of labor is not rigid: if one system is compromised, the other may compensate, at least in part. The UPS cannot handle protein aggregates or large cytoplasmic structures, like organelles or endocytosed foreign matter (e.g., bacteria). These systems thus complement each other. In addition, there are molecular interactions among the different types of autophagy, and impairment of one such pathway may lead to compensatory activation of another.

Both the autophagic pathway and the UPS operate continuously, and inhibition of either often has harmful consequences. Although autophagy can act as a bulk recycling mechanism for nutrients in times of starvation, both systems can be remarkably selective. This specificity reflects the participation of many molecules in the process of selective identification of materials for degradation. This ability to accommodate diverse targets is reminiscent of the body's antigen recognition and drug-metabolizing (P450) systems. The Ub pathway contains over 1000 proteins that confer comparable precision in target selection. Autophagy relies on the diversity of the Ub system and the parallel Atg proteins to maintain a similarly broad scope and accuracy. As mentioned above, conjugation of either Ub or Atg proteins to aggregated proteins or organelles can lead to recognition of the doomed structure by the p62 linker protein, followed by transport to phagophores to complete autophagic and degradative processes.

Why is selectivity important? A significant proportion of newly synthesized proteins are translated or folded incorrectly. Oxidative damage further increases the cell's load of defective proteins. Such molecules must be removed, lest the cell risk continuing to accumulate proteins that can form large, insoluble aggregates that lead to abnormal protein–protein interactions or exhibit other poisonous properties.

Autophagy and Disease

Autophagy maintains cellular homeostasis during starvation and removes obsolete or damaged cell constituents, whose retention could lead to diverse harmful consequences (cancer, infection, etc.). It may be for this reason that periodic fasting, which activates autophagy, has been practiced by many cultures.

The links between autophagy and many diseases are such that considerable energy is now being invested to develop

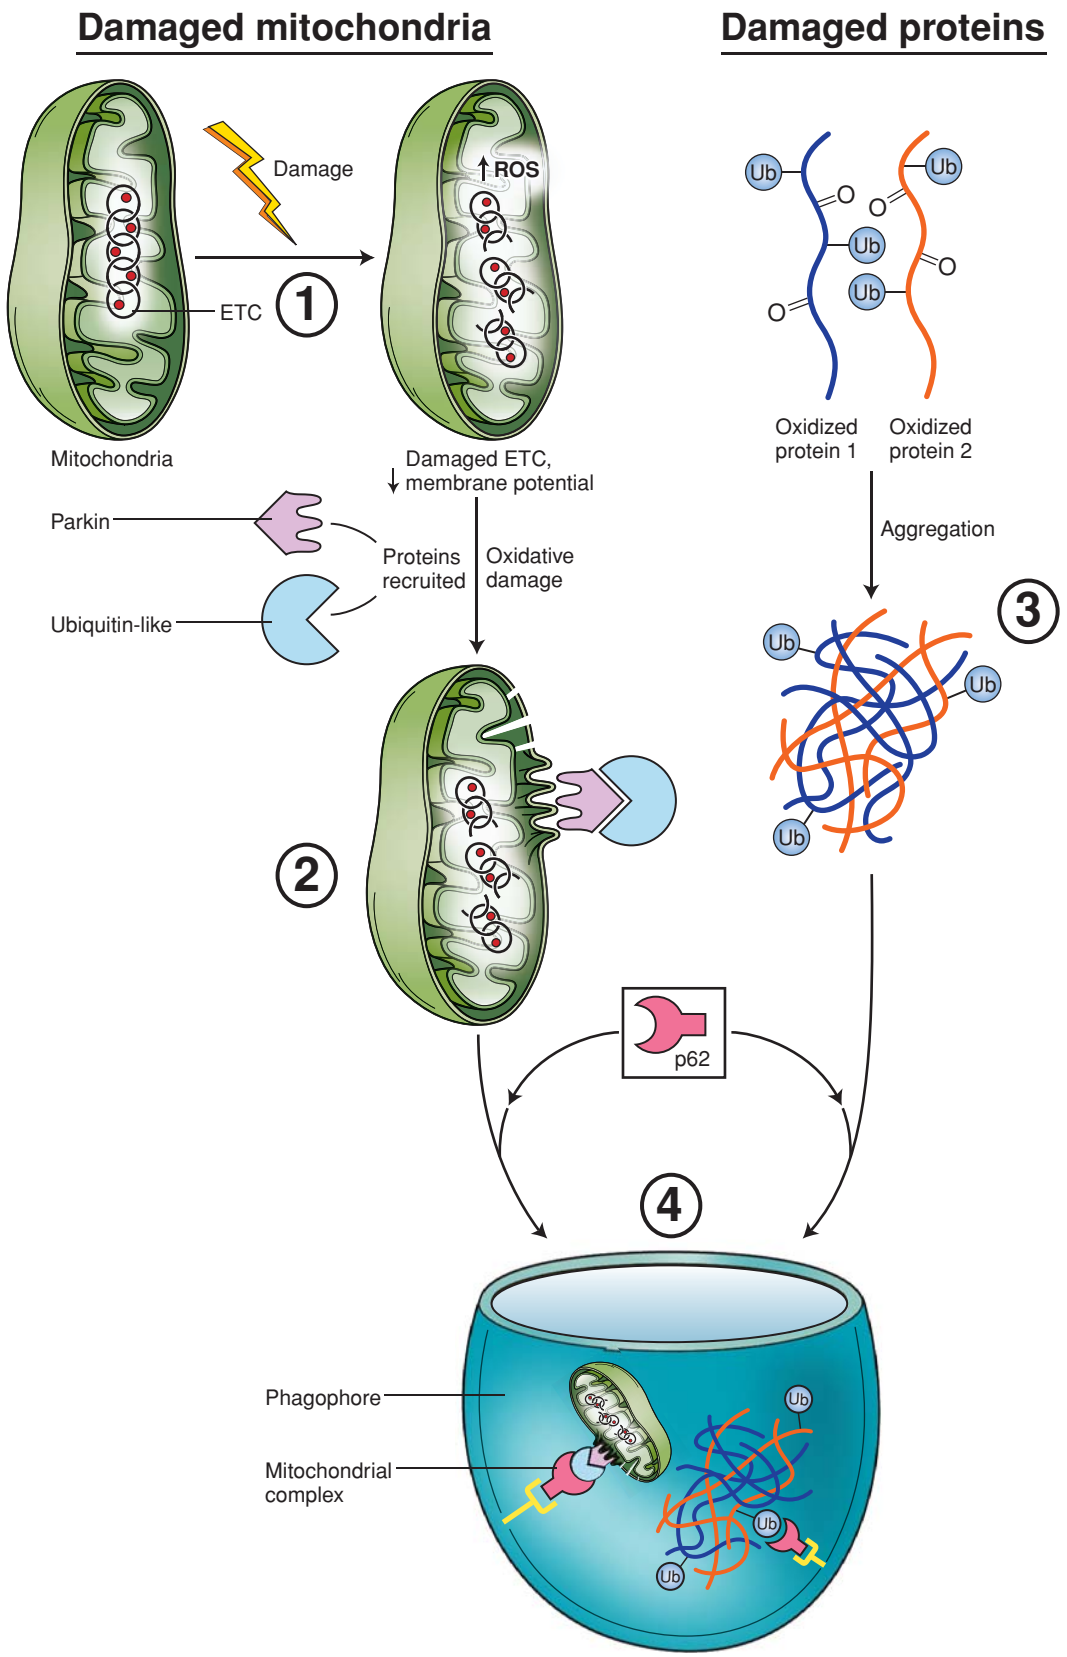

FIGURE 1-26. Role of autophagy in handling damaged cellular organelles and protein aggregates. Damaged cellular organelles (left). 1. Damage (here) to mitochondria disrupts electron transport and dissipates the electrochemical gradient across the mitochondrial membrane. Increased ROS result and produce oxidative damage. This leads to recruitment of cytosolic proteins, parkin and a UBL. **2.** The complex of fragmented mitochondria–parkin–UBL binds to p62. **3.** Proteins that have sustained oxidative damage are conjugated to Ub or a UBL and form aggregates, which are then bound by p62. **4.** The p62-bound complexes with damaged mitochondria or aggregated proteins are recognized by a specific receptor in the phagophore, thereby leading to autophagy. *ETC* = electron transport chain; *ROS* = reactive oxygen species; *Ub* = ubiquitin; *UBL* = Ub-like protein.

ways to manipulate the process pharmacologically. Autophagy and defective autophagy contribute to:

- **Neurodegenerative diseases:** Many inherited neurodegenerative diseases involve mutations in proteins of the autophagic pathways, as do many lysosomal storage diseases. In some cases, like Alzheimer and Parkinson diseases, autophagy may fail to keep pace with the pace at which protein aggregates accrue. This may be due in part to age-related decreases in Beclin-1 synthesis.
- **Aging:** Macroautophagy and CMA decline with age, in parallel with Beclin-1 and certain lysosomal membrane proteins. This type of dysfunction in autophagy may account for age-related changes in organ systems such as the central nervous system (CNS), heart and so forth.
- **Pancreatitis:** There is evidence that impaired autophagy in this necroinflammatory disease may be responsible for inappropriate conversion of trypsinogen to trypsin, thereby creating autodigestion of the pancreas.
- **Infectious diseases:** Autophagy generally represents an important host defense mechanism against pathogens. Not surprisingly, many invasive organisms have developed ways to evade or subvert this process. A microorganism may inhibit the autophagic pathway, thereby avoiding a gruesome death. Other bacteria may interfere with phagosome–lysosome fusion, a strategy exploited by, for example, *Mycobacterium tuberculosis* and *Shigella flexneri,* to survive and replicate unmolested. Herpes simplex virus type 1 (HSV-1) encodes a protein that inactivates Beclin-1, thereby protecting the virus from autophagic degradation. Conversely, some viruses, particularly RNA viruses such as poliovirus and hepatitis C virus, benefit from increased autophagy; autophagic vesicles serve as membrane scaffolds for their replication.
- **Crohn disease:** There is a robust association between the occurrence of mutations in two genes and the risk of Crohn disease. Mutations in both genes, which normally facilitate autophagic clearance of invasive bacteria, impair bacterial clearance and promote increased production of molecules that stimulate inflammation.
- **Cancer:** The involvement of autophagy in the development and progression of cancer is complex and represents a double-edged sword. Several autophagy genes (e.g., Beclin-1 and some Atg genes) act as tumor suppressors (see Chapter 5) and are deleted or mutated in many human tumors. Autophagy can also protect cancer cells if they are deprived of nutrients or oxygen because of therapy or insufficient blood supply.
- **Miscellaneous:** Mutations in genes that encode proteins involved in autophagosome–lysosome fusion are linked to a disease of skeletal muscle (inclusion body myopathy), Paget disease of bone and frontotemporal dementia. Autophagy has been implicated in other diseases (cardiac ischemia and ischemia/reperfusion injury [see later], type II diabetes [see Chapter 13], stroke, etc.), but its role is not well defined.

Molecular Chaperones Establish and Maintain Functional Protein Conformations

Nascent proteins must assume particular three-dimensional configurations by folding appropriately as they exit ribosomes. Left to their own devices, newly produced proteins are in great danger of folding abnormally and then aggregating, thereby potentially overwhelming the cell with harmful species. To prevent such a disaster, cells have evolved a network of supervisory molecules that use ingenious approaches to ensure and maintain appropriate folding. Molecular chaperones are proteins that associate with client proteins and help them assume their final, functional, three-dimensional configurations. Some chaperones also help to sustain that conformation over time, thereby preventing accumulation of abnormal proteins.

The ongoing process of quality control by chaperones is called **proteostasis**. The folding-energy landscape of cells is complex, and ATP-dependent chaperones are needed to help other proteins navigate it successfully in a crowded intracellular environment. There are several hundred chaperone proteins, which are organized into distinct families based on structural homologies. Many of these molecules are induced by stress and are called heat shock proteins (Hsp). These are now grouped into clans based on prototypical members. They were originally designated by molecular weight (e.g., Hsp70, Hsp90), although terminologies are in transition and each subserves different functions, including acting as cofactors for other heat shock proteins.

As they exit ribosomes, nascent proteins are met by one or more chaperones, which direct their folding. If the resulting conformation is sufficient for functionality, the chaperone and the new protein dissociate, and the latter proceeds to its appropriate location (Fig. 1-27). However, some proteins behave like unruly children and require additional education. In that case, they are encapsulated by cylindrical channels called chaperonins, which provide an environment that fosters their final tertiary structures.

The chaperone system consists of a proteostasis hub that influences many cellular functions, including cell cycle progression, apoptosis (see below), telomere maintenance (see Chapter 5), intracellular transport, innate immunity and specific degradation of proteins. This mechanism collaborates closely with the UPS and with autophagy machinery to establish an integrated proteostasis network (Fig. 1-28). The circuitry of this network provides cradle-to-grave care for proteins. It (1) guides conversion of single polypeptide chains into proteins, (2) maintains active three-dimensional structures and (3) at the appropriate juncture, presides over their destruction.

Chaperonopathies

Defects in molecular chaperones are implicated in several disorders, called "chaperonopathies." These diseases are characterized by defects, excesses or mistakes in chaperone proteins.

Genetic chaperonopathies, which mainly reflect inherited germline mutations in one or another of the molecular chaperones, have been implicated in developmental disorders, neuropathies, dilated cardiomyopathy and polycystic liver and kidney diseases. A mutation in a chaperone cofactor causes a form of X-linked retinitis pigmentosa. Hereditary spastic paraplegia is related to a mutation in Hsp60, a mitochondrial chaperone. If von Hippel-Lindau protein (VHL) is mutated, it may bind its chaperone poorly, leading to its being misfolded and inactive as a tumor suppressor. Affected people develop tumors of the adrenal, kidney and brain. Moreover, mutant chaperone genes are responsible for certain types of cancer.

Acquired chaperonopathies arise for several reasons. Impairment of stress responses may result in inadequate amounts of chaperone proteins. By contrast, high levels of substrate (misfolded or degraded) proteins may exceed the capacity of the chaperone system. Chaperone molecules

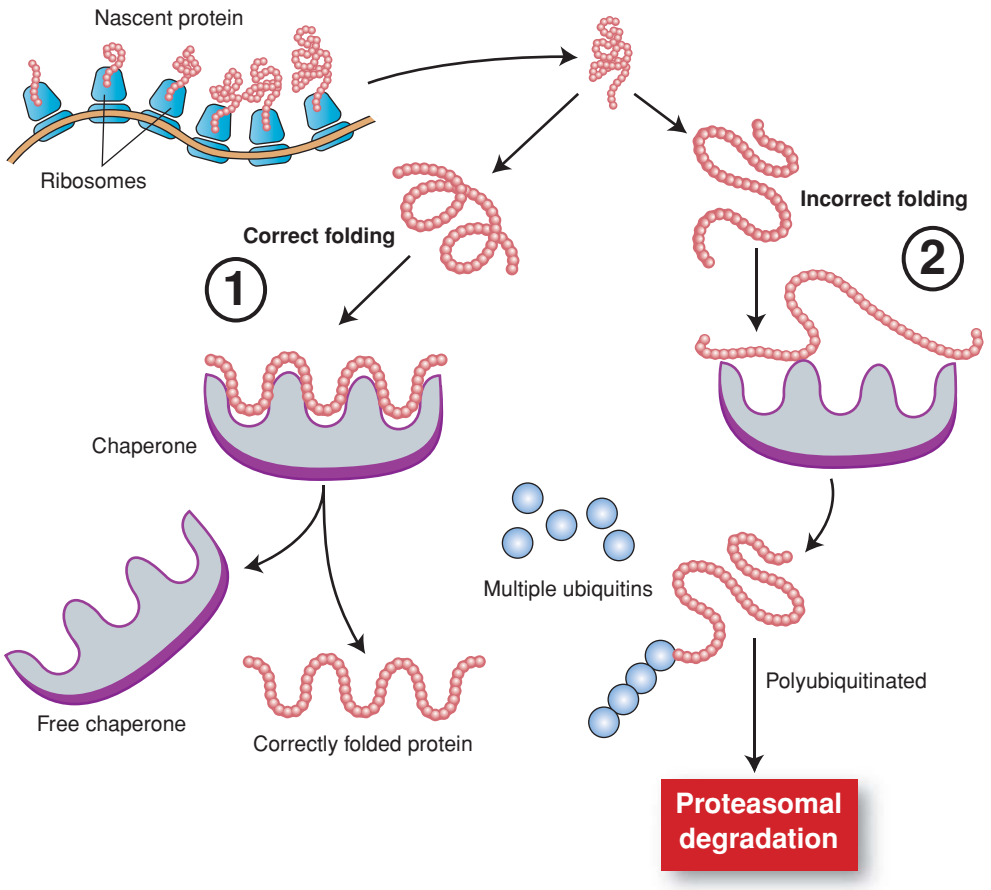

FIGURE 1-27. Differential handling of protein that is (1) correctly folded and protein that is (2) incorrectly folded. Correctly folded proteins are chaperoned from the ribosomes that produce them to their ultimate cellular destination. Incorrectly folded proteins are polyubiquitinated, which directs them to proteasomes, where they are degraded.

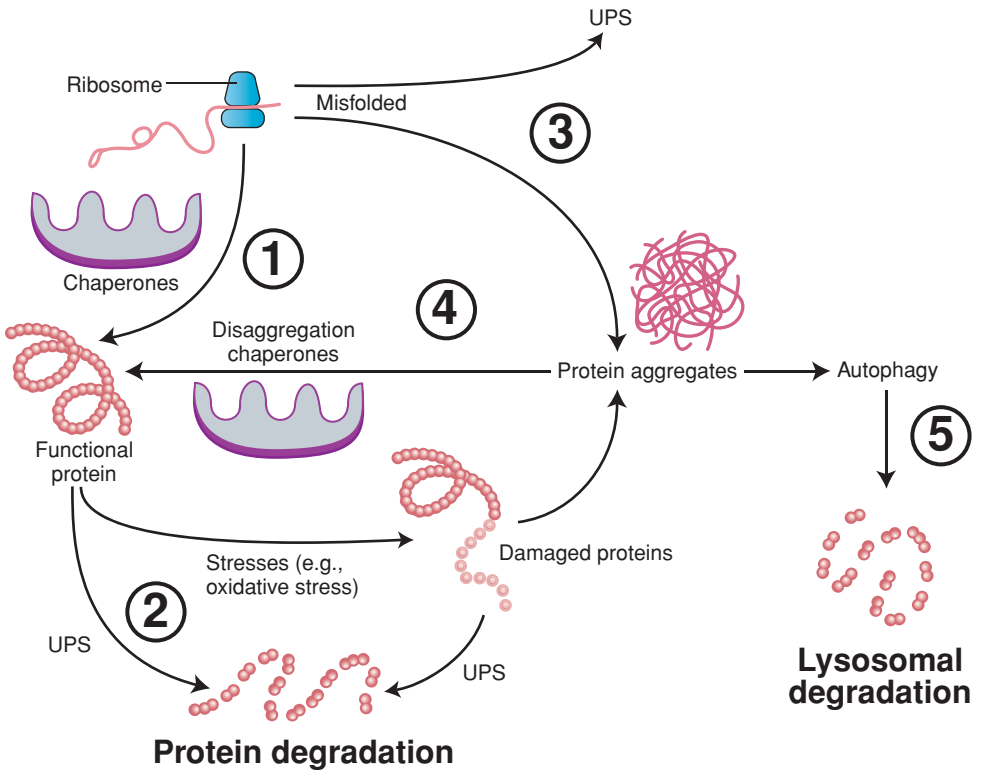

FIGURE 1-28. The fate of proteins: the roles of chaperones, stress-related modifications and autophagy. 1. Nascent polypeptides are folded into functional proteins with the assistance of chaperones. **2.** A small proportion of proteins originate in a misfolded state and may be degraded by the ubiquitin–proteasome system (UPS) directly, or they may form aggregates. **3.** The correctly folded protein may experience one of three fates. It may (a) continue as a functional protein, (b) reach the end of the cell's need for it and then be degraded by the UPS or (c) be damaged by a variety of stresses. In the last event, if protein conformations are distorted because of oxidative or other stresses, the tertiary structures of these proteins can be deformed. They may then be degraded by the UPS or aggregate in the cytosol. **4.** Chaperones may also mediate disaggregation of agglutinated proteins, thereby preventing accumulation of toxic particulates and so allowing proteins to resume productive functionality. **5.** Protein aggregates may also undergo autophagy, with consequent degradation in lysosomes.

may also be sequestered in protein deposits or inactivated by exogenous toxins (e.g., an enzyme from a virulent strain of *E. coli* cleaves Hsp70). Chaperones may also contribute to tumorigenesis through effects on proteins that regulate the cell cycle and cell death (see below). Acquired chaperonopathies are also implicated in biological aging and in cardiovascular and neurodegenerative diseases.

Mutations May Impair Cell Function without Causing Cell Death

Although mutations in genes that encode a variety of proteins may be responsible for a wide array of clinical syndromes, they do not necessarily involve the death of affected cells. Increasingly, such mutations provide pathogenetic links among seemingly unrelated diseases.

Channelopathies

Channelopathies are inherited or acquired disorders of ion channels. Ion channels are transmembrane pore-forming proteins that allow ions, such as Na^+, K^+, Ca^{2+} and Cl^-, to enter or exit cells. Such ion traffic is critical for control of heartbeat, muscle contraction and relaxation, regulation of insulin secretion in pancreatic β cells and many other functions. For example, activation and inactivation of Na^+ and K^+ channels determine the action potential in neurons, and Ca^{2+} channels are important in contraction and relaxation of cardiac and skeletal muscle. Mutations in many ion channel genes cause a variety of diseases, including cardiac arrhythmias (e.g., short and long QT syndromes) and neuromuscular syndromes (e.g., myotonias, familial periodic paralysis). Several inherited human disorders affecting skeletal muscle contraction, heart rhythm and nervous system function are due to mutations in genes that encode voltage-gated Na^+ channels. Channelopathies are also implicated in certain pediatric epilepsy syndromes.

In addition, nonexcitable tissues may also be affected. Cystic fibrosis, which is caused by a mutation in a chloride channel, is a channelopathy affecting mucus- and sweat-secreting cells of various organs. In pancreatic β cells, ATP-sensitive K^+ channels regulate insulin secretion, and mutations in these channel genes lead to certain forms of diabetes. Some types of retinitis pigmentosa are attributed to mutations in ion channels. It deserves mention that mutations in gap junctions, channels that provide direct communication between cells, are also associated with a variety of inherited diseases.

Channelopathies may reflect gains (epilepsy, myotonia) or losses (weakness) of ion channel function. Different mutations that affect the same ion channel may result in different disorders. For instance, inherited mutations in a single Na^+ channel in skeletal muscle can lead to either hyperkalemic or hypokalemic periodic paralysis. By contrast, sometimes mutations in different genes may give rise to the same phenotype; mutations in different skeletal muscle Na^+ channels all cause hyperkalemic periodic paralysis.

Acquired channelopathies have also been identified in various other disorders, including the evolution of some cancers (see Chapter 5) and autoimmune neurologic conditions. Autoantibodies (see Chapter 4) may cause disorders of both ligand-gated ion channels (receptors) and voltage-gated ones. In this context, myasthenia gravis and autoimmune neuropathy have been related to autoantibodies versus nicotinic acetylcholine receptors, which control ion channels. Autoantibodies against voltage-gated Ca^{2+} and K^+ channels are also responsible for diverse neuromuscular disorders. Ion channels are involved in cell cycle progression and may play a role in tumor development.

Channelopathies are not merely esoteric diseases, but often are matters of life and death. Up to 20% of sudden unexplained deaths and 10% of sudden infant death syndrome (SIDS; see Chapter 6) are attributable to cardiac arrhythmias associated with mutations in the Na^+ channel responsible for long-QT syndrome. Remarkably, a large majority of patients with mucolipidosis type IV, as well as those with autosomal dominant polycystic kidney disease, have mutations in cell membrane Ca^{2+} channels.

Abnormal Proteins

Many acquired and inherited diseases are characterized by intracellular accumulation of abnormal proteins. A protein's deviant tertiary structure may result from a mutation that alters the amino acid sequence or may reflect an acquired defect in protein folding. The following are a few examples:

- **α_1-Antitrypsin deficiency** is a heritable disorder in which mutations in the gene coding for α_1-antitrypsin yield an insoluble protein that is not easily exported. It accumulates in liver cells (Fig. 1-29), thereby causing cell injury and eventually cirrhosis (see Chapter 19).
- **Prion diseases** are neurodegenerative disorders (spongiform encephalopathies) caused by accumulation of abnormally folded prion proteins. The normal α-helical structure is changed to a β-pleated sheet. Abnormal prion proteins may result from inherited mutations or from exposure to the aberrant form of the protein (see Chapter 32). The function of the normal prion protein is unclear, but data suggest several activities, including a role in myelination, antioxidant (SOD-like) activity, a role in T-lymphocyte–dendritic cell interactions, enhancing neural progenitor proliferation and a key role in development of long-term memory.
- **Lewy bodies** (α-synuclein) are seen in neurons of the substantia nigra in Parkinson disease (see Chapter 32).
- **Neurofibrillary tangles** (tau protein) characterize cortical neurons in Alzheimer disease (see Chapter 32).
- **Mallory bodies** (intermediate filaments) are hepatocellular inclusions in alcoholic liver injury (see Chapter 20).

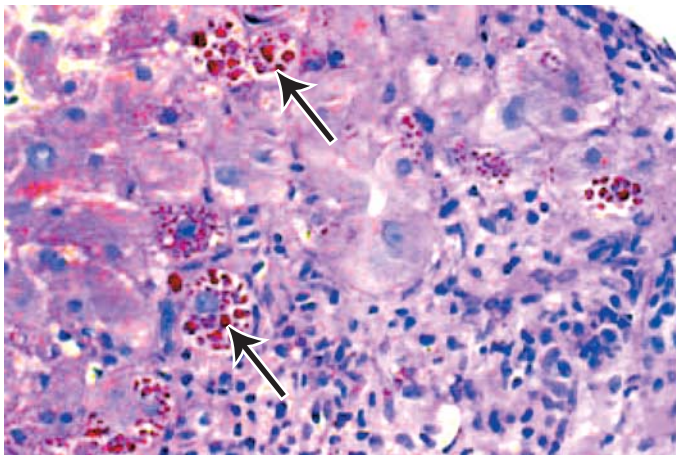

FIGURE 1-29. Storage of abnormal, mutant α_1-antitrypsin in the liver. Periodic acid–Schiff stain after diastase treatment to remove glycogen highlights the aggregates of α_1-antitrypsin protein (*arrows*).

MOLECULAR PATHOGENESIS: As discussed above, when ribosomes translate messenger RNA (mRNA), they make a linear chain of amino acids without a defined three-dimensional structure. Curiously, it is energetically more favorable for cells to produce many foldings, even abnormal ones, and then edit the protein repertoire than to construct only a single correct conformation. Thus, protein misfolding is an intrinsic tendency of proteins and occurs continuously. However, there is an escape valve, because evolutionary preference for energy conservation has dictated that a substantial proportion of newly formed proteins are rogues unsuitable for the society of civilized cells. Protein synthesis presents a number of possible outcomes:

- The primary sequence is correct and proper folding into the appropriate functional conformation occurs.
- The primary sequence may be correct but the protein does not fold correctly, owing to random energetic fluctuations.
- A mutant protein (with an incorrect amino acid sequence) folds incorrectly.
- A conformationally correct protein may become unfolded or misfolded due to an unfavorable environment (e.g., altered pH, high ionic strength, oxidation, etc.). The protein quality control system may fail because of a malfunction of protein quality control or overload of this mechanism. In either case, misfolded proteins accumulate as amorphous aggregates or fibrils and may cause cell injury by (1) decreasing a necessary activity **(loss of function)** or (2) a harmful increase in a cellular enterprise that alters a delicate balance of forces within the cell **(gain of function)**.
- **Loss of function:** Some mutations prevent correct folding of crucial proteins, which then do not function properly or cannot be incorporated into the correct site. For example, abnormal cystic fibrosis proteins are misfolded chloride ion channels, which are then degraded. The protein does not reach its intended destination at the cell membrane, creating a defect in Cl^- transport that produces the disease. Other examples of loss of function include mutations of the low-density lipoprotein (LDL) receptor in certain types of hypercholesterolemia and mutations of a copper-transporting ATPase in Wilson disease.
- **Formation of toxic protein aggregates:** Defects in protein structure may be acquired as well as genetic. Thus, particularly in nondividing cells, impairment of cellular antioxidant defenses is accompanied by protein oxidation, which alters protein tertiary structure and exposes interior hydrophobic amino acids that are normally hidden. In situations of mild to moderate oxidative stress, 20S proteasomes recognize the exposed hydrophobic moieties and degrade these proteins. However, if oxidative stress is severe, these proteins aggregate by virtue of a combination of hydrophobic and ionic bonds (Fig. 1-30). Such proteins may form disordered aggregates, which are insoluble and tend to sequester Fe^{2+} ions. In turn, Fe^{2+} helps to produce additional ROS (see above), further increasing aggregate size. Disordered aggregates may be degraded (e.g., by autophagy; see above) or may become partially ordered into denser structures in which the normal α-helical protein conformation is transformed

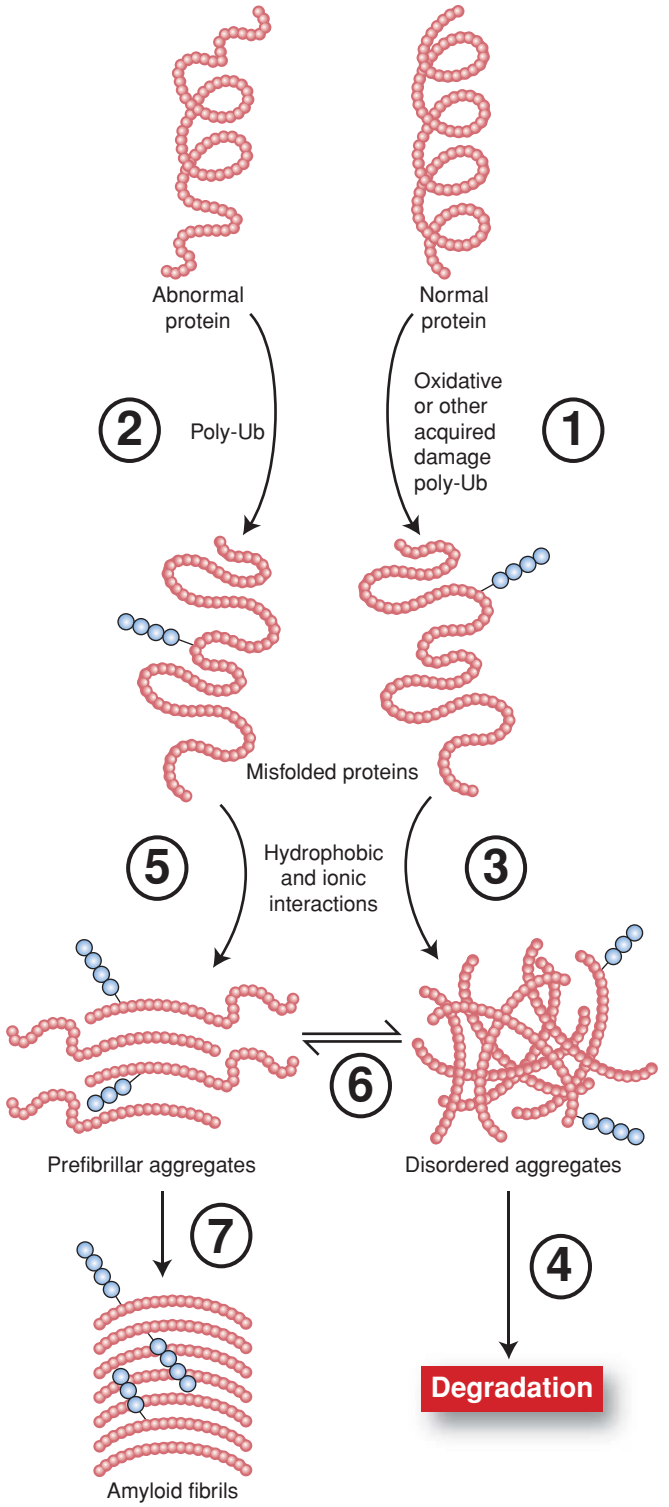

FIGURE 1-30. Formation of toxic protein aggregates. 1. Normal proteins can become damaged by exposure to reactive oxygen species and other stresses. **2.** Nonnative proteins may result from genetic mutations or translational errors. In any event, the resulting abnormal proteins may become misfolded and polyubiquitinated, after which two paths are open. **3.** Some of the misfolded proteins may become disordered aggregates, which can be degraded **(4)**. Alternatively **(5)**, the normal α-helical structure may be transformed into less soluble forms, consisting, to a variable extent, of β-pleated sheets **(**prefibrillar aggregates**)**. The latter may exist to some extent **(6)** in equilibrium with disordered aggregates or they may evolve irreversibly into insoluble amyloid fibrils **(7)**. *Ub* = ubiquitin.

to a variable degree into insoluble fibrillar β-pleated sheet structures. These latter tend to accumulate as indigestible agglomerations, which may resemble amyloid (see **Chapter 21**). Any Ub bound to them is lost, which may cause a cellular deficit in Ub and impair protein degradation in general. By virtue of both their generation of toxic ROS and their inhibition of proteasomal degradation, these aggregates may lead to cell death. Accumulation of β-amyloid protein in Alzheimer disease and α-synuclein in Parkinson disease may occur by this type of mechanism.

- **Retention of secretory proteins:** Many proteins that are destined to be secreted by the cell must be correctly folded to be transported through cellular compartments and released at the cell membrane. Mutations in genes that encode such proteins (e.g., α_1-antitrypsin) lead to cell injury because of massive accumulation of misfolded proteins within the cell. Failure to secrete this antiprotease into the circulation also leads to unregulated proteolysis of connective tissue in the lung and loss of pulmonary parenchyma (emphysema).
- **Extracellular deposition of aggregated proteins:** Misfolded proteins tend to assume β-pleated conformations in place of random coils or α-helices. These abnormal proteins often form insoluble aggregates, which may be deposited extracellularly, the appearance depending on the specific disease. These accumulations often assume the forms of various types of amyloid and produce cell injury in systemic amyloidoses (see Chapter 15) and a variety of neurodegenerative diseases (see Chapter 32).

Cell Death

> "To be or not to be–that is the question
> Whether 'tis nobler in the mind to suffer
> The slings and arrows of outrageous fortune
> Or to take arms against a sea of troubles
> And by opposing end them. To die . . ." (*Hamlet, III:i*)

Throughout recorded history, death has been considered as tragic, especially when youth has been cut short. Similarly, traditional concepts viewed cell death simply as the endpoint of disease processes. However, it is now clear that a cell's death is often needed for an organism to live; it is crucial for both development and survival of multicellular organisms. Just as the grim reaper himself assumes many guises, so cell death takes diverse forms. In some cases it represents the consequences of nonphysiologic and unregulated injury, but in others, complex intracellular molecular pathways respond to external and internal triggers to cause the cell's demise. Such programmed cell death oversees the size and diversity of many tissue compartments by eliminating obsolescent cells, as in the gastrointestinal tract, skin and hematopoietic system. Not all such mechanisms eliminate only older, senescent cells; in some cases younger upstarts, like autoreactive lymphocyte clones, may be targeted for destruction.

In addition to the unplanned murder of a cell by external violence, which is called necrosis, diverse suicide programs have been identified: apoptosis, autophagic cell death, necroptosis, NETosis and so forth. To further complicate matters, many of these programmed pathways interrelate extensively, so that clear-cut distinctions are not always possible. The outcomes of such overlapping mechanisms are parallel, but on occasion they are opposite. For example, while autophagy may impede malignant transformation, it also protects malignant cells from the effects of chemotherapy. In its many forms, programmed cell death is integral to many disease processes.

The multiplicity and connectivity of the various networks are confusing and challenge the student to understand how processes whose consequences seem so different can be tightly linked. The field of cell death is evolving rapidly, and the following discussion is necessarily limited to those issues about which there is a consensus and that are important for an appreciation of disease development.

Understanding cell death is not simply an academic exercise; manipulation of cell viability is currently a major area of research. For example, if we understand the biochemistry of ischemic death of cardiac myocytes, which is responsible for the leading cause of death in the Western world, we may be able to prolong myocyte survival after a coronary occlusion until circulation is restored.

Once upon a time, all cell death was referred to as necrosis. Now, we know better. Three main avenues leading to cell death have been delineated: necrosis, apoptosis and autophagy. Other, more specialized forms of cell death are also described (see below). These processes had formerly been viewed as separate, nonintersecting roads. Necrosis was defined as an accidental form of cell death caused by a hostile environment to which a cell could not adapt effectively. It was thus seen as a passive process in which the cell was more sinned against than sinning itself. By contrast, apoptosis is a form of cellular suicide in which the cell participates actively in its own demise. It is a mechanism by which individual cells activate their own signaling systems to sacrifice themselves for the preservation of the organism. Autophagy (see above) is also an active signaling process that is elicited when a stressful environment requires autodigestion of a portion of the cell's macromolecular constituents. Since the principal pathways of cell death may overlap, it is important to understand how the processes manifest morphologically.

MORPHOLOGY OF CELL DEATH

Necrosis Is Reflected in Geographic Areas of Cell Death

Necrosis occurs when hostile external forces overwhelm cells' adaptive abilities. Diverse insults can cause necrotic cell death, which typically affects geographically localized groups of cells. The response to this process is usually acute inflammation, which itself may generate further cell injury (see Chapter 2). The stimuli that initiate pathways leading to necrosis are highly variable and produce diverse and recognizable histologic and cytologic patterns.

Coagulative Necrosis

Coagulative necrosis refers to specific light microscopic appearances of dead or dying cells (Fig. 1-31). Shortly after a cell's death, its outline is maintained. When stained with

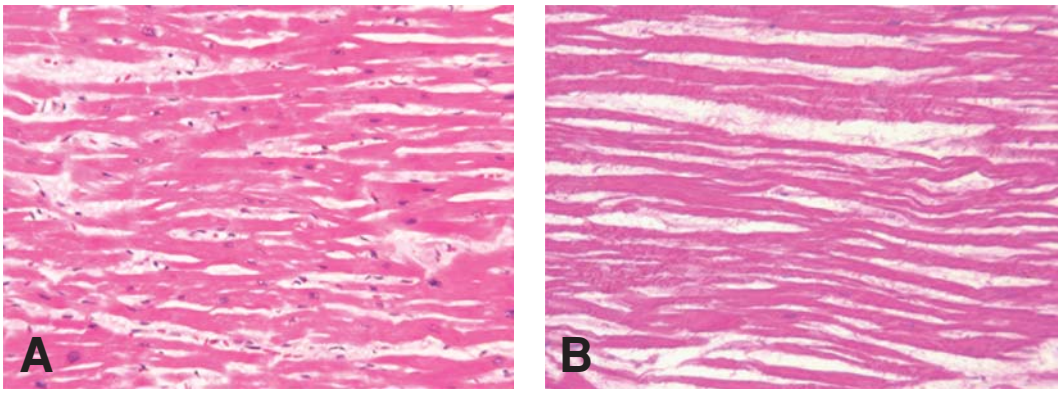

FIGURE 1-31. Coagulative necrosis. A. Normal heart. All myocytes are nucleated, and striations are clear. **B. Myocardial infarction.** The heart from a patient following acute myocardial infarction. The necrotic cells are deeply eosinophilic and most have lost their nuclei.

the usual combination of hematoxylin and eosin, the cytoplasm of a necrotic cell is more deeply eosinophilic than usual. Nuclear chromatin is initially clumped and then redistributes along the nuclear membrane. Three morphologic changes follow:

- **Pyknosis:** The nucleus becomes smaller and stains deeply basophilic as chromatin clumping continues.
- **Karyorrhexis:** The pyknotic nucleus breaks up into many smaller fragments scattered about the cytoplasm.
- **Karyolysis:** The pyknotic nucleus may be extruded from the cell or it may progressively lose chromatin staining.

Early ultrastructural changes in a dying or dead cell reflect an extension of alterations associated with reversible cell injury (Figs. 1-3 and 1-4). In addition to the nuclear changes described above, the dead cell features dilated endoplasmic reticulum, disaggregated ribosomes, swollen and calcified mitochondria, aggregated cytoskeletal elements and plasma membrane blebs.

After a variable time, depending on the tissue and circumstances, the lytic activity of intracellular and extracellular enzymes causes the cell to disintegrate. This is particularly the case when necrotic cells have elicited an acute inflammatory response.

The appearance of necrotic tissue has traditionally been described as **coagulative necrosis** because it resembles the coagulation of proteins that occurs upon heating. This term, while based on obsolete concepts, remains useful as a morphologic descriptor.

Liquefactive Necrosis

When the rate at which necrotic cells dissolve greatly exceeds the rate of repair, the resulting appearance is termed **liquefactive necrosis**. Polymorphonuclear leukocytes of the acute inflammatory reaction contain potent hydrolases capable of digesting dead cells. A sharply localized collection of these acute inflammatory cells, generally in response to bacterial infection, produces rapid cell death and tissue dissolution. The result is often an **abscess** (Fig. 1-32), a cavity formed by liquefactive necrosis in a solid tissue. In time, the abscess is walled off by a fibrous capsule that contains its contents.

Coagulative necrosis of the brain may occur after cerebral artery occlusion and is often followed by rapid dissolution—liquefactive necrosis—of the dead tissue by a mechanism that cannot be attributed to the action of an acute inflammatory response. It is not clear why coagulative necrosis in the brain and not elsewhere is followed by the disappearance of necrotic cells, but the abundant lysosomal enzymes, or different hydrolases specific to cells of the CNS, may be responsible. Liquefactive necrosis of large areas of the CNS can lead to an actual cavity or cyst that persists for the life of the person.

Fat Necrosis

Fat necrosis specifically affects adipose tissue and most commonly results from pancreatitis or trauma (Fig. 1-33). The unique feature determining this type of necrosis is the presence of triglycerides in adipose tissue. In the peripancreatic fat, for example, the process begins when digestive enzymes that are normally found only in the pancreatic duct and small intestine lumen are released from injured pancreatic acinar cells and ducts into extracellular spaces. Upon extracellular activation, these enzymes digest both the pancreas itself and surrounding tissues, including adipocytes.

1. Phospholipases and proteases attack plasma membranes of adipocytes, releasing their stored triglycerides.

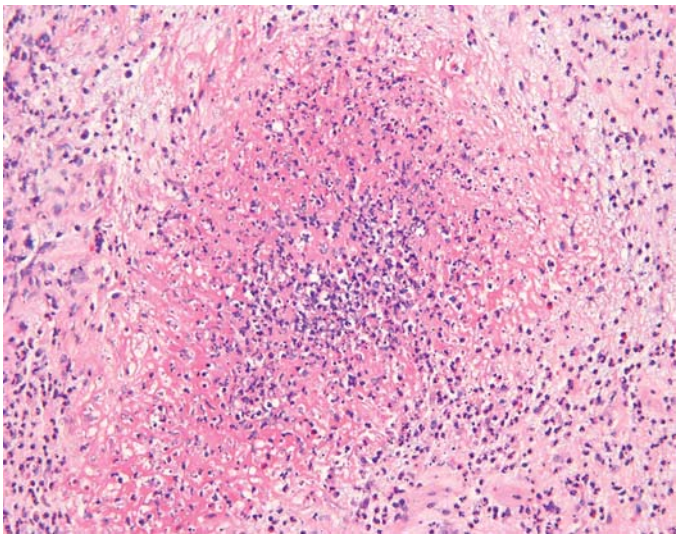

FIGURE 1-32. Liquefactive necrosis in an abscess of the skin. The abscess cavity is filled with polymorphonuclear leukocytes.

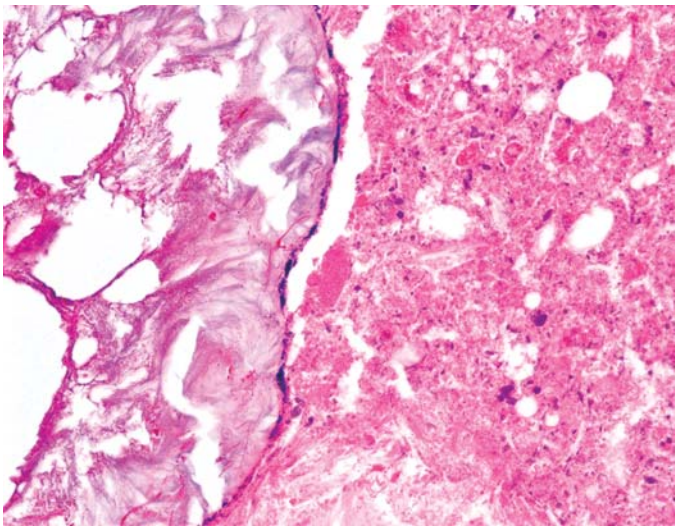

FIGURE 1-33. Fat necrosis. Peripancreatic adipose tissue from a patient with acute pancreatitis shows fatty acids precipitated as calcium soaps, which appear as amorphous, basophilic deposits **(left)**. These appear at the periphery of the irregular island of necrotic adipocytes **(right)**.

2. Pancreatic lipase hydrolyzes the triglycerides, which produces free fatty acids.
3. Free fatty acids bind Ca^{2+} and precipitate as soaps. These appear as amorphous, basophilic deposits at the edges of irregular islands of necrotic adipocytes.

Grossly, fat necrosis appears as an irregular, chalky white area embedded in otherwise normal adipose tissue. In the case of traumatic fat necrosis, triglycerides and lipases are released from the injured adipocytes. In the breast, fat necrosis due to trauma is common and may mimic a tumor, particularly if calcification has occurred.

Caseous Necrosis

Caseous necrosis is characteristic of tuberculosis and is seen, less often, in other settings as well. The lesions of tuberculosis are granulomas, or tubercles (Fig. 1-34). In the center of such granulomas, the accumulated mononuclear cells that mediate a chronic inflammatory reaction to the offending mycobacteria are killed. Unlike coagulative necrosis, the necrotic cells in granulomas lose their cellular outlines. They do not disappear by lysis, however, as in liquefactive necrosis. Rather, the dead cells persist indefinitely as amorphous, coarsely granular, eosinophilic debris. Grossly, this material is grayish white, soft and friable. It resembles clumpy cheese, hence the name **caseous necrosis**. This distinctive type of necrosis is generally attributed to the toxic effects of mycobacterial cell walls, which contain complex waxes (peptidoglycolipids) that exert potent biological effects. Recent work suggests that granuloma formation may actually be orchestrated by mycobacteria and may in fact facilitate the organism's survival in the face of host immune responsiveness.

Fibrinoid Necrosis

Fibrinoid necrosis is an alteration of injured blood vessels, in which insudation and accumulation of plasma proteins cause the wall to stain intensely with eosin (Fig. 1-35). The term is a misnomer, however, as the eosinophilia of the accumulated plasma proteins obscures the underlying alterations in the blood vessel, making it difficult, if not impossible, to determine whether there truly is necrosis in the vascular wall.

Apoptosis Produces Individual Cell Death Amidst Viable Cells

Morphology of Apoptosis

Apoptosis is a pattern of cell death that is triggered by a variety of extracellular and intracellular stimuli and is carried to its conclusion by organized cellular signaling cascades. Apoptotic cells are recognized by nuclear fragmentation and pyknosis, generally against a background of viable cells. Importantly, apoptosis occurs in single cells or small groups of cells, whereas necrosis characteristically involves larger geographic areas of cell death. Ultrastructural features of apoptotic cells include (1) nuclear

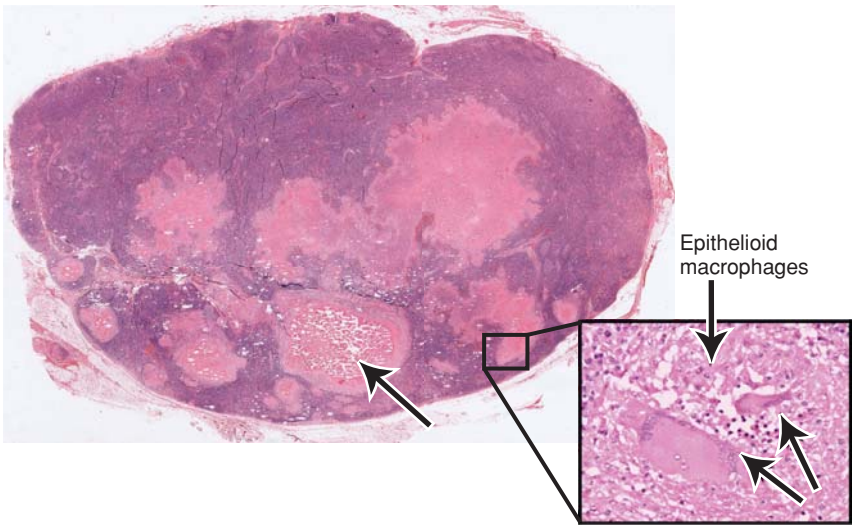

FIGURE 1-34. Caseous necrosis in a tuberculous lymph node. Hilar lymph node from a patient with active tuberculosis. Irregular pink areas of caseous necrosis (*arrow*) are evident against a background of lymphocytes. **Inset:** Granulomas on the periphery of necrotic areas show epithelioid macrophages and multinucleated giant (Langhans) cells (*arrows*).

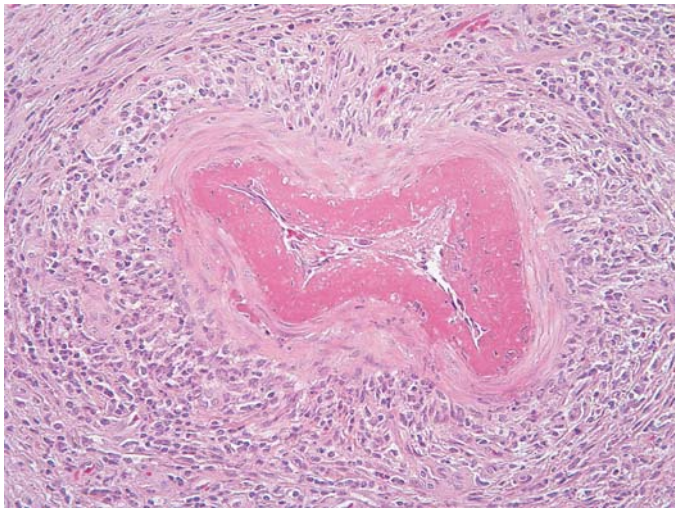

FIGURE 1-35. Fibrinoid necrosis. An inflamed muscular artery in a patient with systemic arteritis shows a sharply demarcated, homogeneous, deeply eosinophilic zone of necrosis.

condensation and fragmentation, (2) segregation of cytoplasmic organelles into distinct regions, (3) blebs of the plasma membrane and (4) membrane-bound cellular fragments, which often lack nuclei (Fig. 1-36).

Removal of Apoptotic Cells

Once the self-destructive process of apoptosis has propelled a cell to DNA fragmentation and cytoskeletal dissolution, the final phase, the ***apoptotic body***, remains. Apoptotic bodies are phagocytosed by tissue macrophages.

Phosphatidylserine (PS), a phospholipid that is normally on the interior aspect of the cell membrane, is externalized in cells undergoing apoptosis. PS is recognized by macrophages and activates ingestion of an apoptotic cell's mortal remains without release of intracellular constituents, thus avoiding an inflammatory reaction (Fig. 1-37). Mononuclear phagocytes ingest the debris from apoptotic cells, but recruitment of neutrophils or lymphocytes is rare. This

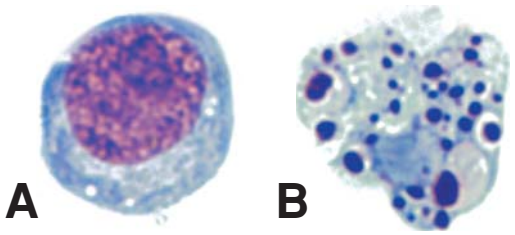

FIGURE 1-36. Apoptosis. A viable cell **(A)** contrasts with an apoptotic cell **(B)** in which the nucleus has undergone condensation and fragmentation.

situation is unlike that of cells that undergo necrotic cell death, which tends to elicit acute inflammatory responses (see Chapter 2).

Cells May Participate Actively in Their Own Death

There is increasing agreement that the various forms of cell death are not strictly separate, but rather share molecular effectors and signaling pathways. Cell processes incriminated in one may be co-conspirators with the others, and a particular cell's death may involve combinations of two, or all, of these mechanisms. For the sake of clarity, mechanisms of cell death by necrosis, apoptosis and autophagy are presented separately, but it is important to understand that all of these processes involve signaling, borrow from one another and collaborate with each other.

NECROSIS

Ischemia Injures Cells during Both Deprivation and Restoration of Oxygen Supply

Ischemic Injury

As noted above, ischemia is the interruption of blood flow (e.g., myocardial infarction, stroke). Loss of blood flow leads to decreased O_2 and key nutrients, such as glucose, and increased CO_2 in cells. A number of deleterious events

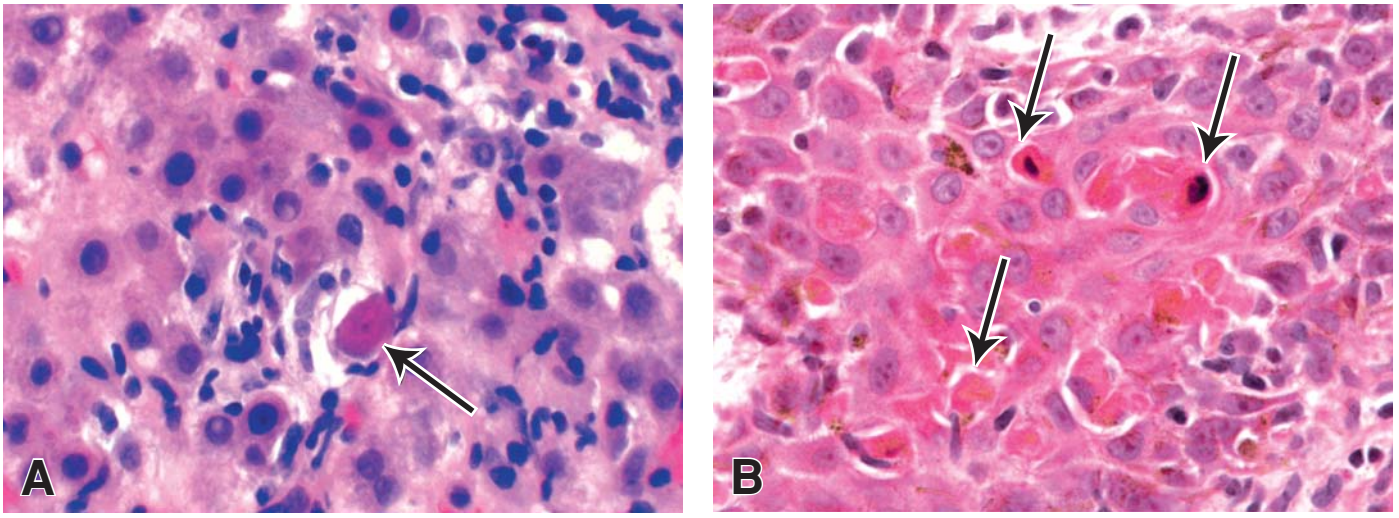

FIGURE 1-37. Apoptosis in the liver in viral hepatitis (A) and in the skin in erythema multiforme (B). Apoptotic cells are indicated by *arrows*.

occur, including acidosis, generation of ROS, loss of glycogen stores, disruption of intracellular Ca^{2+} homeostasis, increased intracellular Ca^{2+}, mitochondrial injury and DNA damage.

Ischemic Cell Death

Myocardial infarction and stroke together represent the most common cause of mortality in the Western world and are both due to ischemic cell death. Thus, mechanisms of cellular injury and death due to ischemia represent the most important example of necrosis.

Cells exist in a skewed equilibrium with their external environment. The extracellular fluid is separated from the internal cellular milieu by the plasma membrane. Extracellular levels of Na^+ and Ca^{2+} are normally orders of magnitude more than intracellular concentrations. The opposite holds for K^+. This selective ion permeability requires (1) considerable energy (ATP), (2) structural integrity of the lipid bilayer, (3) intact ion channel proteins and (4) normal association of the membrane with cytoskeleton. Whatever the lethal insult, cell necrosis is heralded by loss of the plasma membrane's permeability barrier function. If ischemia is incomplete or if the episode of ischemia is brief, normal ionic equilibrium can be re-established without tissue damage. However, if one or more of the elements mentioned above is severely damaged, the resulting disturbance of ionic balance is thought to represent the "point of no return" for the injured cell. Thus, ischemic cell injury and death share the same pathophysiologic spectrum.

The role of calcium in the pathogenesis of cell death deserves special mention. Ca^{2+} concentration in extracellular fluids is in the millimolar range (10^{-3} M). By contrast, cytosolic Ca^{2+} concentration is 1/10,000 of that outside the cell (i.e., about 10^{-7} M). Many crucial cell functions are exquisitely regulated by minute fluctuations in cytosolic free calcium concentration ($[Ca^{2+}]_i$). Thus, **massive influx of Ca^{2+} through a damaged plasma membrane is key to ischemic cell damage** and may ensure loss of viability.

The processes of cell death by necrosis vary according to the cause, organ and cell type. The best-studied and most clinically important example is ischemic necrosis of cardiac myocytes. The mechanisms underlying the death of these cells are in part unique, but the basic processes involved are comparable to those in other organs. Some of these events may occur simultaneously; others may be sequential (Fig. 1-38).

1. **Interruption of blood supply decreases delivery of O_2 and glucose.** For most cells, but especially for cardiac myocytes and neurons, which do not store much energy, this combined insult is formidable.
2. **Anaerobic glycolysis leads to overproduction of lactate and decreased intracellular pH.** The lack of O_2 during myocardial ischemia both blocks ATP production and inhibits mitochondrial oxidation of pyruvate. Instead of entering the citric acid cycle, pyruvate is reduced to lactate in the cytosol, a process called anaerobic glycolysis. Lactate accumulation lowers cytosol pH (acidification), thus initiating a spiral of events that propels the cell downward toward disaster.
3. **Distortion of the activities of pumps in the plasma membrane skews the ionic balance of the cell.** Na^+ accumulates because lack of ATP impairs the Na^+/K^+ ion exchanger. This effect leads to activation of the Na^+/H^+ ion exchanger. This pump is normally quiescent, but when intracellular acidosis threatens, it pumps H^+ out of the cell in exchange for Na^+ to maintain proper intracellular pH. The resulting increase in intracellular sodium activates the Na^+/Ca^{2+} ion exchanger, which increases calcium entry. Ordinarily, excess intracellular Ca^{2+} is extruded by an ATP-dependent calcium pump. However, with ATP in very short supply, Ca^{2+} accumulates in the cell.
4. **Activation of phospholipase A_2 (PLA_2) and proteases disrupts the plasma membrane and cytoskeleton.** Elevated $[Ca^{2+}]_i$ in an ischemic cell activates PLA_2, leading to degradation of membrane phospholipids and consequent release of free fatty acids and lysophospholipids. The latter act as detergents that solubilize cell membranes. Both fatty acids and lysophospholipids are also potent mediators of inflammation (see Chapter 2), an effect that may further disrupt the integrity of the already compromised cell.

   Calcium also activates a series of proteases that attack the cytoskeleton and its attachments to the cell membrane. As cohesion between cytoskeletal proteins and the plasma membrane is disrupted, membrane blebs form, causing the cell's shape to change. The combination of electrolyte imbalance and increased cell membrane permeability makes the cell swell, often a morphologic prelude to its dissolution.
5. **Lack of O_2 impairs mitochondrial electron transport, thereby decreasing ATP synthesis and facilitating production of ROS.** Normally, 1–3% of oxygen entering mitochondria is converted to ROS, because of inefficiencies in the electron transport chain. During ischemia, generation of ROS increases because of damage to ROS detoxification mechanisms and impaired processing of reactive oxygen intermediates. ROS cause peroxidation of cardiolipin, a membrane phospholipid that is unique to mitochondria and is sensitive to oxidative damage by virtue of its high content of unsaturated fatty acids. This attack inhibits the function of the electron transport chain and decreases its ability to produce ATP.
6. **Mitochondrial damage promotes release of cytochrome c (Cyt c) to the cytosol.** In normal cells the mitochondrial permeability transition pore (MPTP) opens and closes sporadically. Ischemic injury to mitochondria causes sustained opening of the MPTP. Resulting loss of Cyt c from the electron transport chain further diminishes ATP synthesis and may also trigger apoptotic cell death (see below).
7. **The cell dies.** When a cell can no longer maintain itself as a metabolic unit, it dies. The line between reversible and irreversible cell injury (i.e., the "point of no return") is not precisely defined.

Reperfusion Injury

Reperfusion is the restoration of blood flow after a period of ischemia. Although reperfusion is beneficial in salvaging cells that have remained viable, the process itself can cause damage, to which the term "reperfusion injury" is applied. Such injury occurs most often in settings of organ ischemia, such as myocardial infarction, but also in other situations (e.g., organ transplantation).

Reperfusion injury reflects the interplay of transient ischemia, consequent tissue damage and exposure of damaged tissue to the oxygen that arrives when blood flow is re-established (reperfusion). Lethal reperfusion injury is significant. In the heart, it may account for up to half of the final size of myocardial infarcts. Initially, ischemic cellular damage

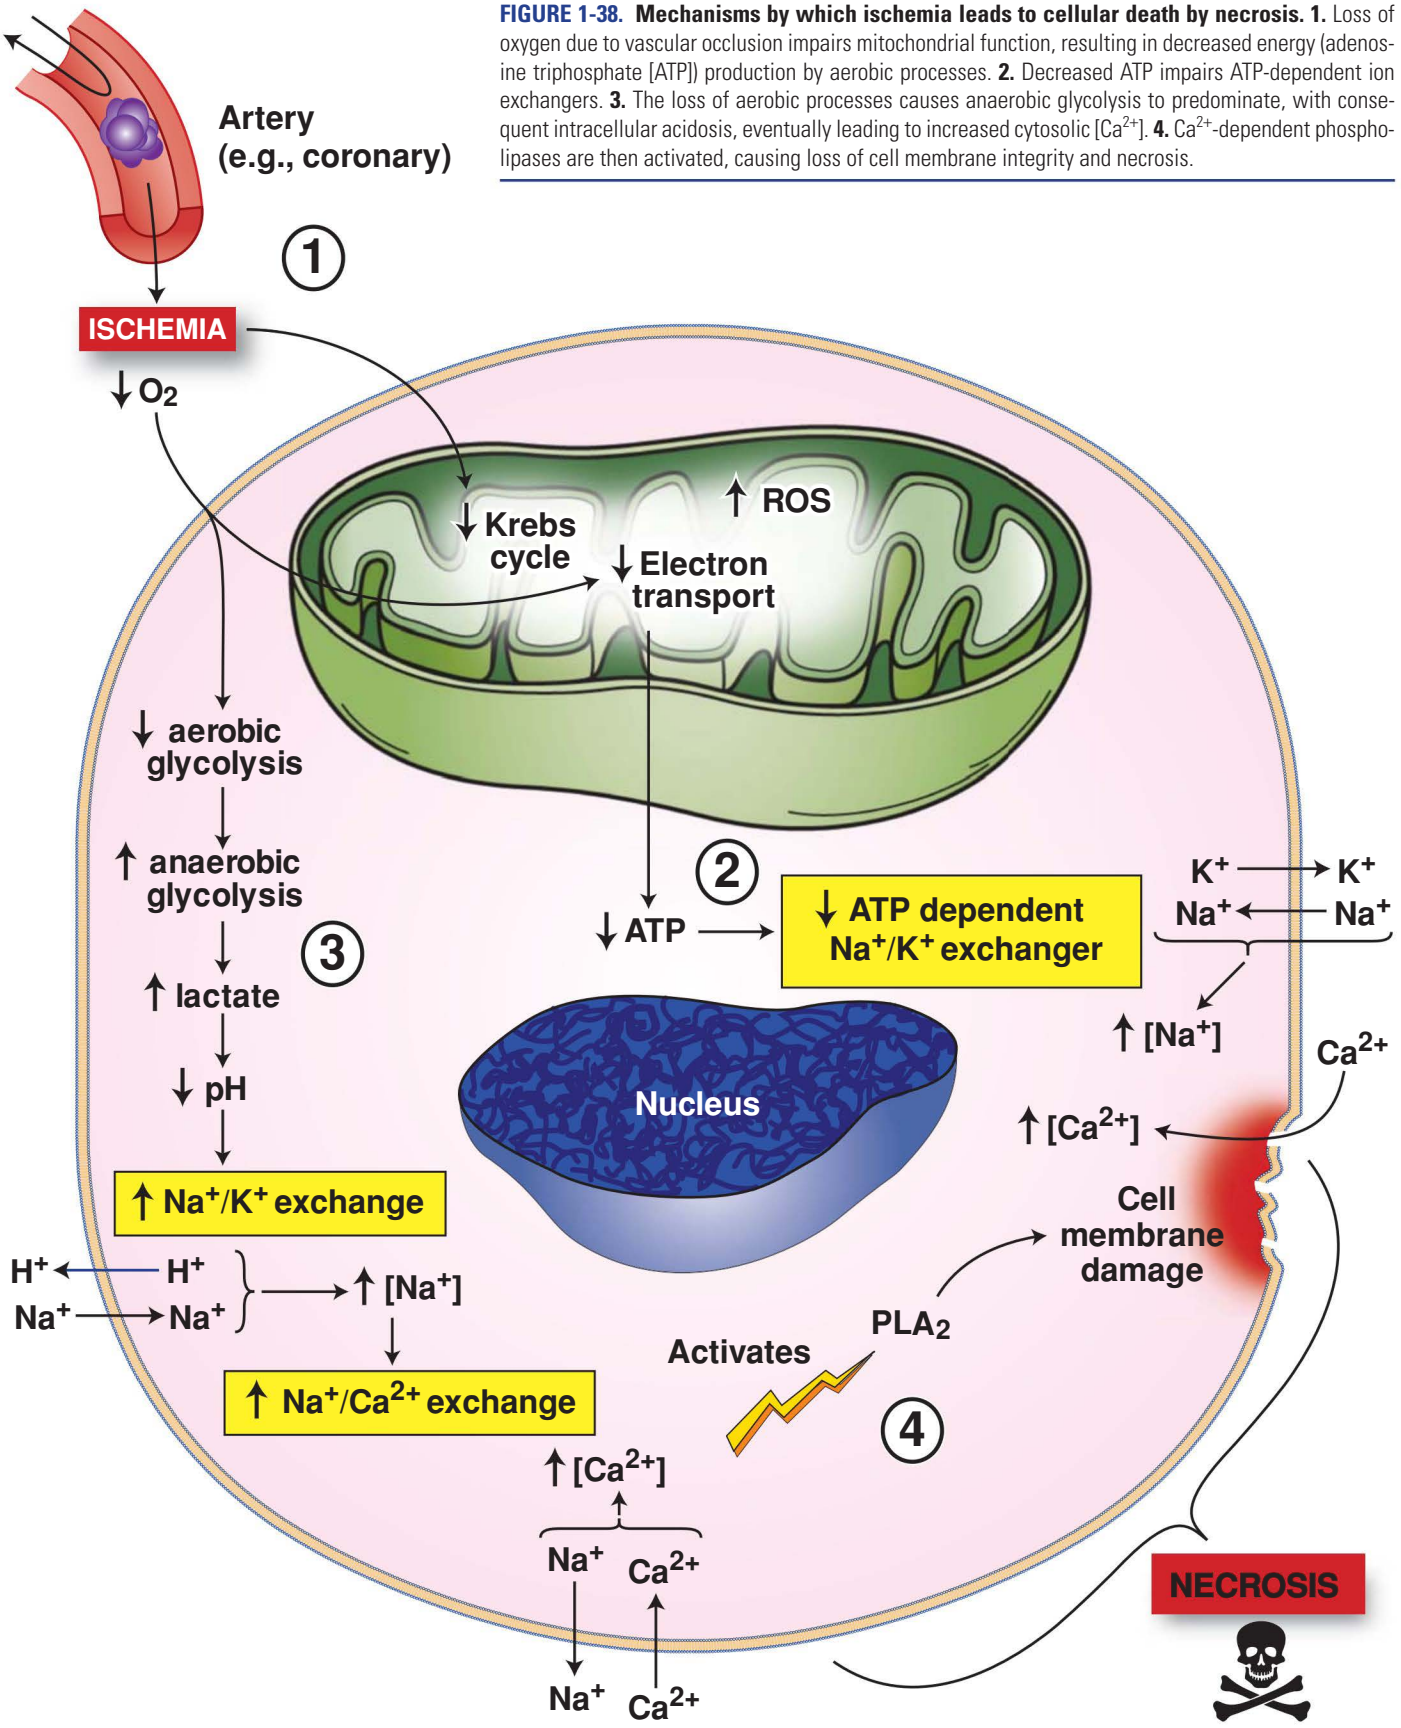

FIGURE 1-38. Mechanisms by which ischemia leads to cellular death by necrosis. 1. Loss of oxygen due to vascular occlusion impairs mitochondrial function, resulting in decreased energy (adenosine triphosphate [ATP]) production by aerobic processes. **2.** Decreased ATP impairs ATP-dependent ion exchangers. **3.** The loss of aerobic processes causes anaerobic glycolysis to predominate, with consequent intracellular acidosis, eventually leading to increased cytosolic [Ca^{2+}]. **4.** Ca^{2+}-dependent phospholipases are then activated, causing loss of cell membrane integrity and necrosis.

leads to generation of free radical species (see above). Reperfusion then provides abundant molecular O_2 to combine with free radicals to form additional ROS. The evolution of reperfusion injury also involves many other factors, including inflammatory mediators, platelet-activating factor (PAF), NOS and NO•, intercellular adhesion molecules, dysregulation of Ca^{2+} homeostasis and many more.

Xanthine Oxidase

Xanthine oxidase activity, particularly in vascular endothelium, increases during ischemia. The enzyme converts ATP-derived xanthine into uric acid in an oxygen-requiring reaction, producing superoxide in the process. On reperfusion, oxygen returns and the abundant purines derived from ATP catabolism during ischemia become substrates for xanthine oxidase. Since this enzyme requires oxygen, restoration of oxygen supply during reperfusion leads to a sudden increase in ROS. This occurs after ischemia-related impairment leaves mitochondrial antioxidant systems ill-prepared for the sudden increase in ROS. Mitochondrial oxidant stress is further magnified by two events. One is the sudden increase in electron transport, which is driven by the renewed availability of oxygen. The other is changes in pH and calcium concentrations (see below).

The Role of Neutrophils

An additional source of ROS during reperfusion is the neutrophil. Reperfusion prompts endothelial cells to move preformed P-selectin to the cell surface, increasing neutrophil binding to intercellular adhesion molecule-1 (ICAM-1) at the endothelial cell membrane (see Chapter 2). Neutrophils release large quantities of ROS and hydrolytic enzymes, both of which further injure the previously ischemic cells.

Ion Fluxes During Reperfusion

Ischemia changes cellular ion transporter activities, which become even more problematic with reperfusion. When blood flow is re-established, cellular pH is suddenly rectified. The Ca^{2+} overload that began during ischemia is then exacerbated by reversal of the Na^+/Ca^{2+} exchanger. Increased $[Ca^{2+}]_i$ activates Ca^{2+}-dependent proteases and increases ROS generation. It also acts in concert with increased mitochondrial ROS to open the MPTP and triggers mitochondria-related cell death programs (see below).

The Role of Nitric Oxide and Nitric Oxide Synthase

NO is generated from arginine by both constitutive and inducible NOSs. NO exerts a protective effect, dilating microvasculature by relaxing smooth muscle, inhibiting platelet aggregation and decreasing leukocyte adhesion to endothelial cells. NO also decreases transferrin-mediated iron uptake, limiting the amount of iron available to generate OH• from other ROS. These activities largely reflect the ability of NO to decrease cytosolic Ca^{2+} by extruding it from the cell and by sequestering it within intracellular stores.

NO and NOS are double-edged swords, however. In the setting of ischemia-triggered ATP depletion, Ca^{2+} overload and nutrient deprivation, mitochondrial NOS tends to produce NO. NO• also reacts with O_2^- to form $ONOO^-$, a highly reactive species. Normally, O_2^- is detoxified by SOD and little $ONOO^-$ is produced. However, reperfusion both inactivates SOD and provides abundant O_2^-, which together favor production of $ONOO^-$. This free radical gives rise to DNA strand breaks and lipid peroxidation in cell membranes.

Inflammatory Cytokines

Reperfusion injury is complicated by the release of cytokines, which both promote inflammation and modulate its severity. Proinflammatory cytokines such as TNF-α, IL-1 and IL-6 are key. These (1) promote vasoconstriction, (2) stimulate adherence of neutrophils and platelets to endothelium and (3) have effects at sites distant from the ischemic insult itself.

Platelets

Platelets adhere to the microvasculature of injured tissue and release a number of factors that play a role in both tissue damage and cytoprotection. These include cytokines, TGF-β, serotonin and NO•.

Complement

Activation of the complement system (see Chapter 2) during reperfusion leads to deposition of membrane attack complexes and elaboration of chemotactic agents and proinflammatory cytokines. The net result is recruitment and adhesion of neutrophils.

Summary of Ischemia and Reperfusion Injury

We can put reperfusion injury in perspective by emphasizing that there are three different degrees of cell injury, depending on the duration of the ischemia:

- With short periods of ischemia, reperfusion (and, thus, the resupply of oxygen) completely restores the cell's structural and functional integrity. Cell injury in this case is completely reversible.
- With longer periods of ischemia, reperfusion is associated with cell deterioration and death. In this case, lethal cell injury occurs during the period of reperfusion.
- Lethal cell injury may develop during the period of ischemia itself, in which case reperfusion need not be a factor. A longer period of ischemia is required to produce this third type of cell injury.

Processes involved in reperfusion injury are summarized in Table 1-4.

Ischemic Preconditioning

Sudden and complete ischemia may cause cell death before adaptive mechanisms can come into play, but repeated episodes of ischemia, as in recurrent angina due to coronary artery disease, stimulate adaptive responses. In the heart, these are collectively called **ischemic preconditioning**. The transcription factor hypoxia-inducible factor-1α (HIF-1α) is the master regulator of transcriptional responses to low O_2 tension. HIF-1α activates genes whose protein products limit production of ROS, Ca^{2+} accumulation and ATP depletion. As a result, HIF-1α tends to protect against mitochondrial injury, DNA damage and oxidative stress, and so facilitates survival of the ischemic cell.

PROGRAMMED CELL DEATH

Programmed cell death (PCD) refers to processes that are lethal to individual cells and are regulated by pre-existing signaling pathways. It was first observed 170 years ago and was thought to represent a passive form of cell death. However, we now recognize various forms of PCD that entail activation of cellular signaling cascades.

PCD is part of the balance between the life and death of cells and determines that a cell dies when it is no longer useful or when its survival may be harmful to the larger

TABLE 1-4
CELL INJURY MECHANISMS ACTIVE IN REPERFUSION INJURY

Formation of reactive oxygen species
Generated by xanthine oxidase
Produced by neutrophils
Made by mitochondria
Altered ionic composition
Rapid pH normalization following period at acidic pH
Increased [Na^+]
Increased [Ca^{2+}]
Abnormalities of nitric oxide metabolism
Decreased endothelial cell NOS with subsequent vasoconstriction, increased **platelet aggregation and neutrophil recruitment**
ONOO generation
Altered vascular function and inflammation
Vasoconstriction and inhibition of vasodilatation
Increase in proinflammatory cytokines
High cell membrane levels of adhesion molecules
Clumping of platelets
Migration of neutrophils
Complement
Cell death
Opening of MPTP
Activation of apoptosis
Activation of autophagy

MPTP = mitochondrial permeability transition pore; NOS = nitric oxide synthase; ONOO = peroxynitrite.

organism. Without programmed cell death to limit the size of bodily compartments, it is estimated that two tons of bone marrow and lymph nodes and 16 km (10 miles) of intestines would have accumulated by age 80. PCD is also a self-defense mechanism: cells that are infected with pathogens or that sustain genomic alterations are destroyed.

Classification of PCD

Recent work in this field has uncovered a bewildering variety of mechanisms that eventuate in PCD. Originally, this term was synonymous with apoptosis. However, mutant mice lacking the key elements of the apoptotic machinery develop almost normally. This observation indicated that alternatives to apoptosis exist. Thus, a number of mechanisms of PCD have been identified:

- Apoptosis
- Autophagy-associated cell death
- Necroptosis
- Pyroptosis
- Anoikis
- NETosis
- Pyrosis
- Entosis

The fact that nonapoptotic PCD pathways are best studied when apoptosis is inhibited does not mean that other mechanisms are subordinate to apoptosis. Rather, each seems to predominate in specific circumstances. The various cell death networks do not function in isolation from each other, and there are interconnections between them. As a result, multiple PCD mechanisms may contribute to cell death in any given situation. Detailed discussion of all these processes is beyond the scope of this chapter, and we focus here on the highlights of the major pathways: apoptosis, autophagy and necroptosis. The other more restricted forms of PCD are mentioned briefly.

There is ambiguity in the nomenclature of PCD, so that the same or similar phenomena may be labeled differently by different authors. Intersecting signaling among cell death pathways is a further source of confusion. For the sake of clarity, we use the term "apoptosis" for PCD involving caspase signaling (see below). "Necroptosis" refers to a cell death resembling necrosis that entails programmed signaling pathways.

APOPTOSIS IS A FORM OF PCD THAT RELIES EXCLUSIVELY ON THE CASPASE CASCADE

Apoptosis is a highly conserved cell death process that depends on a family of cysteine proteases (caspases) as crucial signaling intermediates and as executioners.

Apoptosis in Development and Physiology

Fetal development involves the sequential appearance and regression of many evolutionary relics. Some aortic arches do not persist. The pronephros and mesonephros regress in favor of the metanephros. Structures required by only one sex disappear in embryos of the other sex. Thus, the müllerian duct, the progenitor of the uterus, is deleted in males, and the wolffian duct, which forms part of the male genital tract, disappears in females. In some organs, such as the brain and ovaries, cells are overproduced, then culled by apoptosis. Apoptosis also mediates the disappearance of interdigital tissues to yield discrete fingers and toes, converts solid primordia to hollow tubes (e.g., gastrointestinal tract), produces the four-chamber heart and mediates other body-sculpting activities. Lymphocyte clones that recognize self-antigens are deleted by apoptosis, thereby avoiding potentially dangerous autoimmune disease.

Physiologic apoptosis principally affects progeny of stem cells that are constantly dividing (e.g., stem cells of the hematopoietic system, gastrointestinal mucosa and epidermis). Apoptosis of mature cells in these organs prevents overpopulation of the respective cell compartments by removing excess cells. Thus, normal organ size and architecture are maintained (Fig. 1-39).

Apoptosis Eliminates Obsolescent Cells

Cell turnover is essential to maintaining the size and function of many organs. For example, as cells are continuously supplied to the circulating blood, older and less functional white blood cells must be eliminated to maintain the normal complement of the cells. Indeed, pathologic accumulation of polymorphonuclear leukocytes in chronic myeloid leukemia results from a mutation that inhibits apoptosis and so

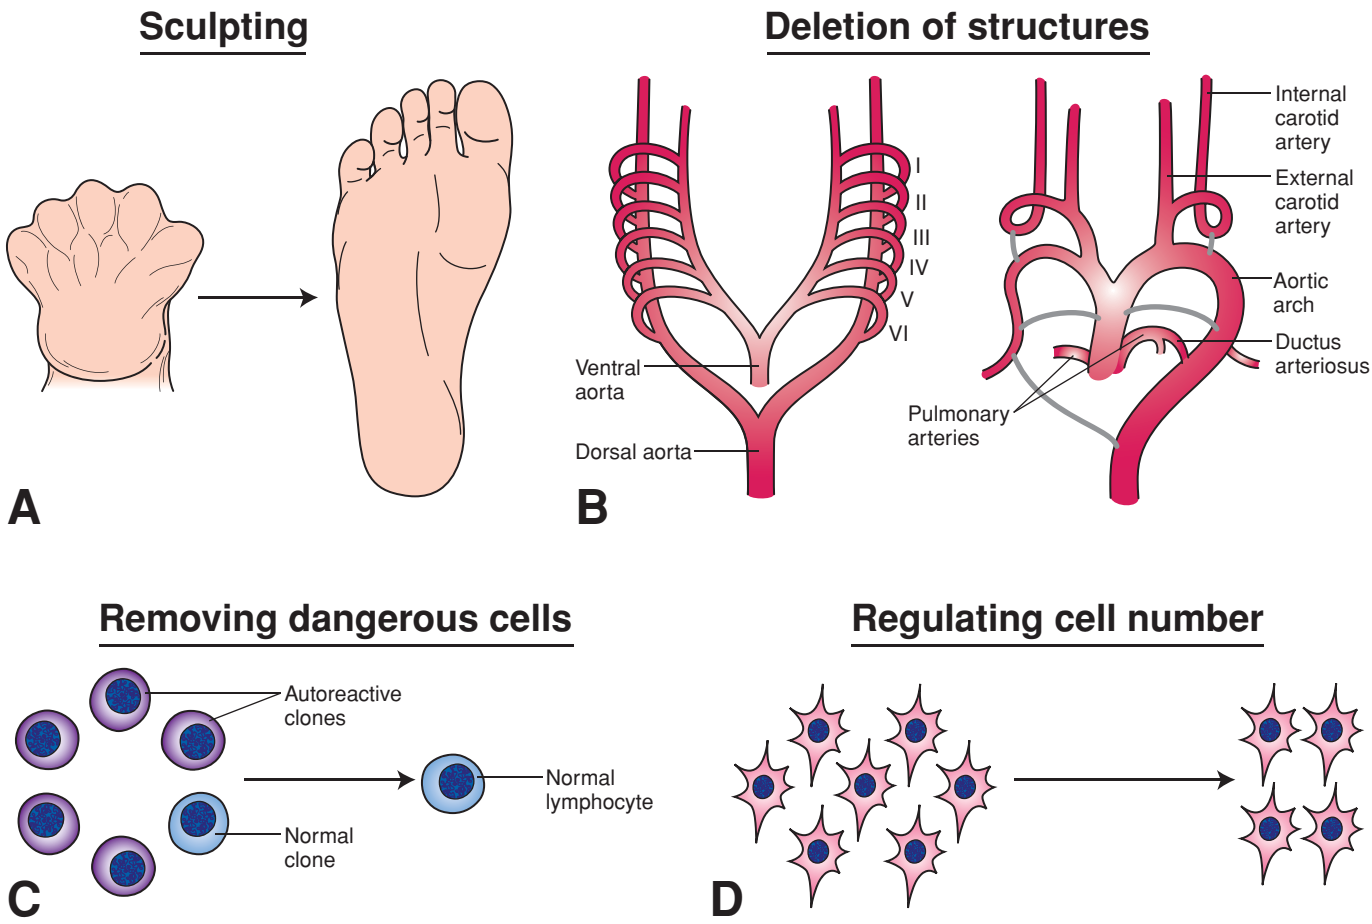

FIGURE 1-39. Activities of apoptosis during embryonic development. A. Sculpting. Apoptosis eliminates interdigital tissue. **B. Aortic arches.** Multiple embryonic aortic arches **(left)**, which are evolutionary relics, are eliminated and transformed by apoptosis into the eventual adult circulatory system **(right)**. **C. Dangerous cells.** Autoreactive lymphocytes and other errant cells are eliminated by apoptosis. **D. Population control.** Excessive numbers of diverse cell types, such as central nervous system neurons, are pruned by apoptosis.

allows these cells to persist. In the small intestine mucosa, cells migrate from the depths of the crypts to the tips of the villi, where they undergo apoptosis and are sloughed into the lumen.

Apoptosis also maintains the balance of cellularity in organs that respond to trophic stimuli, such as hormones, as in the regression of lactational hyperplasia of the breast in women who have stopped nursing their infants. Later in life, postmenopausal atrophy of the endometrium follows loss of hormonal support.

An interesting facet of apoptosis is its impact on gametogenesis. Adult men produce about 1000 new spermatozoa per second, of which most undergo apoptosis because of intrinsic defects or external damage. Excessive apoptosis among spermatozoa has been implicated in some forms of male infertility. An analogous effect occurs in females, in whom 99% of neonatal ovarian oocytes are eventually deleted by apoptosis.

Apoptosis Deletes Mutant Cells

The integrity of an organism requires that damaged cells be eliminated. There is a finite, albeit low, error rate in DNA replication, owing to the imperfect fidelity of DNA polymerases. Environmental stresses such as ultraviolet (UV) light, ionizing radiation and DNA-binding chemicals may also alter DNA structure. There are several means, the most important of which probably involve p53, by which cells recognize genomic abnormalities and "assess" whether or not they can be repaired. If the DNA damage is too severe to be repaired, a cascade of events leads to apoptosis. This process protects an organism from the consequences of a nonfunctional cell or one that cannot control its own proliferation (e.g., a cancer cell). Perversely, cancer cells often evolve mechanisms to circumvent apoptosis that might otherwise eliminate them (see Chapter 5).

Apoptosis as a Defense Against Dissemination of Infection

When a cell "detects" nonchromosomal DNA replication, as in a viral infection, it tends to initiate apoptosis. In destroying infected cells, the body limits the spread of the virus. Many viruses have evolved mechanisms that manipulate cellular apoptosis. Many viruses are known to carry genes whose products inhibit apoptosis. Some of these viral proteins bind and inactivate cellular proteins (e.g., p53) that are important in triggering apoptosis. Others may interfere with the signaling pathways that activate apoptosis.

MECHANISMS OF APOPTOSIS

Apoptosis Comprises Several Signaling Pathways

The several apoptosis pathways include:

- In ***extrinsic apoptosis,*** certain plasma membrane receptors are activated by their ligands.
- The ***intrinsic pathway*** is initiated by diverse intracellular stresses and is characterized by a central role for mitochondria.
- ***Inflammatory or infectious processes*** may lead to apoptosis. Intracellular and extracellular infectious agents both elicit this type of apoptosis, by diverse routes.
- The ***perforin/granzyme pathway*** is triggered when cytotoxic T cells attack their cellular targets, with transfer of granzyme B from the killer cell to its intended victim.
- ***p53-activated apoptosis*** occurs in response to cellular stress or DNA damage.
- The ***endoplasmic reticulum*** may elicit apoptosis in which calcium signaling plays a central role.

These pathways are not rigid categories, but rather are paradigms of varied signaling mechanisms that lead to apoptosis. In fact, the different routes to apoptosis intersect and overlap.

A family of cysteine proteases, called caspases, is central to apoptosis. Sequential activation of these enzymes, which entails conversion from proenzyme forms to catalytically effective enzymes, is central to apoptotic pathways. Some 14 caspases are now known, of which about half are important participants in apoptotic signaling (other functions, unrelated to apoptosis, are also known; see below).

Although the various pathways to apoptosis may start differently and signal via different members of this enzyme family, these diverse roads all generally lead to the killer enzymes: caspases-3, -6 and -7.

Extrinsic Apoptosis Is Triggered by Receptor–Ligand Interactions at the Cell Membrane

Prominent examples of initiation of apoptosis at the cell membrane are the binding of TNF-α to its receptor (TNFR) and the recognition of FasL (Fas ligand) by its receptor, Fas. TNF-α is a soluble cytokine, whereas FasL is found at the plasma membrane of certain cells, such as cytotoxic effector lymphocytes.

At the cell surface, TNFR and Fas become activated upon binding their ligands. Specific amino acid sequences in the cytoplasmic tails of these transmembrane receptors, called death domains, act as docking sites for the corresponding death domains of other proteins (Fig. 1-40). After binding to the ligand-activated receptors, the docking proteins stimulate downstream signaling molecules, especially procaspases-8 and -10, which are converted to their operational forms, caspases-8 and -10. In turn, these caspases activate downstream caspases in the apoptosis pathway.

The ultimate caspases in this process are "effector," or "executioner," caspases-3, -6 and -7. Caspase-3 is the most commonly activated effector caspase. It stimulates enzymes that cause nuclear fragmentation (e.g., caspase-activated DNase [CAD], which degrades chromosomal DNA). Caspase-3 also destabilizes the cytoskeleton as the cell begins to fragment into apoptotic bodies.

Notably, TNFR activation by TNF-α may also stimulate the antiapoptotic protein NFκB, a transcription factor that directs production of proteins that inhibit apoptosis. This is described in more detail below, in the discussion of necroptosis.

The extrinsic (death receptor) pathway of apoptosis intersects the intrinsic (mitochondrial) pathway via caspase-8, which cleaves a cytoplasmic protein, Bid (Fig. 1-41). Truncated Bid (tBid) translocates to mitochondria, where it can activate apoptosis through a separate signaling mechanism (see below).

Diverse Intracellular Stimuli Activate the Mitochondrial Intrinsic Pathway of Apoptosis

From the perspective of cell survival and adaptation, mitochondria are akin to Dr. Jekyll and Mr. Hyde. On the one hand, in their Dr. Jekyll persona, they generate the energy needed to sustain the cell and participate in carbohydrate and fatty acid metabolism. On the other hand, as Mr. Hyde, they store molecules that can lead to cell death.

Current understanding of this route of apoptosis can be viewed as involving two sequential series of events. The specific order of events is not completely understood, and some steps presented below may occur simultaneously or in a different sequence.

Mitochondrial Matrix and Inner Membrane Pathways

The components of the mitochondrial matrix, which is the interior of these organelles, are constrained by the impermeability of the inner mitochondrial membrane. This barrier is traversed by the MPTP, which is closed under normal circumstances. Attached to the inner membrane are several molecules that play key roles as the apoptotic drama unfolds. These molecules include Cyt c (a member of the electron transport chain), Smac/diablo (second mitochondria-derived activator of caspases, which promotes caspase activation; see below), apoptosis-inducing factor (AIF) and others. There is an electrochemical potential ($\Delta\Psi_m$) across the inner membrane, with the interior of the mitochondrion charged negatively and the exterior positively. Thus:

1. If mitochondria accumulate Ca^{2+} or generate excessive ROS or if $\Delta\Psi_m$ or mitochondrial pH decrease, the MPTP opens (Fig. 1-42).
2. MPTP opening lets water, protons (H^+) and salts into the mitochondrial matrix.
3. The influx of H^+, water and solutes collapses $\Delta\Psi_m$, and the loss of membrane potential impairs mitochondrial ATP production.
4. In parallel, the entry of large amounts of water causes mitochondria to swell.
5. The outer mitochondrial membrane then becomes more permeable, either due to its rupture or to the opening of outer membrane pores.
6. Consequent release of inner membrane constituents (AIF, Smac/diablo, Cyt c, etc.) into the cytosol has two important effects. First, there are metabolic consequences relating to these proteins exiting the mitochondria. Second, released mitochondrial constituents activate the next phase of apoptotic signaling.

The Outer Membrane Components

The normal constituents of the outer mitochondrial membrane include both proapoptotic and antiapoptotic proteins of the Bcl-2 family.

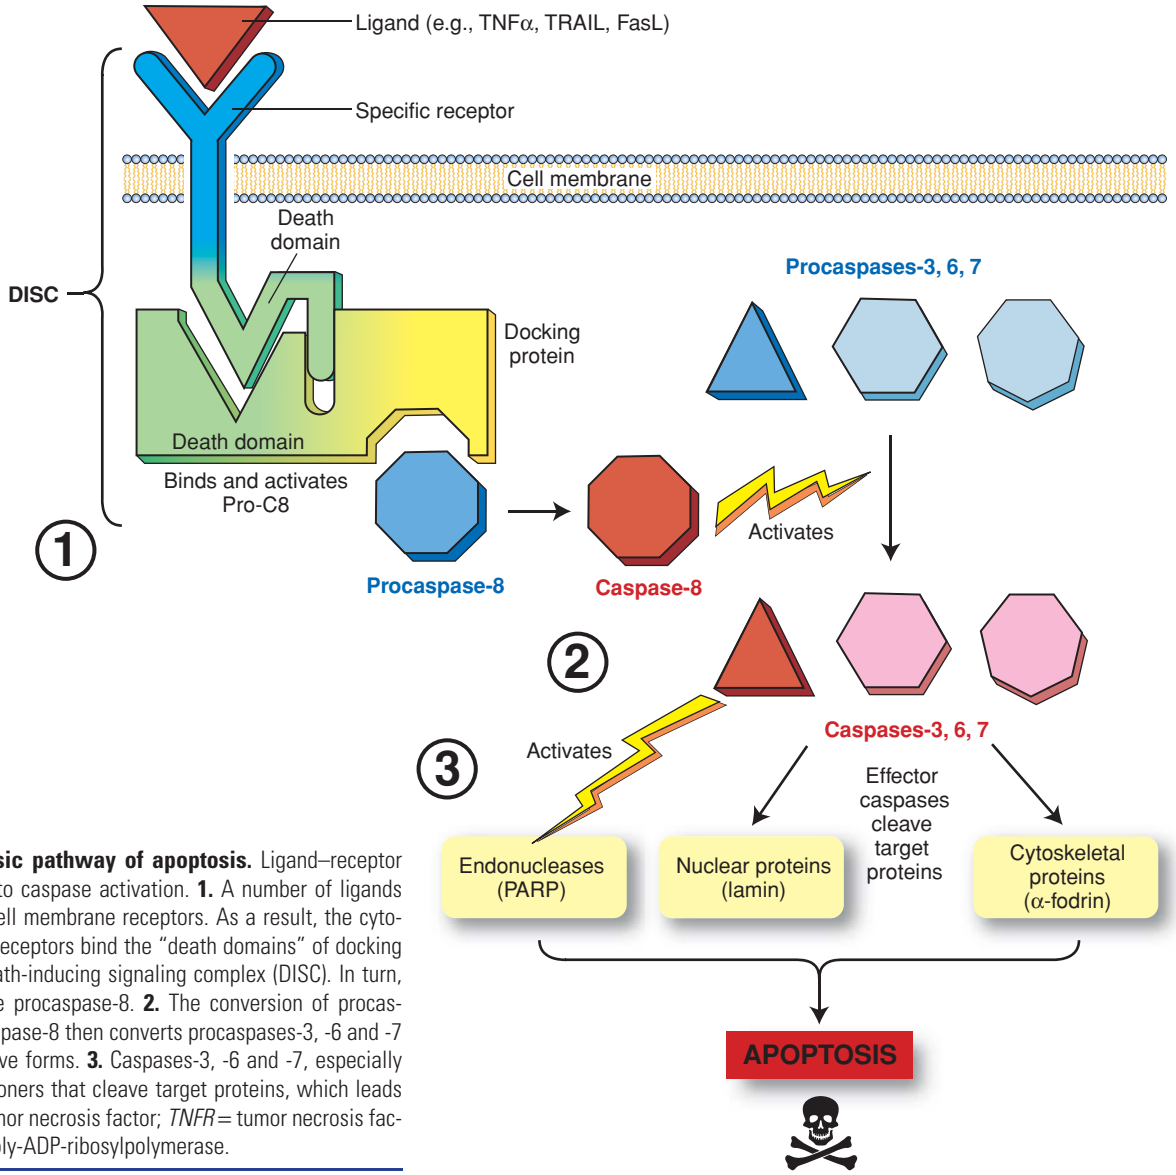

FIGURE 1-40. Extrinsic pathway of apoptosis. Ligand–receptor interactions that lead to caspase activation. **1.** A number of ligands bind their respective cell membrane receptors. As a result, the cytoplasmic tails of these receptors bind the "death domains" of docking proteins, to form a death-inducing signaling complex (DISC). In turn, these proteins activate procaspase-8. **2.** The conversion of procaspase-8 to activated caspase-8 then converts procaspases-3, -6 and -7 to their respective active forms. **3.** Caspases-3, -6 and -7, especially caspase-3, are executioners that cleave target proteins, which leads to apoptosis. *TNF* = tumor necrosis factor; *TNFR* = tumor necrosis factor receptor; *PARP* = poly-ADP-ribosylpolymerase.

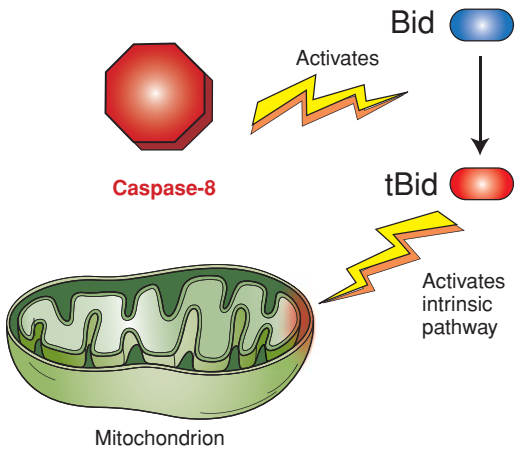

FIGURE 1-41. Intersection of the extrinsic and intrinsic pathways of apoptosis. Caspase-8, activated by, for example, a receptor–ligand interaction such as in Fig. 1-40, may in turn cleave cytosolic Bid to yield a truncated derivative, tBid. In turn, tBid translocates to mitochondria, thereby activating the intrinsic (mitochondrial) pathway of apoptosis.

The Bcl-2 Family as the Life/Death Switch of the Cell

The members of the Bcl-2 family can be viewed as belonging to one of three subfamilies, depending on the number of Bcl-2 homology (BH) domains (Fig. 1-43).

1. The antiapoptotic (i.e., prosurvival) members have four BH domains (labeled BH1, BH2, etc.) and are often referred to as multi-BH domain proteins. These include Bcl-2, Bcl-xL, Mcl-1 and others.
2. Proapoptotic (antisurvival) members are divided into two groups:
   a. One group contains three BH domains (Fig. 1-43). The key members of this group are Bak and Bax. A third member, Bok, is less well understood. Bak is mainly a mitochondrial protein, while Bax is largely cytoplasmic.
   b. A larger group of proapoptotic proteins, BH3-only proteins, carry a single BH3 domain. These include Bim, Bid, Bik, Bad and others. Different BH3-only proteins can elicit apoptosis by inactivating prosurvival functions of Bcl-2 family members or by directly stimulating death-inducing properties of Bax and Bak.

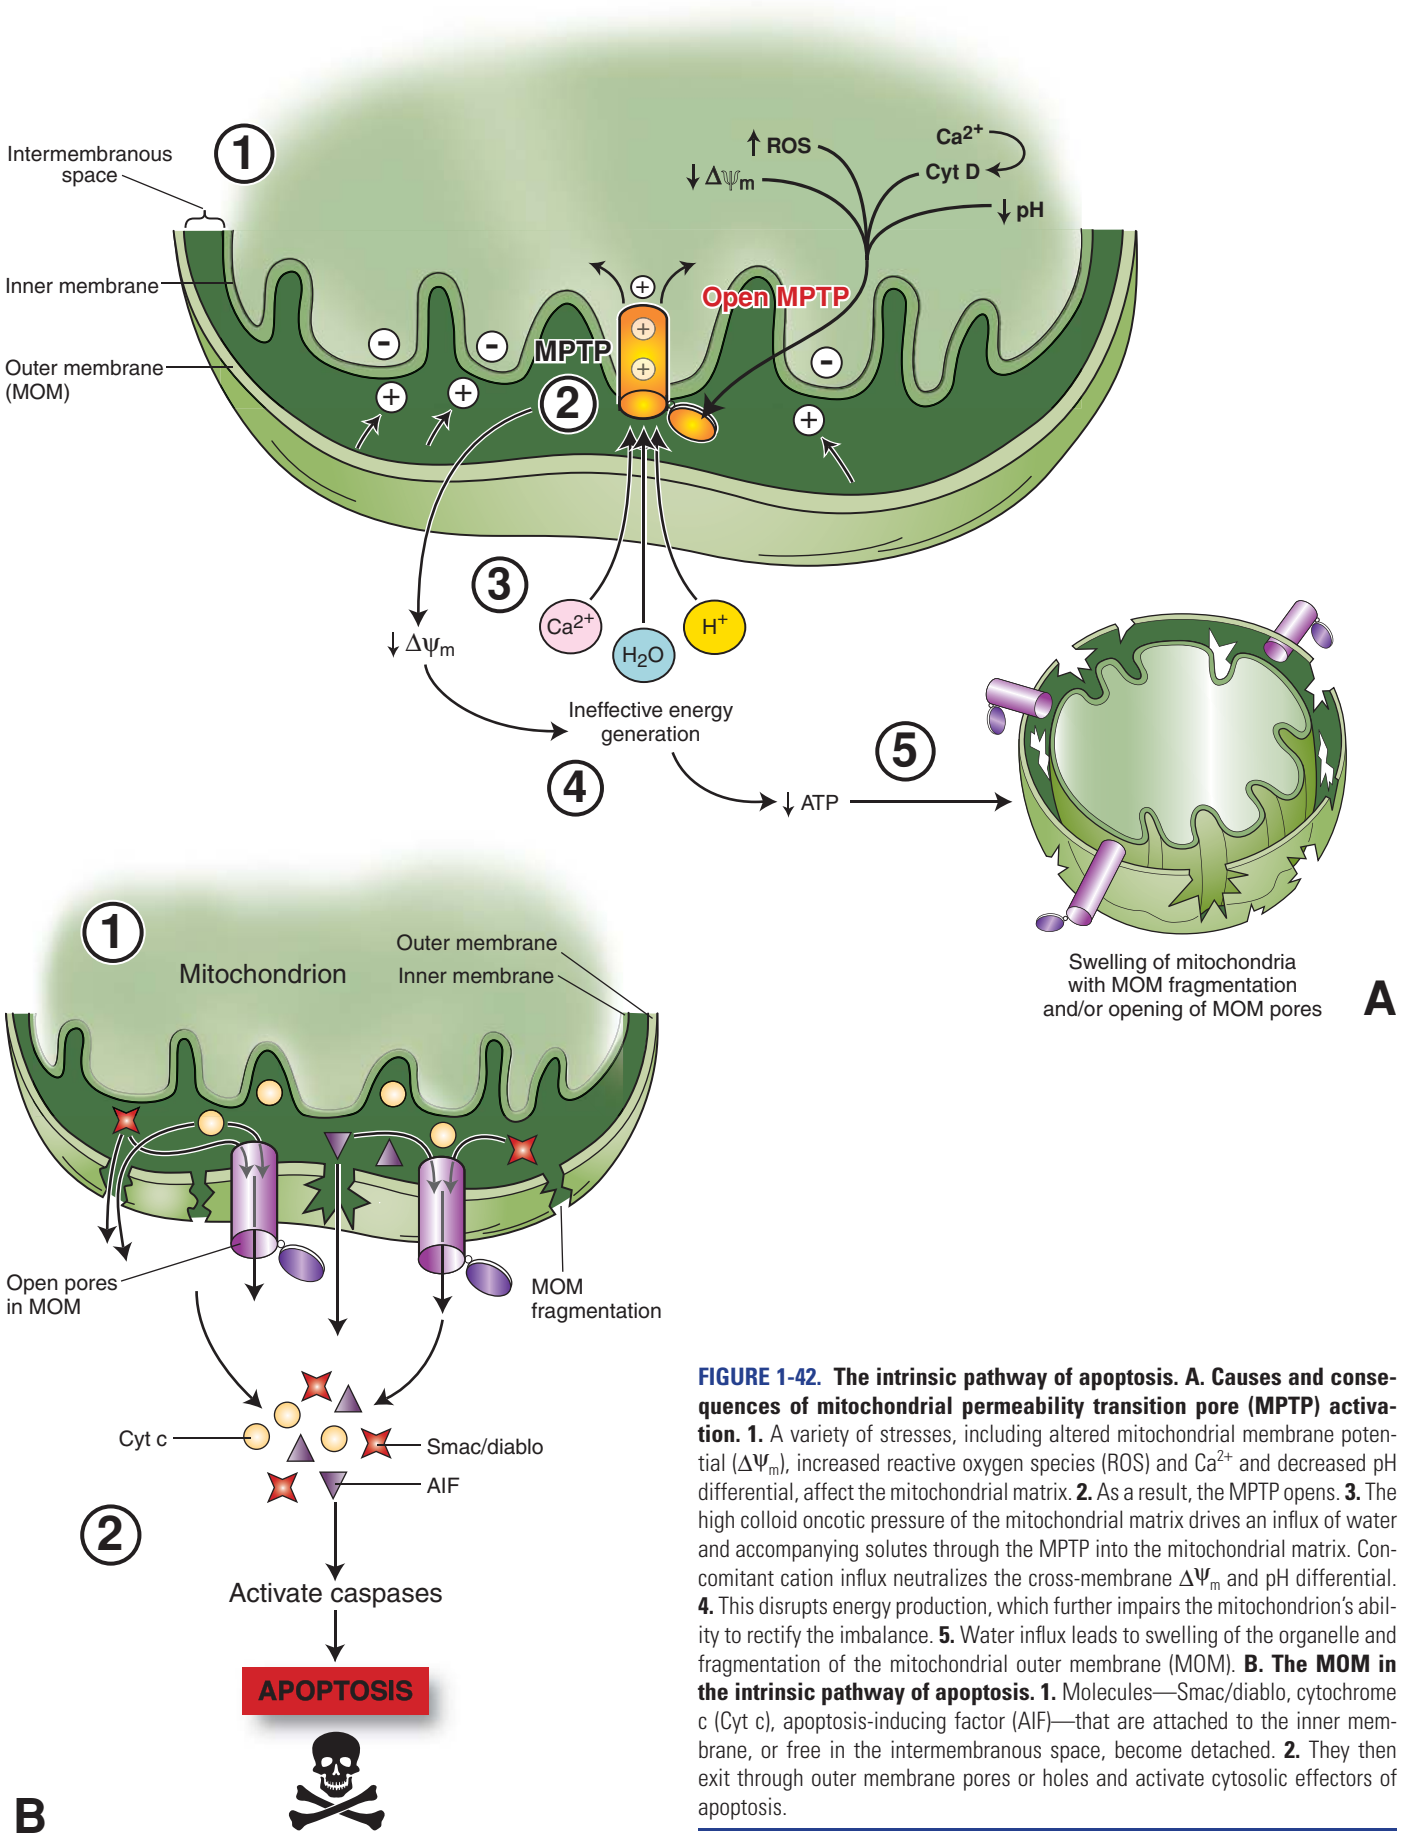

FIGURE 1-42. The intrinsic pathway of apoptosis. A. Causes and consequences of mitochondrial permeability transition pore (MPTP) activation. 1. A variety of stresses, including altered mitochondrial membrane potential ($\Delta\Psi_m$), increased reactive oxygen species (ROS) and Ca^{2+} and decreased pH differential, affect the mitochondrial matrix. **2.** As a result, the MPTP opens. **3.** The high colloid oncotic pressure of the mitochondrial matrix drives an influx of water and accompanying solutes through the MPTP into the mitochondrial matrix. Concomitant cation influx neutralizes the cross-membrane $\Delta\Psi_m$ and pH differential. **4.** This disrupts energy production, which further impairs the mitochondrion's ability to rectify the imbalance. **5.** Water influx leads to swelling of the organelle and fragmentation of the mitochondrial outer membrane (MOM). **B. The MOM in the intrinsic pathway of apoptosis. 1.** Molecules—Smac/diablo, cytochrome c (Cyt c), apoptosis-inducing factor (AIF)—that are attached to the inner membrane, or free in the intermembranous space, become detached. **2.** They then exit through outer membrane pores or holes and activate cytosolic effectors of apoptosis.

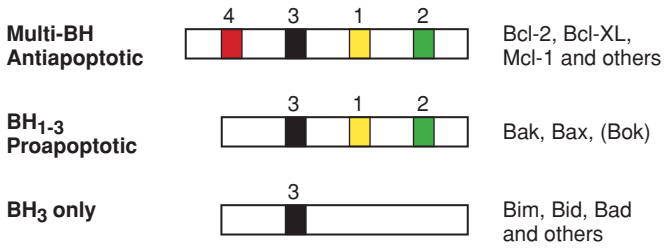

FIGURE 1-43. Bcl-2 family of apoptosis-related proteins. These proteins are divided into three groups, differentiated by structure and function. This division reflects the numbers of Bcl-2 homology (BH) domains in the protein. The presence of the BH4 domain characterizes the antiapoptotic family members. By contrast, proapoptotic Bcl-2 family members lack the BH4 domain and may have BH1-3 or only BH3. The latter are referred to as BH3-only proteins.

Mechanisms That Control the Intrinsic Pathway

The Normal Mitochondrion

Among other proteins, Cyt c and Smac/diablo are attached to the inner mitochondrial membrane, facing the intermembranous space. Opposite these, and attached to the outer membrane, are complexes of Bax and/or Bak bound to antiapoptotic Bcl-2 family members. In this peaceful equilibrium, Bcl-2 (Bcl-xL, Mcl-1, etc.) inhibits proapoptotic functions of Bax/Bak, and the mitochondrial default setting is prosurvival.

Triggering the Intrinsic Pathway of Apoptosis via the Bcl-2 Family of Proteins

Many intracellular agent provocateurs, often involving stress or injury, act via BH3-only family members. Such actions may include increasing concentrations of some BH3-only proteins (e.g., by activating transcription), altering their conformations from quiescent to active, modifying enzymes and so forth. The now-active BH3-only molecules may interpose themselves into Bcl-2 (Bcl-xL, etc.) complexes with Bak and Bax, causing these complexes to dissociate, and thus liberate Bax and Bak to form channels in the outer mitochondrial membrane. These channels, called mitochondrial apoptosis-induced channels (MACs), allow release of toxic mitochondrial proteins (Cyt c, Smac/diablo, etc.) into the cytosol (Fig. 1-44). Free Bax can also be directly activated by BH3-only proteins to form MACs.

Apoptosis Activated by p53

Cells are continually perched on a precipice between life and death. p53 is pivotal to the outcome of that balancing act. It may maintain vital functions and repair injury, thereby sustaining life. Alternatively, it may push the cell toward death. This discussion focuses on the role of p53 in cell death. (p53 is discussed in greater detail in Chapter 5.)

Homeostasis of p53

Normally, p53 is present in very small amounts, mostly in the cytosol, where it is bound mainly to Mdm2, an E3 Ub ligase. Mdm2 promotes p53 degradation via polyubiquitination. Even so constrained, p53 can foster cell health and effective responses to stress.

When a cell is injured or its equilibrium is disturbed, p53 undergoes diverse molecular modifications. These include phosphorylation, monoubiquitination at multiple sites (i.e., adding single Ub moieties at several points on p53 protein, rather than polymeric Ub chains at a single site) and others.

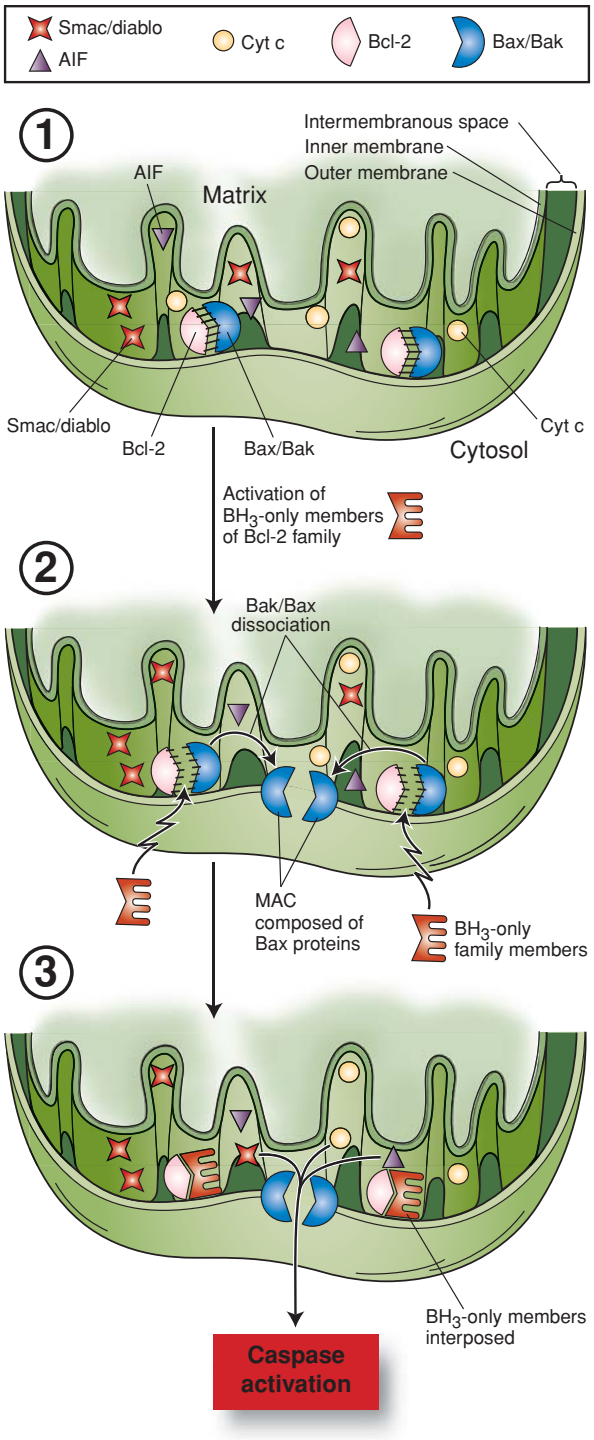

FIGURE 1-44. Formation of pores in the outer mitochondrial membrane during activation of the intrinsic pathway of apoptosis. 1. At equilibrium, Cyt c, Smac/diablo and apoptosis-inducing factor (AIF) either are attached to the mitochondrial inner membrane or float in the intermembranous space. The complex of oligomeric Bak/Bax with antiapoptotic Bcl-2 family cousins resides at the outer membrane. **2.** When BH3-only members of the Bcl-2 clan are activated, they interpose themselves between their prosurvival relatives and Bak/Bax, thereby freeing Bak/Bax proteins. The latter then form a pore (MAC) in the outer mitochondrial membrane. **3.** Proapoptotic proteins Cyt c, Smac/diablo, AIF and others exit from the mitochondrion via the MAC pore. Once in the cytosol, these proteins facilitate activation of the caspase cascade and so cause apoptosis. *Cyt c* = cytochrome C; *MAC* = mitochondrial apoptosis-induced channel.

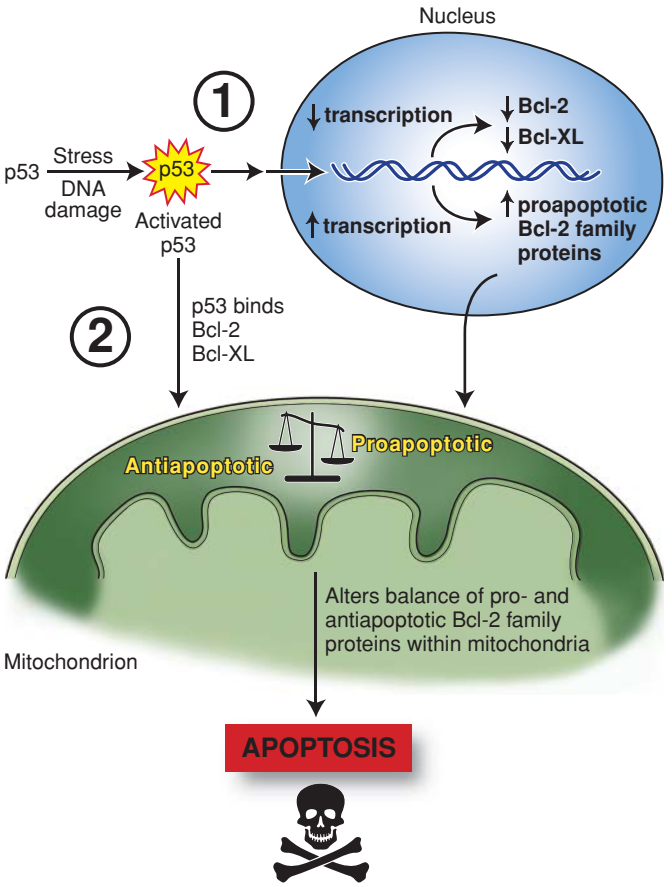

FIGURE 1-45. Activation of p53 and apoptosis. When p53 is activated (e.g., by DNA damage), it translocates to the nucleus. **1.** If DNA damage is irreparable, p53 promotes transcription of proapoptotic proteins, which then migrate to mitochondria. p53 also decreases transcription of prosurvival (antiapoptotic) Bcl-2 family proteins, such as Bcl-2 and Bcl-xL. **2.** In parallel, high concentrations of p53 in the cytosol translocate to mitochondria, where they bind to the prosurvival proteins Bcl-2 and Bcl-xL, releasing their bound proapoptotic partners (e.g., Bax/Bak). As a result, the balance of Bcl-2 family members at the mitochondrial membrane shifts to favor proapoptotic forces, and the cell undergoes apoptosis.

These alterations relax p53 binding by Mdm2, which both allows p53 to accumulate and targets it to the mitochondria or nucleus, depending on the specific molecular modification (Fig. 1-45).

Apoptosis-Related Activities of p53

Within the nucleus, p53 is both a transcriptional activator and a repressor, depending on the target gene. It activates transcription of many proapoptotic proteins, such as Bad, Bax, NOXA, PUMA and others, while simultaneously repressing transcription of prosurvival proteins, including Bcl-2, Bcl-xL and Mcl-1.

Protein–protein interactions between p53 and Bcl-2 family members also enhance induction of apoptosis. Cytosolic p53 may directly activate Bax, whereupon Bax relocates to mitochondria to cause apoptosis via release of mitochondrial proteins (see above). Mitochondria-targeted (i.e., [poly]-monoubiquitinated) p53 acts as a functional BH3-only protein. In this mode, it disrupts complexes between Bak and its inhibitor, Mcl-1, and tips the mitochondrial Bcl-2 family equilibrium to favor apoptosis.

p53 also regulates cell cycle, metabolism and many other cell functions. These are addressed more fully in Chapter 5.

Ca^{2+} Release by the Endoplasmic Reticulum May Elicit Apoptosis

Cells maintain a large calcium concentration ($[Ca^{2+}]$) gradient relative to the extracellular space, which has about four orders of magnitude higher $[Ca^{2+}]$ than does the cytosol. Ligand-induced and other changes in cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) are often secondary signals in many cellular processes. However, excessive changes in $[Ca^{2+}]_i$ may also induce apoptosis. The ER stores considerable calcium, which may be released in response to various stimuli (stress response). When ER Ca^{2+} is released, and particularly if Ca^{2+} release is prolonged, apoptosis ensues.

The proximity of the ER to mitochondria is key to this process. Ca^{2+} released by the ER may be taken up by mitochondria, especially where the two organelles meet. Resulting increases in mitochondrial $[Ca^{2+}]$ cause the MPTP to open, releasing Cyt c and activating downstream apoptosis pathways.

Sustained release of Ca^{2+} from ER stores also promotes release of caspase-12. This protein, which is normally bound to the ER membrane, becomes activated upon its release. Activated caspase-12 then activates caspase-9 in the apoptosome (see below), in turn triggering the executioner caspases (mainly caspase-3).

Metabolic Factors in the Mitochondrial Apoptosis Pathway

Just as effective mitochondrial functioning is fundamental to cell survival, its loss can contribute to the mitochondrial mechanism of apoptosis. Thus:

- Because Cyt c, AIF and other mitochondrial proteins released into the cytosol are also integral to the electron transport chain, their loss impairs mitochondrial ATP generation. The cell's ability to repair injury is consequently suboptimal. If the causative insult is limited or transient, remaining functional mitochondria may compensate for the temporary loss of energy generation and sustain repair.
- Bax alters mitochondrial metabolism, directly and indirectly, to both increase generation and decrease detoxification of ROS, which in turn magnify mitochondrial injury. ROS increase the release of Cyt c and other proteins.
- Caspase-3 directly impairs parts of the electron transport complex.
- Antioxidant defenses are weakened, both because of decreased production of antioxidant enzymes (related to p53) and because the defects in electron transport allow increased ROS generation.
- Imbalances in Ca^{2+} metabolism affect mitochondria. Increases in $[Ca^{2+}]$ (e.g., in excitable cells like neurons and myocytes) may be transient, coinciding with stimulated release from the ER and leading to brief MPTP opening, which does not impair cell viability. However, if Ca^{2+} influx into mitochondria is prolonged, increases in mitochondrial ROS and other factors can lead to sustained, fatal MPTP opening.
- p53 may promote mitochondrial respiration, which, when electron transport is impaired (see above), generates more ROS. The harmful consequences of this phenomenon

may be further exacerbated by p53-related transcriptional repression of SOD, which decreases antioxidant protection.

It should be noted that ATP, even depleted by the events mentioned above, is required for apoptosome activity (see below). Thus, if MPTP opening is prolonged and ATP supply is exhausted, a cell may undergo necrotic, rather than apoptotic, death.

Proteins Released from Mitochondria Lead to Apoptosis via Several Pathways

As noted above, permeabilization of the outer mitochondrial membrane causes several mitochondrial molecules—Cyt c, Smac/diablo, AIF and others—to exit into the cytosol. Once in the cytosol, Cyt c binds cytosolic Apaf-1 (apoptotic protease-activating factor) and procaspase-9 to form the **apoptosome**. This structure releases activated caspase-9, which then cleaves procaspases-3, -6 and -7, resulting in cell death (Fig. 1-46, left side).

The enzymes, caspases-3, -7 and -9, may be inactivated by a family of E3 ubiquitin ligases, called inhibitors of apoptosis (IAPs). Smac/diablo, and other similar proteins, bind IAPs and free caspases from IAP-mediated inhibition, thereby allowing them to execute the cell (Fig. 1-46, right side).

In addition, AIF and other proteins that are released from mitochondria through MACs can initiate apoptosis directly. They do so by activating the destructive enzymes (including

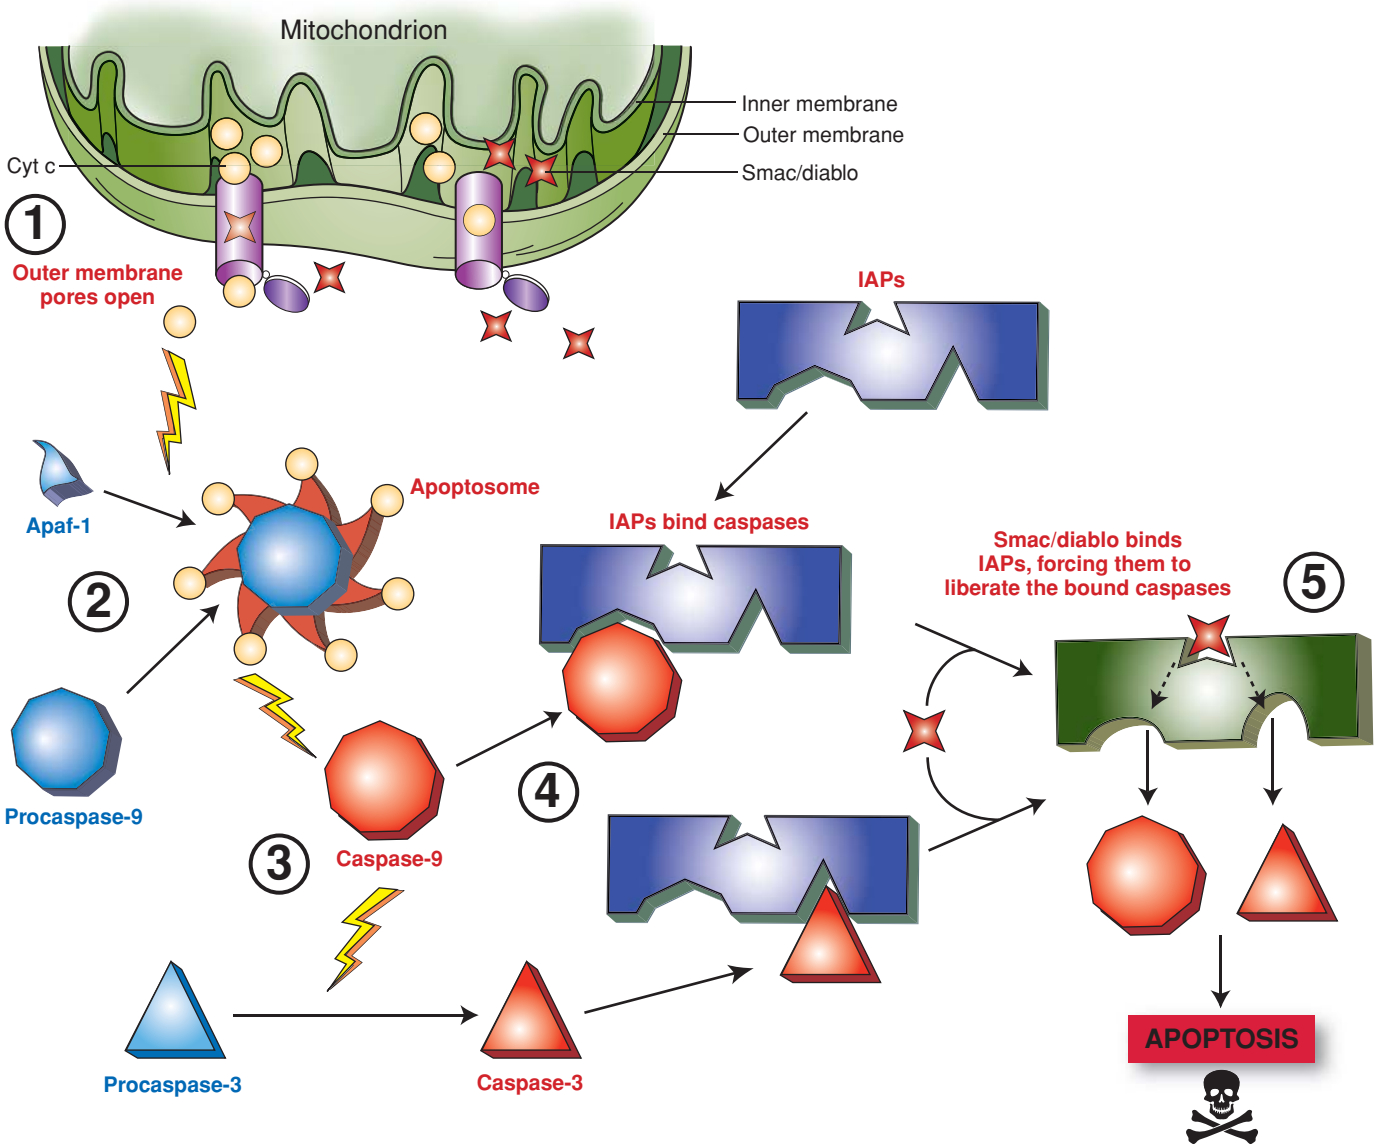

FIGURE 1-46. Opening of the mitochondrial outer membrane, leading to Apaf-1 activation, thereby triggering the apoptotic cascade. 1. Upon triggering by proapoptotic stimuli, pores in the outer membrane open and release proapoptotic proteins. **2.** Cyt c activates multiple molecules of Apaf-1 and both together recruit procaspase-9 to form a structure called the apoptosome, in which the procaspase is activated to caspase-9. Two sets of events may then occur to caspase-9. **3.** It may activate the effector caspases, particularly caspase-3. **4.** As well, IAPs may bind and sequester active forms of several caspases, including caspase-3 and -9. In so doing, IAPs impede apoptosis. **5.** However, Smac/diablo and other mitochondrial proteins that are released when apoptosis is triggered may bind IAPs, causing them to release their bound caspases. The latter then cause the cell to undergo apoptosis. *Apaf-1* = apoptosis-activating factor; *Cyt c* = cytochrome c; *IAP* = inhibitor of apoptosis.

CAD; see above) that cause nuclear condensation and DNA fragmentation, thus generating a *caspase-independent form of programmed cell death.*

Pathways That Regulate Apoptosis

As discussed above, multiple specific mechanisms give rise to and prevent apoptosis. These are, in turn, regulated by many other cellular pathways. For example, the ubiquitin–proteasome system can target proapoptotic proteins, such as caspases, for degradation. This may occur via the IAP family of proteins or by other means. Ubiquitination in turn is controlled by deubiquitinating enzymes and other modulators. The balance between apoptosis and cell survival is influenced by the interplay between inducers and inhibitors of apoptosis, heat shock proteins, protein kinases that may alter caspases or other enzymatic activities and a host of other factors. Recent studies have also implicated microRNAs in regulating intracellular levels of many of these proteins and, consequently, the cell's survival. *Whether or not a cell lives is therefore not determined solely by unique apoptosis-related mechanisms, but rather by a complex array of pathways whose functions converge on that single point.*

Other Functions of Caspases

It is important to recognize that the caspase family has many functions unrelated to apoptosis. Caspases participate in (1) inflammation and immunity, (2) cell proliferation and differentiation in embryonic and extraembryonic life, (3) remodeling of cellular structures and projections, (4) mitogenesis and (5) many other processes.

The Equilibrium between Proapoptotic and Antiapoptotic Signals

Cell survival and programmed cell death are part of an intricate and highly complex balance, like a symphony orchestra. Each member of the symphony has many parts to play and the outcome depends on the coordination of all the members. However, unlike a symphony, the cell does not have a conductor that tightly controls its music. In this vein, it is useful to emphasize that a cell's fate is driven by the balance between proapoptotic and prosurvival influences. Some survival signals are transduced through receptors linked to PI3K. By antagonizing apoptosis, PI3K plays a critical role in cell viability. A prototypical receptor that signals via PI3K is insulin-like growth factor-I receptor (IGF-IR). Paradoxically, PI3K is also activated by TNFR after binding TNF-α. Thus, the same cell membrane receptor that induces apoptosis in some cases may initiate survival signaling in other situations.

PI3K exerts antiapoptotic effects through intracellular mediators, which favor survival by activating a protein kinase, called Akt. The latter inactivates several important proapoptotic proteins (e.g., Bad). More importantly, Akt activates NFκB, thus driving expression of prosurvival proteins (Bcl-xL and A1).

Apoptosis Is Central to Many Disease Processes

When regulation of apoptosis goes awry, there is the devil to pay. Apoptosis is vital for correct progression of embryologic development, elimination of self-reactive B- and T-lymphocyte clones and many other normal functions. Apoptosis guards against uncontrolled cell proliferation (e.g., cancer) due to mutations in DNA (see Chapter 5).

Insufficient Apoptosis

If a major protein that mediates the defense of the organism, such as p53, is mutated, the protection afforded by apoptosis is compromised. Further mutations may then accumulate unhindered. Such pathways are commonly considered to be important in tumor development and progression (see Chapter 5). As another example, the ability of some viruses to block apoptosis allows those pathogens to replicate with less interference, and so to disseminate more widely than would otherwise be possible. Oncogenic viruses often inhibit apoptosis (e.g., human papillomavirus inactivates p53), increasing susceptibility of infected cells to progress to cancer.

Excessive Apoptosis

In some cases, decreases in cell numbers due to "excessive" apoptosis may lead to the development of certain diseases. For example, some neurodegenerative diseases are characterized by accumulation of intracellular proteins within neurons, thus triggering apoptosis and leading to decreased numbers of neurons and loss of specific functions.

SPECIALIZED FORMS OF PCD

Autophagy in PCD: Is It a Killer or an Accomplice?

Autophagy plays an important prosurvival role in cell adaptation to stress and injury, as described above. The function of autophagy as an independent form of cell death is unclear. There is a body of evidence that suggests—but does not prove—that autophagic mechanisms may also represent a separate form of cell death.

Autophagy may promote excessive removal of cell organelles, and so irrevocably interfere with vital cellular functions. It may also destroy proteins that sustain cell survival. Experimental inhibition of autophagy prevents cell death induced by a variety of agents. Autophagy can also contribute to apoptosis. Thus, it is currently unclear whether autophagy is responsible for cell death independently of other forms of PCD and the extent to which such events may occur.

Necroptosis Is a Form of PCD Morphologically Indistinguishable from Necrosis

As discussed above, cellular morphology in necrosis involves cell swelling, plasma membrane fragmentation and nuclear pyknosis, followed by an inflammatory response. Apoptosis, by contrast, is characterized by plasma membrane blebbing and nuclear fragmentation without inflammation. Cells may succumb to a fate resembling necrosis (see above) if a PCD independent of caspases is activated. This is called **necroptosis,** or signaled necrosis.

Necroptosis can be initiated in several ways, but commonly begins when Fas ligand (FasL) or TNF-α binds to its respective receptors. This leads to receptor-bound complexes that incorporate caspase-8; two IAP proteins (E3 Ub ligases), along with several other proteins; and the receptor-interacting proteins (RIP1, RIP3). This complex sits on the knife edge of several alternative fates, but activation of RIP1 and RIP3 leads to cell death by necroptosis.

RIP3 is the epicenter of this process (Fig. 1-47). It leads to increased cytosolic Ca^{2+}, which activates calpain and other

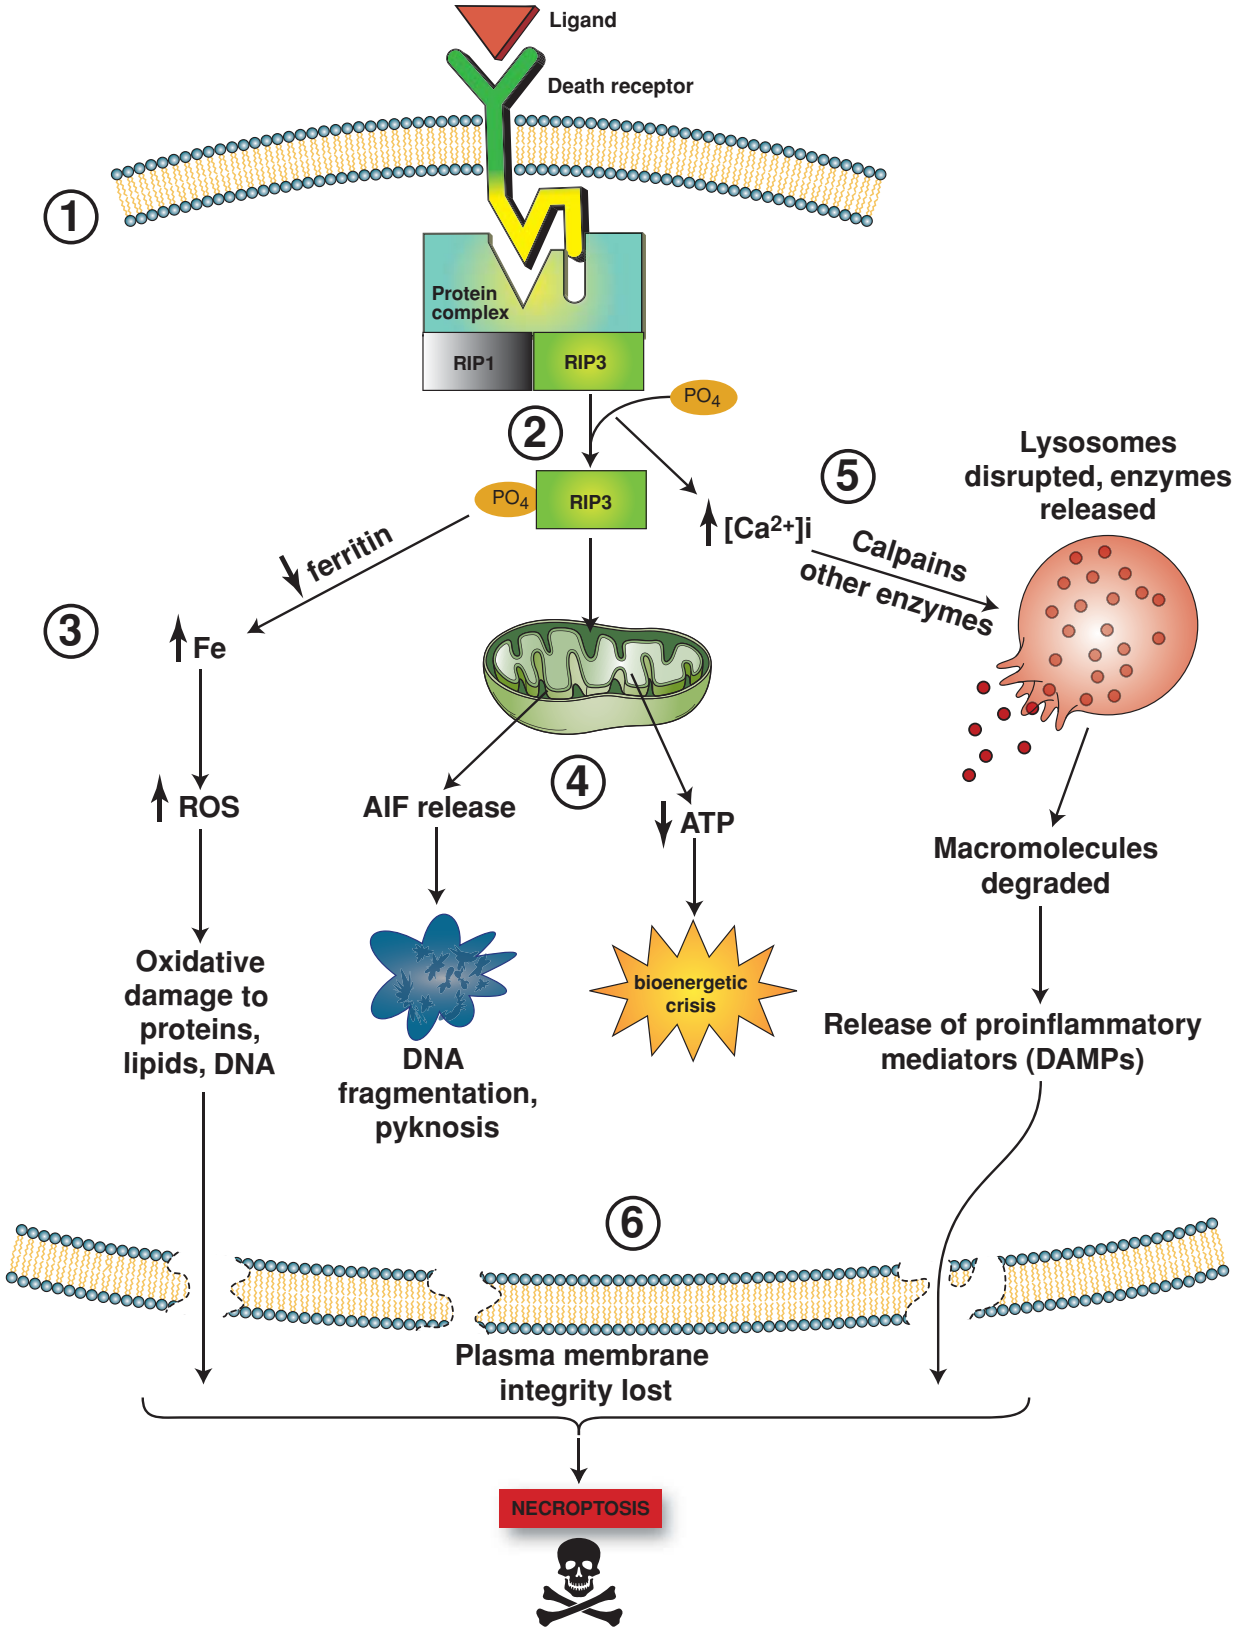

FIGURE 1-47. Pathways leading to necroptosis. 1. Binding of a ligand to a death receptor results in formation of a protein complex that binds RIPs. **2.** As a result, RIP3 is phosphorylated, which leads to necroptosis by several paths. **3.** Phosphorylated RIP3 increases free iron and so increases reactive oxygen species (ROS). **4.** Damage to mitochondria leads to apoptosis-inducing factor (AIF) release and also impairs adenosine triphosphate (ATP) production. **5.** Also, increased [Ca^{2+}] leads to activation of Ca^{2+}-dependent degradative enzymes, which disrupt lysosomes and release lysosomal enzymes that degrade cellular macromolecules. **6.** The final steps in each of these pathways consist of necroptosis: AIF triggers DNase activity and leads to nuclear pyknosis; loss of ATP precipitates a bioenergetic crisis; and plasma membrane damage due to oxidative disruption of membrane lipids produces holes in the cell membrane and leads to release of macromolecular breakdown products that stimulate inflammation (DAMPS). *DAMPs* = damage-associated molecular products; *RIP* = receptor-interacting protein.

degradative enzymes, which attack lysosome membranes and cause release of lysosomal hydrolases into the cytosol. Calpain also damages mitochondria, precipitating metabolic dysfunction with impaired ATP generation and iron release, with consequent increases in ROS (see Fenton and Haber-Weiss reactions above) and damage to proteins, lipids and DNA. At the same time, mitochondria release AIF (see above), which enters the nucleus and activates DNA degradation. A bioenergetic crisis with the morphologic features of necrosis ensues. Cells then release molecules (called damage-associated molecular patterns; see Chapter 2) that provoke inflammation.

Under physiologic circumstances, necroptosis participates in development, particularly at the bone growth plate. It is also active normally in some adult tissues such as the lower portion of the intestinal crypts. If physiologic apoptosis is unavailable to cells, necroptosis may become the default cell death pathway. In this mode, it may be an important mechanism of PCD in cancer cells in which apoptotic pathways are blocked. It is also important in limiting the spread of certain viral infections. Like apoptosis, necroptosis is a double-edged sword and may participate in pathologic processes such as neurodegenerative diseases and ischemia/reperfusion injury.

Anoikis Is Activated by Loss of Cell Attachments

Anoikis (Greek: "homelessness") is a variety of apoptosis that occurs in epithelial cells and is caused by loss of cell adhesion or inappropriate cell adhesion. Correct binding of a cell to the ECM helps to determine whether that cell is in its appointed location. The significance of anoikis is that it efficiently deletes cells that have been displaced from their proper residence. Thus, it prevents wandering cells or cell clusters from developing colonies at distant or improper ECM sites, and so helps protect against the development of cancer metastases.

Anoikis operates via intrinsic or extrinsic classical apoptotic pathways, both of which are upregulated when a cell becomes detached (Fig. 1-48). A cell that loses contact with its normal ECM, like one that is pushed off the tip of an intestinal villus by proliferating cells deeper in the crypts, is stimulated to undergo anoikis by loss of integrin-mediated survival signaling. Similarly, if a detached cancer cell makes contact with inappropriate ECM components, anoikis may be activated (see Chapter 5).

Granzymes Released by Lymphocytes Kill Cells via Apoptosis

Activation of caspase signaling also occurs when cytotoxic T lymphocytes (CTLs) and natural killer (NK) cells recognize a cell as foreign. These lymphocytes release two major molecular species, namely, perforin and granzymes. Perforin, as its name suggests, punches a hole in the plasma membrane of a target cell, through which proteins from the lymphocyte enter. Granzymes are a family of multifunctional serine proteases, among which the best understood is granzyme B.

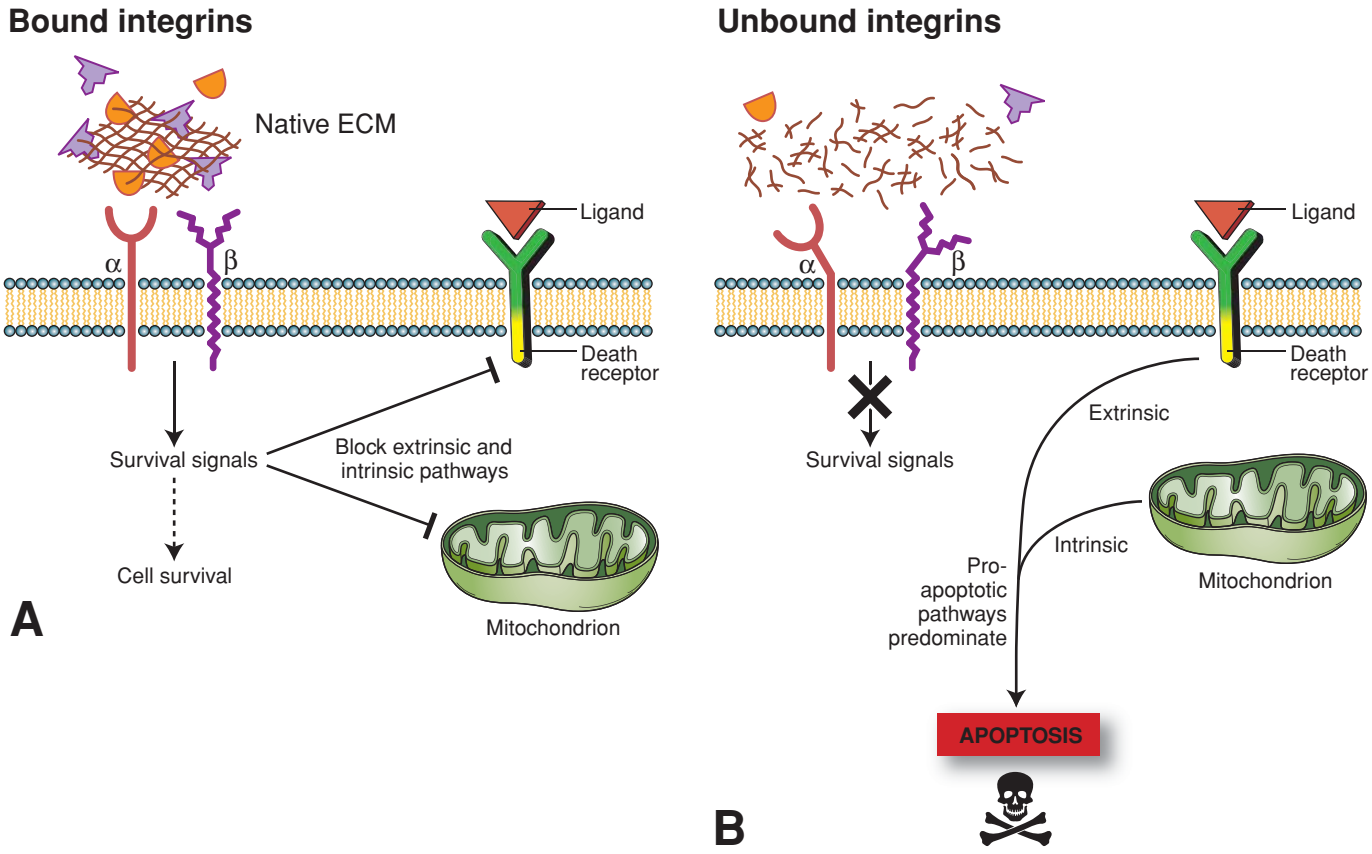

FIGURE 1-48. Mechanisms of anoikis. A. Normal. Under normal circumstances, epithelial cells are bound to their native ECM by transmembrane molecules, including α- and β-integrins. These molecules activate survival signals and block both intrinsic and extrinsic apoptotic signaling pathways. **B. Loss of attachment.** When the cell's integrins are not bound, or not bound by the appropriate ECM moieties, their survival signals are eliminated. Then, activation of apoptosis by death receptor signaling is no longer blocked, and apoptosis may proceed. *ECM* = extracellular matrix.

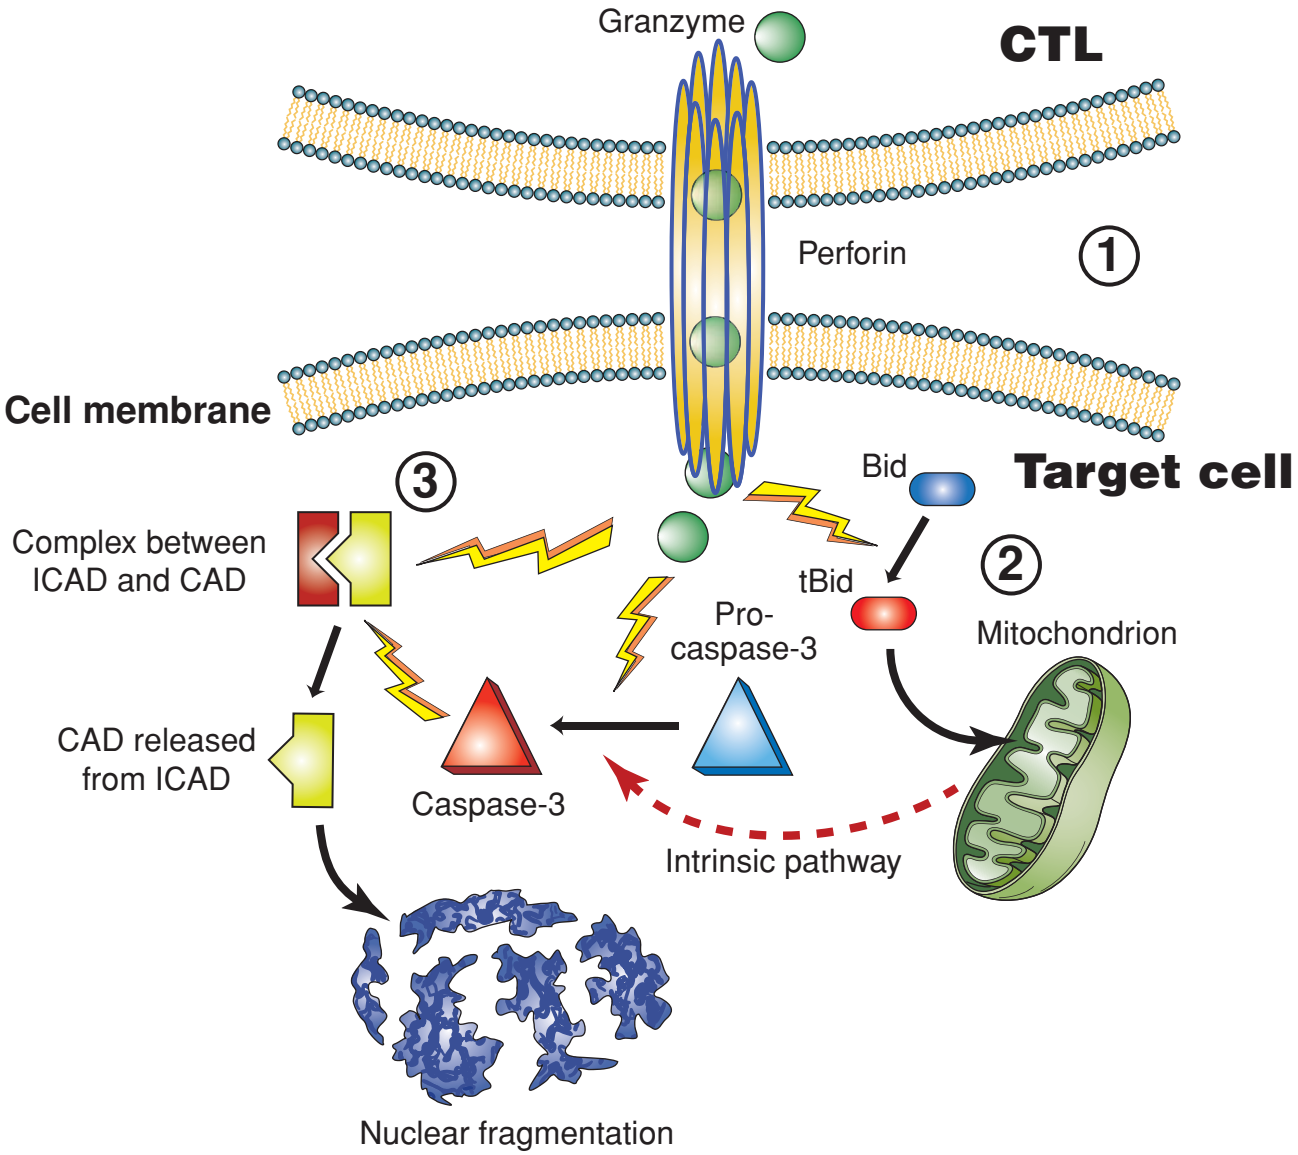

FIGURE 1-49. Cell death caused by CTLs. 1. Granzyme and perforin are two molecules made, mainly, by CTLs and natural killer (NK) cells. After a CTL binds its cellular victim, perforin molecules combine to create an intercellular channel through which granzyme enters the target cell. **2.** Granzyme cleaves cytoplasmic Bid to its active form, tBid, which translocates into mitochondria and triggers the intrinsic pathway of apoptosis. It also activates procaspase-3 to caspase-3, via which apoptosis may proceed. **3.** Granzyme may also disrupt the complex between CAD and its inhibitor, ICAD. This effect releases the DNase (CAD) to elicit a caspase-independent form of apoptosis. The CAD–ICAD complex may also be cleaved by caspase-3. *CAD* = caspase-activated DNase; *CTL* = cytotoxic T lymphocyte; *ICAD* = inhibitor of CAD.

This protease activates cytosolic Bid, a BH3-only protein, by cleaving it to tBid (Fig. 1-49). In turn, tBid increases mitochondrial release of Cyt c and other cell death effector proteins. It also converts several procaspases (notably procaspase-3) to active caspases.

Granzyme A is also released by NK cells and CTLs into target cells. Granzymes A and B together induce cell death by caspase-independent mechanisms. They activate the DNA nicking enzyme, CAD (see above), which degrades genomic DNA (Fig. 1-49).

Pyroptosis Contributes to Innate Immune Defenses

Pyroptosis is a cell death program that relies on caspase-1 (previously called IL-1β–converting enzyme). Many infectious agents, particularly viruses, but also bacteria and others, stimulate inflammatory reactions by interacting with members of a group of cell membrane receptors called **pattern recognition receptors** (see Chapters 2 and 4).

Although caspase-1 is a cysteine protease involved in PCD, it is independent of apoptotic signaling, and its activation does not bring about apoptosis (Fig. 1-50). Instead, caspase-1 is a proinflammatory protease that is produced by a structure called an inflammasome (Fig. 1-50). Once activated, caspase-1 cleaves select cellular molecules, including enzymes that are important for glycolysis, thereby depleting cellular energy. It also produces ion-permeable plasma pores, allowing influx of water and solutes to provoke cell swelling and then death. Furthermore, by activating a number of proinflammatory cytokines, the dead cell elicits inflammation.

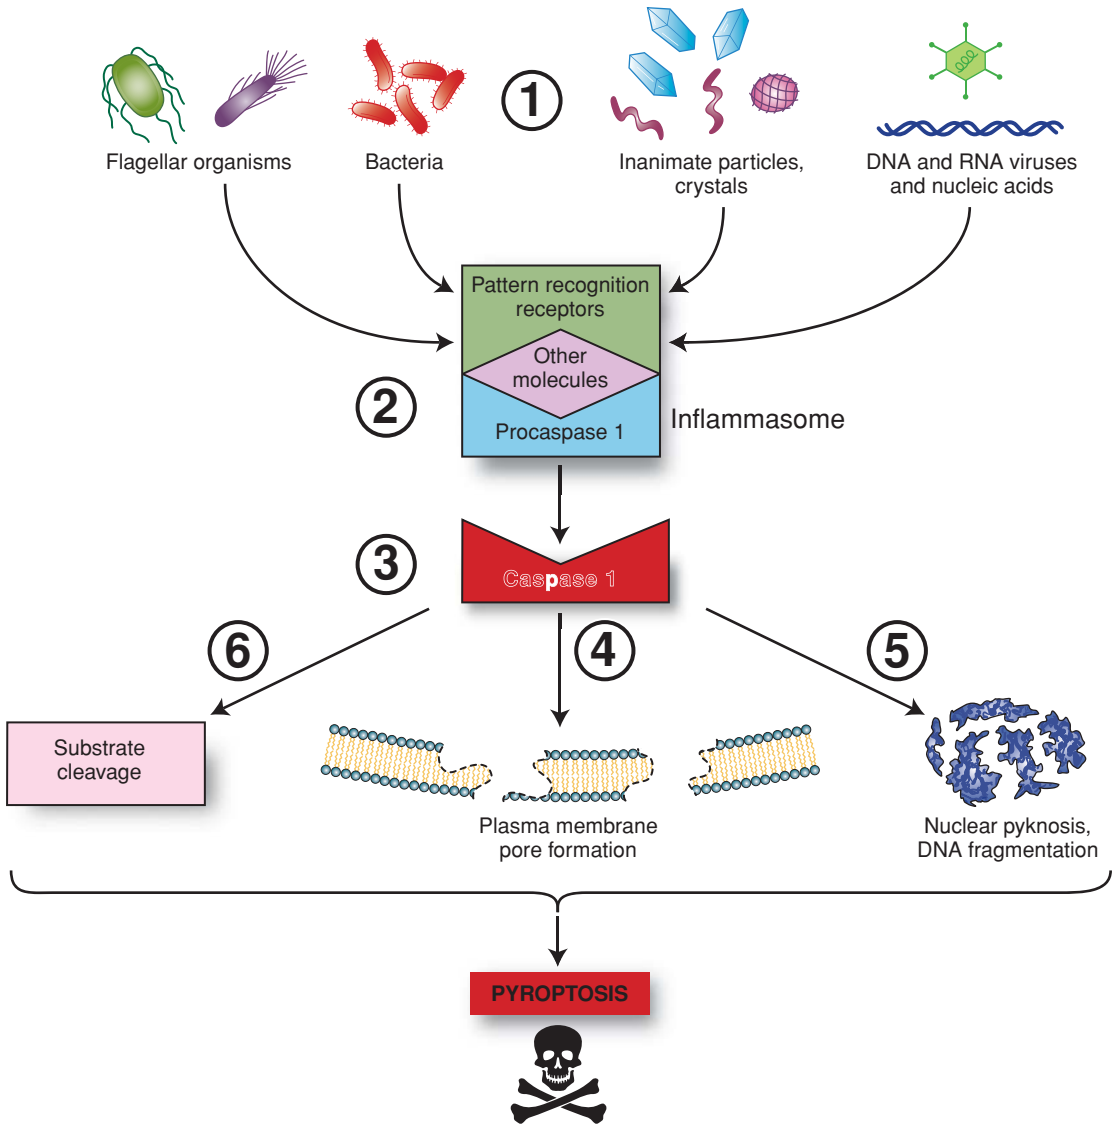

FIGURE 1-50. Pyroptosis. 1. The cell is exposed to injurious agents, both infectious and irritative (e.g., mineral crystals). **2.** Complexes called inflammasomes recognize these exogenous agents via diverse pattern recognition receptors. Inflammasomes contain procaspase-1. **3.** When inflammasome-linked receptors are activated, procaspase-1 is converted to its active form, caspase-1, which has several consequences. **4.** Caspase-1 forms pores in the plasma membrane, allowing intracellular components to leak out of the dying cell. **5.** At the same time, the nucleus is damaged, and **(6)** important intracellular substrates, including cytoskeleton, chaperones, glycolytic proteins and caspase-7, are cleaved. **7.** All these effects contribute to pyroptotic cell death.

In addition to its host-protective role in encounters with nefarious pathogens, pyroptosis has been implicated in the pathogenesis of metabolic syndrome and the etiology of type 2 diabetes mellitus (see Chapter 13).

NETosis Reflects the Action of a Potent Antimicrobial Defense Mechanism

Neutrophil extracellular traps (NETs) are structures produced by polymorphonuclear granulocytes. NETs function as chromatin traps for bacteria and other pathogens and contain antimicrobial cell products. These formations can kill bacterial, fungal and protozoal pathogens, and so constitute an important host defense from infection.

NETs result from activation of a cell death program, mainly in neutrophils, but also including eosinophils and mast cells. This program is called NETosis. Interestingly, NETs may be composed of either nuclear or mitochondrial chromatin and do not necessarily need self-sacrifice of the neutrophil that contributes the chromatin.

NETosis requires both autophagy and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity and is characterized by destruction of the cell's nuclear envelope and the membranes of most cytoplasmic granules (Fig. 1-51). Chromatin disaggregation results, and the cell extrudes a NET containing both chromatin and strongly microbicidal histones and histone cleavage products.

Unlike apoptotic cells, neutrophils and other NETosis-susceptible cells do not present the "eat me" signals (cell membrane phosphatidyl serine; see above) that are characteristic of apoptosis. Lacking such signals, NETotic cells are not preemptively removed by macrophages and are able to stimulate inflammatory responses.

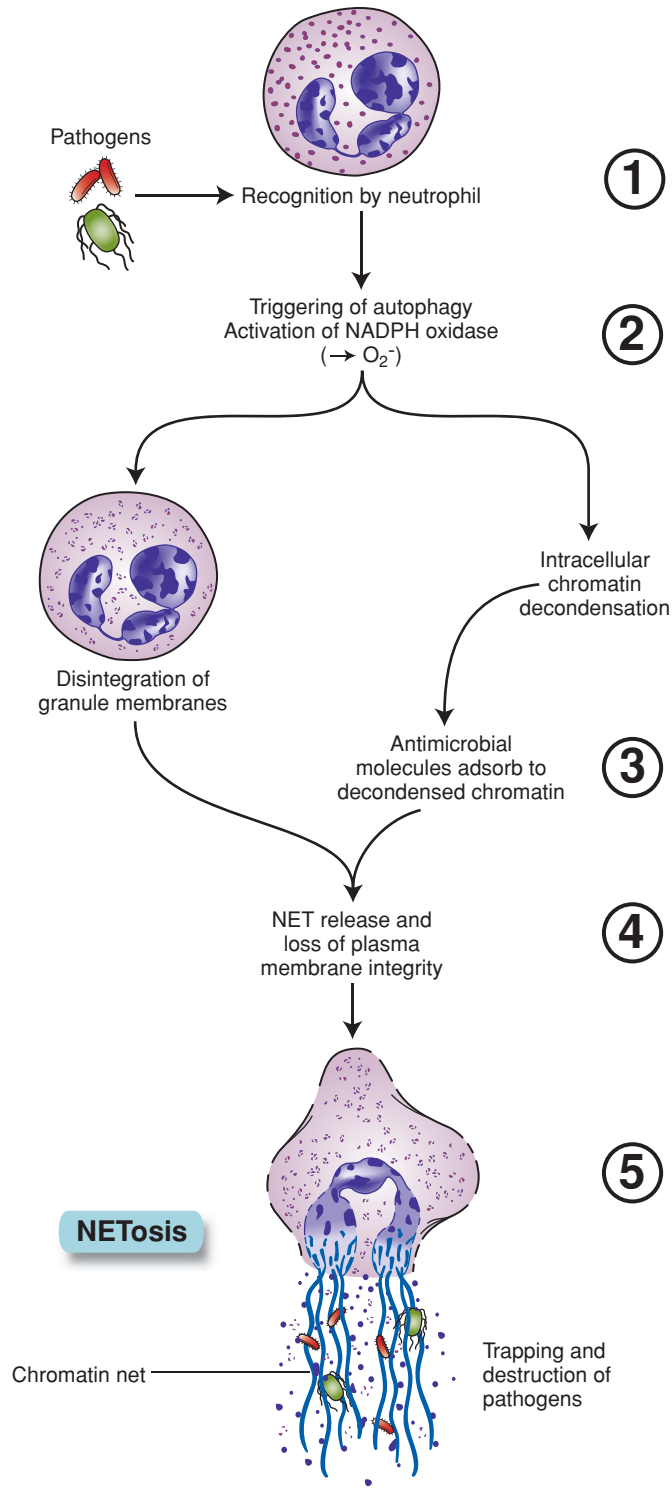

FIGURE 1-51. NETosis. 1. Neutrophils recognize pathogens, after which **(2)** autophagy and NADPH oxidase are activated, the latter yielding reactive oxygen species (ROS). **3.** As a result, intracellular chromatin becomes dispersed and membranes of cytoplasmic granules disintegrate. **4.** NETotic activity leads to release of neutrophil chromatin traps containing antimicrobial cellular products. **5.** These traps then catch and destroy pathogens.

Entosis Is a Cell-Eat-Cell Form of Cell Death

Entosis is a type of cellular cannibalism in which cells that are not professional phagocytes engulf nearby living cells. Aggressor cells may engulf cells of either the same or other lineages. For example, hepatocytes may ingest and destroy autoreactive T lymphocytes, thus inhibiting experimental autoimmune liver disease. More often, entosis is seen in tumors.

Vacuoles containing cells undergoing entosis may fuse with lysosomes, in which case target cells usually die, although death is not an inevitable outcome. The cannibalized cell, or parts thereof, may survive the process. Its nuclear material may become part of the aggressor cell, leading to multinucleate cells, polyploidy or aneuploidy. Some engulfed cells actually escape their captors and re-emerge unscathed. Mechanisms governing entosis are largely obscure.

DEVELOPMENT OF THE CONCEPT OF INFLAMMATION

Inflammation is a systemic and local reaction of tissues and microcirculation to a pathogenic insult. It is characterized by elaboration of inflammatory mediators and movement of fluid and leukocytes from the blood into extravascular tissues. This response localizes and eliminates altered cells, foreign particles, microorganisms and antigens and paves the way for a return to normal structure and function.

The clinical signs of inflammation, called *phlogosis* by the Greek physician Galen, and *inflammation* in Latin, were described in classical times. In the first century AD, the Roman encyclopedist Aulus Celsus described the four cardinal signs of inflammation: **rubor** (redness), **calor** (heat), **tumor** (swelling) and **dolor** (pain). These features correspond to inflammatory events of vasodilation, edema and tissue damage. According to medieval concepts, inflammation was an imbalance of various "humors," including blood, mucus and bile. Modern understanding that inflammation had a vascular basis began in the 18th century with John Hunter, who noted blood vessel dilation and appreciated that pus was accumulated material derived from the blood. Rudolf Virchow first described inflammation as a reaction to prior tissue injury. To Celsus' four cardinal signs Virchow added a fifth: **functio laesa** (loss of function). His pupil Julius Cohnheim first associated inflammation with emigration of leukocytes through microvasculature walls. At the end of the 19th century, the role of phagocytosis in inflammation was emphasized by the eminent Russian zoologist Eli Metchnikoff. Finally, Thomas Lewis described the importance of chemical mediators in 1927, showing that histamine and other substances increased vascular permeability and caused leukocytes to migrate into extravascular spaces. More recent studies have elucidated the molecular and genetic bases of acute and chronic inflammation.

OVERVIEW OF INFLAMMATION

The primary function of the inflammatory response is to eliminate a pathogenic insult and remove injured tissue components, thus allowing tissue repair to take place. In teleologic terms, the body attempts to contain or eliminate offending agents to protect tissues, organs and, ultimately,

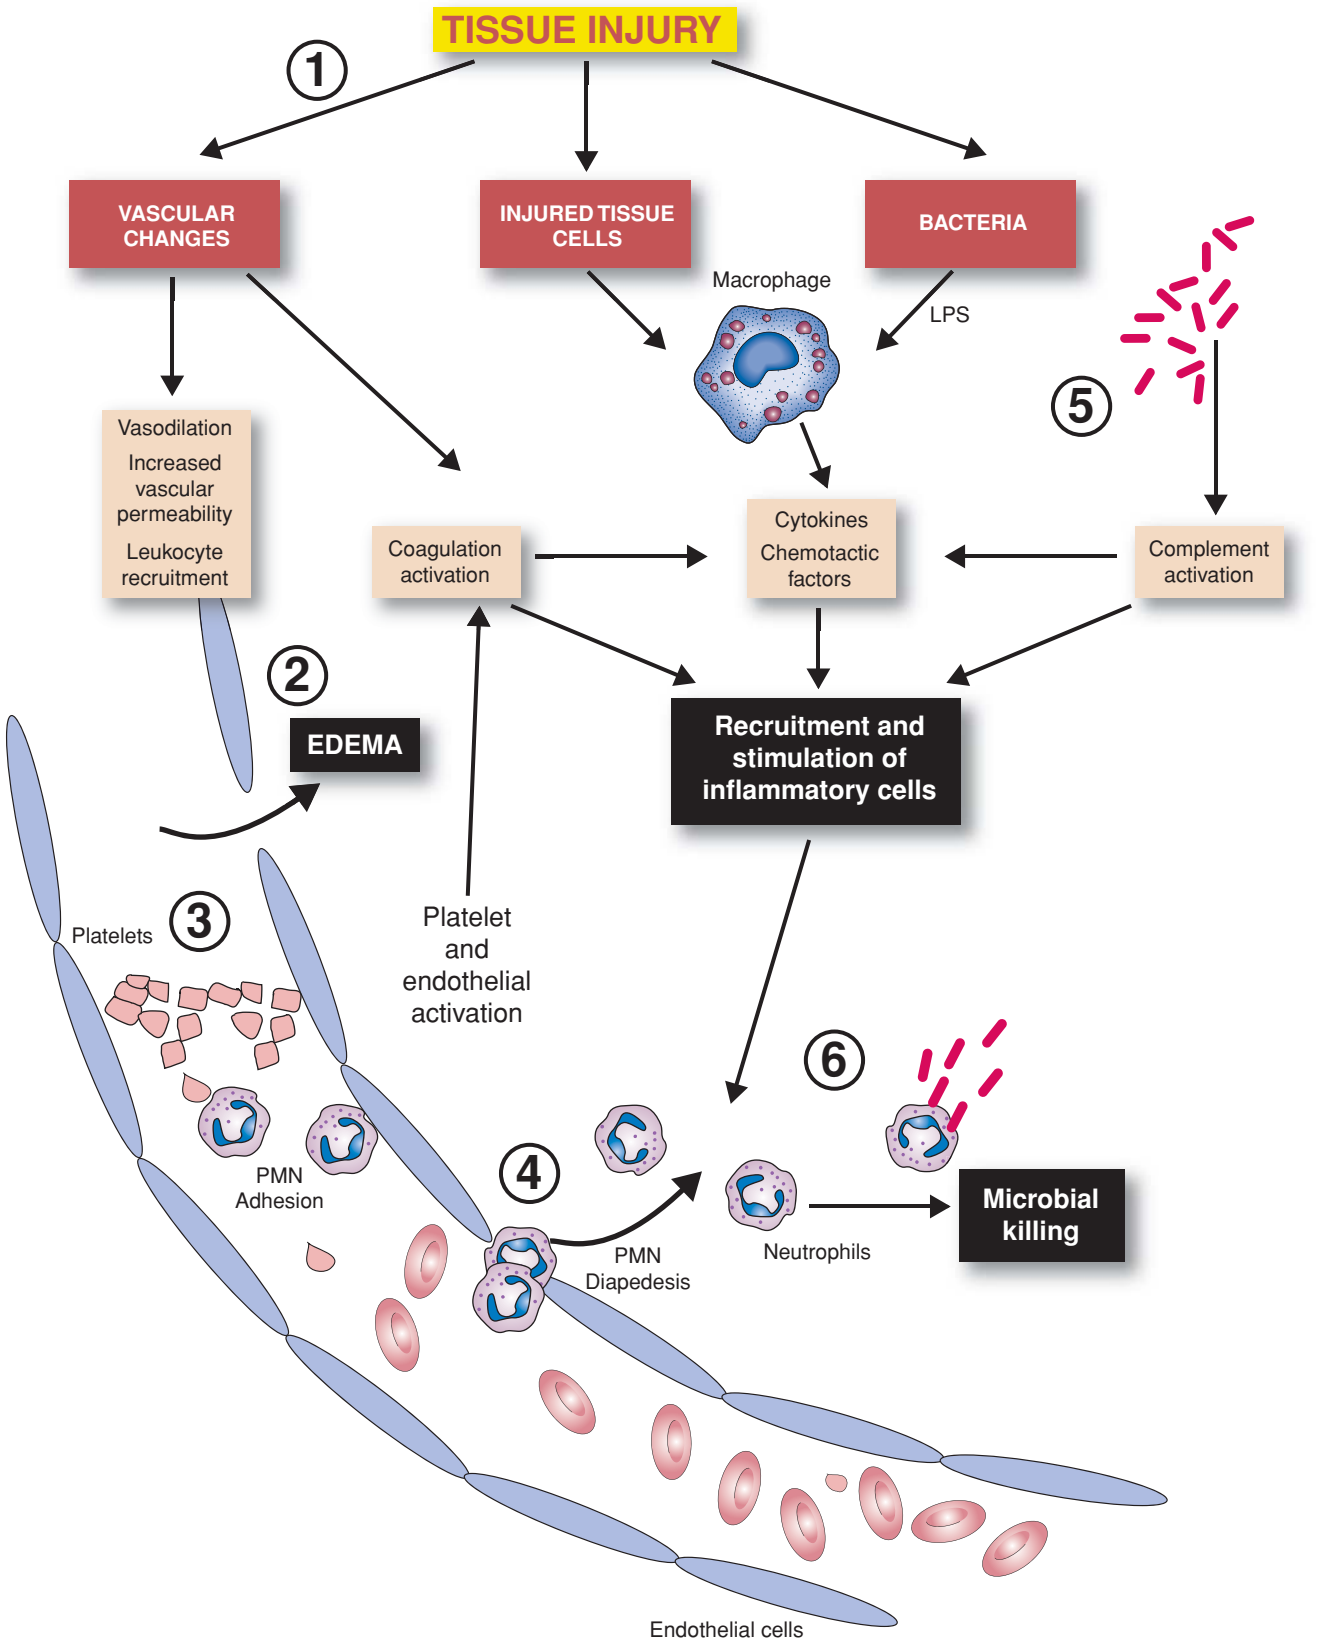

FIGURE 2-1. The inflammatory response to injury. 1. Tissue injury results in immediate and prolonged vascular changes. Chemical mediators and damaged tissue cells stimulate vasodilation and vascular injury, leading to **(2)** leakage of fluid into tissues (edema). **3.** Platelets are activated to initiate clot formation and hemostasis and to increase vascular permeability via histamine release. **4.** Vascular endothelial cells contribute to clot formation, anchor circulating neutrophils via their upregulated adhesion molecules and retract to allow increased vascular permeability to plasma and to inflammatory cells. At the same time, microbes (*red rods*) **(5)** initiate activation of the complement cascade, which, along with soluble mediators from macrophages, **(6)** recruits neutrophils to the site of tissue injury. Neutrophils and macrophages eliminate microbes and remove damaged tissue so that repair can begin. *PMN* = polymorphonuclear leukocyte.

the whole body from damage. Specific cells are imported to attack and destroy injurious agents (e.g., infectious organisms, toxins or foreign material), enzymatically digest and remove them, or wall them off. In the process, damaged cells and tissues are digested and removed to allow repair to occur. Responses to many damaging agents are immediate and stereotypic. The character of the inflammatory response is "modulated," depending on several factors, including the nature of the offending agent, duration of the insult, extent of tissue damage and microenvironment.

- **Initiation** of an inflammatory response results in activation of soluble mediators and recruitment of inflammatory cells to the area. Molecules released from the offending agent, damaged cells and extracellular matrix alter the permeability of nearby blood vessels to plasma, soluble molecules and circulating inflammatory cells. This stereotypic immediate response leads to rapid flooding of injured tissues with fluid, coagulation factors, cytokines, chemokines, platelets and inflammatory cells, neutrophils in particular (Figs. 2-1 and 2-2). This overall process is **acute inflammation.**
- **Amplification** depends on the extent of injury and activation of mediators such as kinins and complement components. Additional leukocytes and macrophages are recruited to the area.
- **Destruction** of the damaging agent brings the process under control. Enzymatic digestion and phagocytosis reduce or eliminate foreign material or infectious organisms. At the same time, damaged tissue components are also removed and debris is cleared, paving the way for repair to begin (see Chapter 3).
- **Termination** of the inflammatory response is mediated by intrinsic anti-inflammatory mechanisms that limit tissue damage and allow repair and a return to normal physiologic function. Alternatively, depending on the nature of the injury and specific inflammatory and repair responses, a scar may develop in place of normal tissue. Importantly, intrinsic mechanisms terminate the inflammatory process; prevent further influx of fluid, mediators and inflammatory cells; and prevent damage to normal cells and tissue.

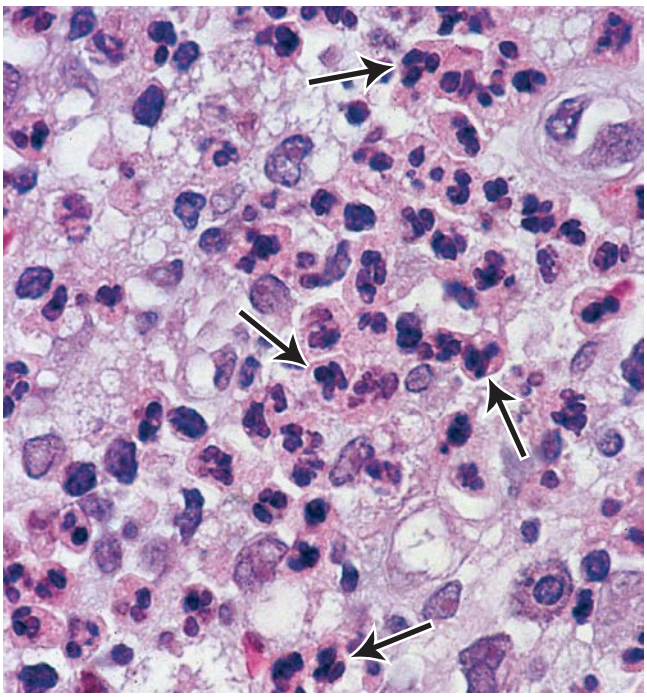

FIGURE 2-2. Acute inflammation. Densely packed polymorphonuclear leukocytes (PMNs) with multilobed nuclei (*arrows*).

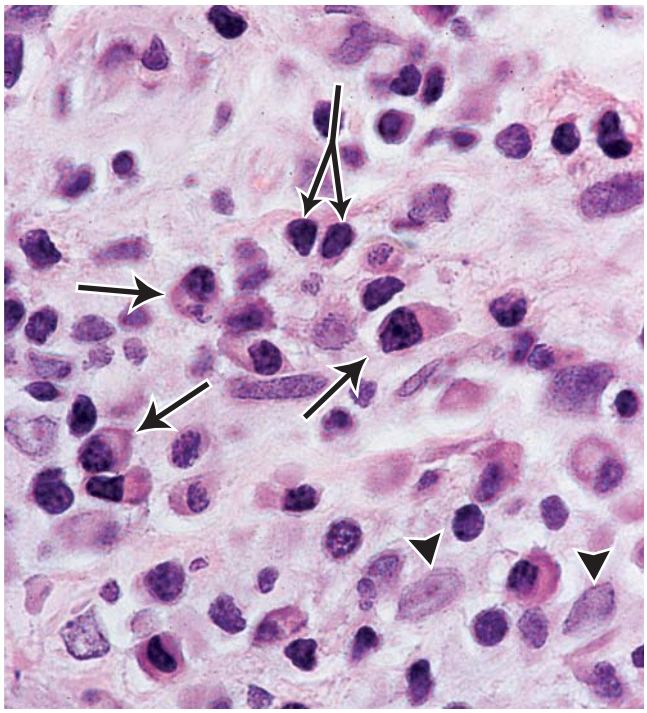

FIGURE 2-3. Chronic inflammation. Lymphocytes (*double-headed arrow*), plasma cells (*arrows*) and a few macrophages (*arrowheads*) are present.

Some types of injury trigger sustained immune and inflammatory responses if injured tissue and foreign agents are not cleared. Such persistent responses are called **chronic inflammation**. Chronic inflammatory infiltrates are largely lymphocytes, plasma cells and macrophages (Fig. 2-3). Acute and chronic inflammatory infiltrates often coexist.

Inflammation usually works to defend the body but may also be harmful. Acute inflammatory responses may be exaggerated or sustained, with or without clearance of the offending agent. Tissue damage may result; witness the ravages of bacterial pneumonia due to acute inflammation or joint destruction in septic arthritis. Chronic inflammation may also damage tissue and cause scarring and loss of function. Indeed, chronic inflammation is the basis for many degenerative diseases.

Weak inflammatory responses may lead to uncontrolled infection, as in immunocompromised hosts. In several congenital diseases, deficient inflammation is due to defects in inflammatory cell function or immunity.

ACUTE INFLAMMATION OFTEN BEGINS WITH TISSUE INJURY

Direct injury or stimulation of cellular or structural components of a tissue includes:

- Parenchymal cells
- Microvasculature

- Tissue macrophages and mast cells
- Mesenchymal cells (e.g., fibroblasts)
- Extracellular matrix (ECM)

A Sequence of Events Follows Initiation of Acute Inflammation

- ***As the immediate response to injury or insult, blood vessels rapidly and transiently constrict and then dilate.*** Under the influence of nitric oxide (NO), histamine and other soluble agents, vasodilation allows increased blood flow and expansion of the capillary bed.
- ***Increased vascular permeability allows fluid and plasma components to accumulate in affected tissues.*** Normally, the endothelium is a permeability barrier as fluid moves between intravascular and extravascular spaces. Endothelial cells are connected to each other by tight junctions and separated from the tissue by a limiting basement membrane (Fig. 2-4A). ***Disruption of this barrier function is a hallmark of acute inflammation.*** Shortly after tissue injury, specific inflammatory mediators are produced at the site of injury that directly increase permeability of capillaries and postcapillary venules. Vascular leakage reflects endothelial cell contraction, endothelial cell retraction and alterations in transcytosis. Endothelial cells are also damaged, either by direct injury to the cells or indirectly by leukocytes. Thus, there may be extensive loss of the permeability barrier, so that fluid and cells leak into the extravascular space, which is called **edema** (Fig. 2-4B, C).
- ***Soluble mediators stimulate intravascular platelets and inflammatory cells.*** These include kinins and complement. Components of the coagulation cascade are activated (Figs. 2-1 and 2-5), causing more vascular permeability and edema.
- ***Neutrophils are recruited to the injured site.*** All these vascular changes, vasodilation and edema increase the concentration of red blood cells and leukocytes within the capillary network. Chemotactic factors then recruit leukocytes, especially neutrophils, from the vascular

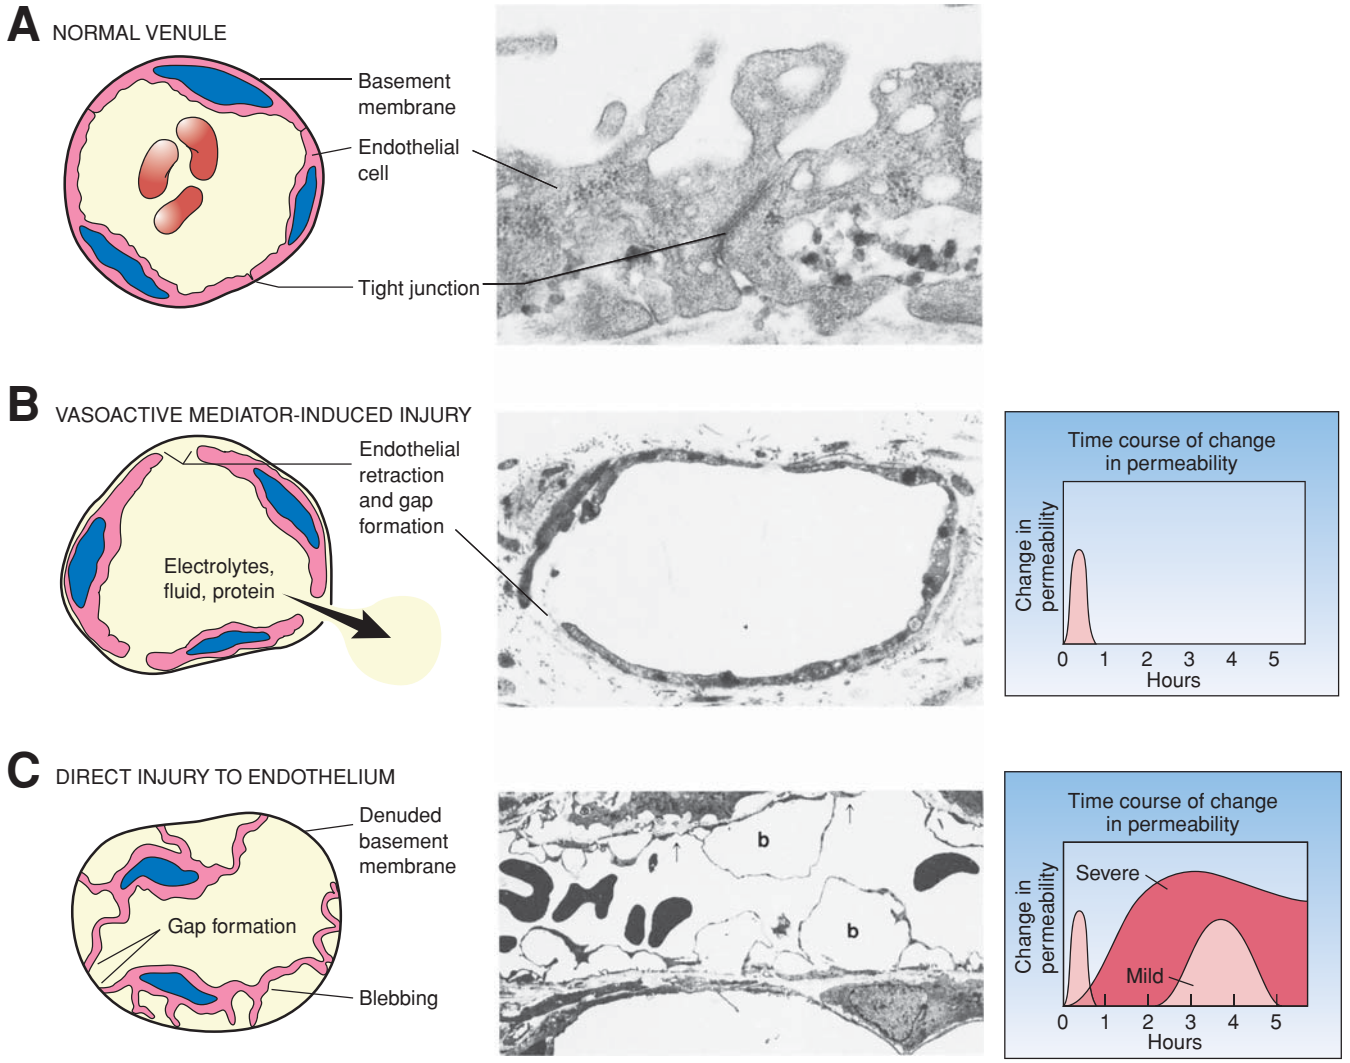

FIGURE 2-4. Responses of the microvasculature to injury. A. The wall of the normal venule is sealed by tight junctions between adjacent endothelial cells. **B.** During mild vasoactive mediator-induced injury, the endothelial cells separate and permit the passage of the fluid constituents of the blood. **C.** With severe direct injury, the endothelial cells form blebs (*b*) and separate from the underlying basement membrane. Areas of denuded basement membrane (*arrows*) allow a prolonged escape of fluid elements from the microvasculature.

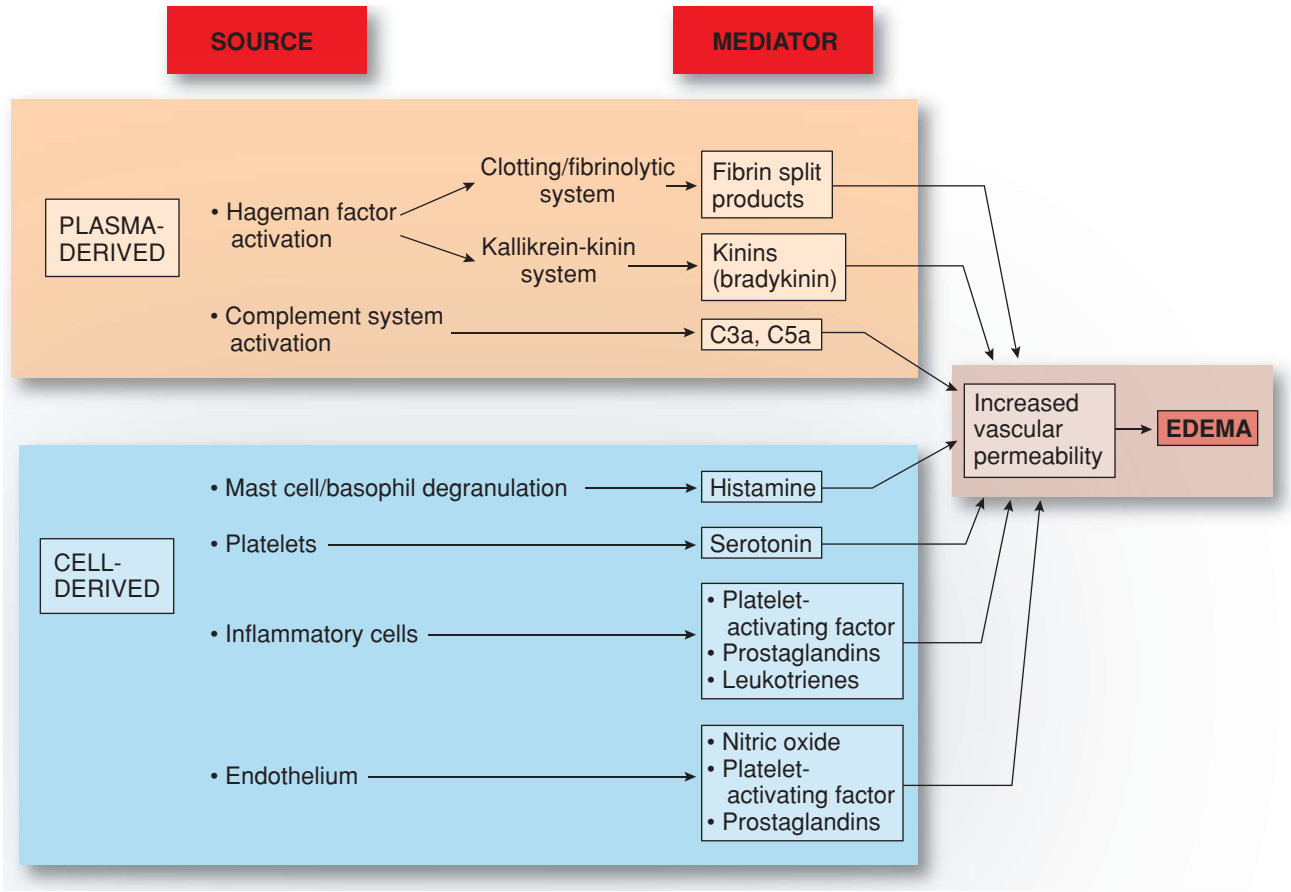

FIGURE 2-5. Inflammatory mediators of increased vascular permeability. Plasma and cell-derived products generate potent vasoactive mediators.

compartment into the injured tissue (Figs. 2-1 and 2-2). Once in tissues, these leukocytes start attacking offending agents so damaged components can be removed and tissue repair can commence. These cells secrete additional mediators, which either enhance or inhibit the inflammatory response.

Intravascular and Tissue Fluid Levels Are Regulated by a Balance of Forces

Normally, there is continual movement of fluid from the intravascular compartment to the extravascular space. Fluid in the extravascular space is cleared via lymphatics and returned to the circulation. Regulation of fluid transport across vascular walls is described in part by the **Starling principle**. According to this law, fluid interchange between vascular and extravascular compartments reflects a balance of forces that draw fluid into vascular spaces or out into tissues (see Chapter 7). These forces include:

- **Hydrostatic pressure** from blood flow and plasma volume. Increased hydrostatic pressure forces fluid out of the vasculature.
- **Oncotic pressure,** due to plasma proteins, draws fluid into vessels.
- **Osmotic pressure** reflects relative amounts of sodium and water in vascular and tissue spaces.
- **Lymph flow,** the passage of fluid through lymphatics, continuously drains fluid out of tissues and into lymphatic spaces.

Noninflammatory Edema

If the balance of forces controlling fluid transport is altered, flow into the extravascular compartment or clearance through lymphatics is disrupted. The net result is fluid accumulation in interstitial spaces **(edema)**. This excess fluid expands spaces between cells and the extracellular matrix and causes tissue swelling. Many clinical conditions, whether systemic or organ specific, lead to edema. For example, obstruction of venous outflow **(thrombosis)** or decreased right ventricular function (congestive heart failure) causes back-pressure in the vasculature, thus increasing hydrostatic pressure (see Chapter 7). Loss of albumin (kidney disorders) or decreased synthesis of plasma proteins (liver disease, malnutrition) reduces plasma oncotic pressure. Any abnormality of sodium or water retention alters osmotic pressure and the balance of fluid forces. Finally, **lymphedema** may result from obstruction to lymphatic flow, most often due to surgical removal of lymph nodes, radiation or obstruction by tumor.

Inflammatory Edema

Among the earliest responses to tissue injury are changes in microvasculature anatomy and function, which may allow fluid to accumulate in tissues (Figs. 2-4 and 2-5). These changes are characteristic of the classic "triple response" first described by Sir Thomas Lewis in 1924. In the original experiments, a dull red line developed at the site of mild trauma to skin, followed by a **flare** (red halo) and then a **wheal** (swelling). Lewis postulated that a vasoactive

mediator caused vasodilation and increased vascular permeability at the site of injury. The triple response can be explained as follows:

1. **Transient vasoconstriction of arterioles** at a site of insult is the earliest vascular response to mild skin injury. This process is caused by neurogenic and chemical mediator systems and usually resolves within seconds to minutes.
2. **Vasodilation of precapillary arterioles** then increases blood flow to the tissue, or **hyperemia**. This is caused by release of specific mediators and is responsible for redness and warmth at sites of tissue injury.
3. **An increase in endothelial cell barrier permeability** results in edema. Fluid passes from intravascular compartments as blood passes through capillaries and venules to produce local stasis and plugging of dilated small vessels with erythrocytes. These changes are reversible after mild injury; within several minutes to hours, extravascular fluid is cleared via lymphatics.

The vascular response to injury is a dynamic event with sequential physiologic and pathologic changes. **Vasoactive mediators,** originating from plasma and cells, are generated at sites of tissue injury (Fig. 2-5). These molecules bind specific receptors on vascular endothelial and smooth muscle cells, causing vasoconstriction or vasodilation. Vasodilation of arterioles increases blood flow and exacerbates fluid leakage into the tissue. Vasoconstriction of postcapillary venules increases capillary bed hydrostatic pressure, further stimulating edema formation. By contrast, vasodilation of venules decreases capillary hydrostatic pressure and acts in the opposite direction.

After injury, vasoactive mediators bind specific receptors on endothelial cells, causing reversible endothelial cell contraction and gap formation (Fig. 2-4B). This break in the endothelial barrier gives rise to extravasation (leakage) of intravascular fluids into the extravascular space. Mild direct endothelial injury causes a biphasic response: an early change in permeability within 30 minutes of injury, followed by a second increase in vascular permeability after 3–5 hours. With severe damage, fluid progressively moves into the extravascular compartment, peaking 3–4 hours after injury.

Severe direct injury to the endothelium, such as is caused by burns or caustic chemicals, may produce irreversible damage. In such cases, the vascular endothelium separates from the basement membrane, promoting cell blebbing (blisters or bubbles between the endothelium and basement membrane). This leaves areas of basement membrane naked (Fig. 2-4C), disrupting the barrier between intravascular and extravascular spaces.

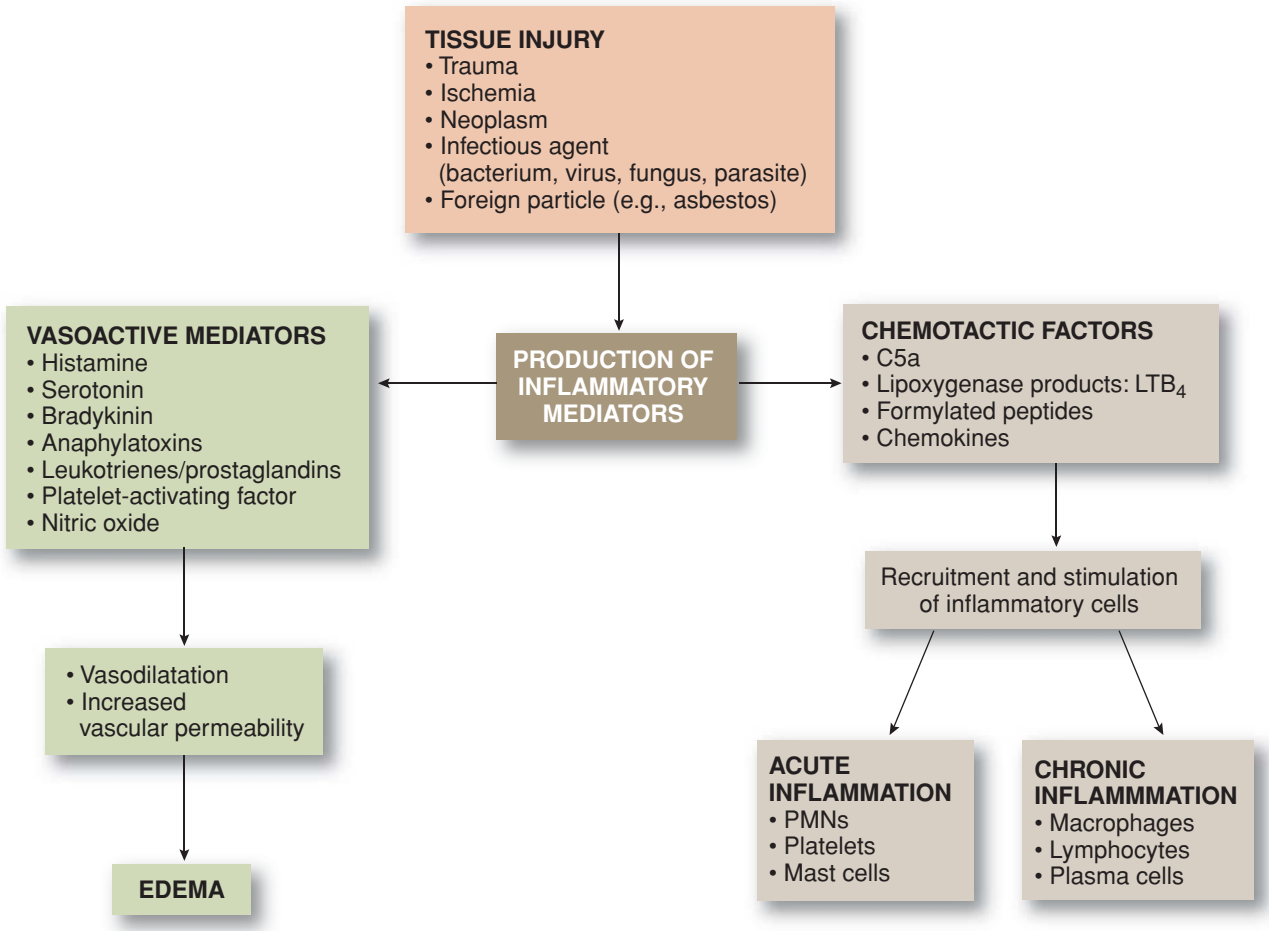

FIGURE 2-6. Mediators of the inflammatory response. Tissue injury stimulates the production of inflammatory mediators in plasma and released into the circulation. Additional factors are generated by tissue cells and inflammatory cells. These vasoactive and chemotactic mediators promote edema and recruit inflammatory cells to the site of injury. *PMNs* = polymorphonuclear leukocytes.

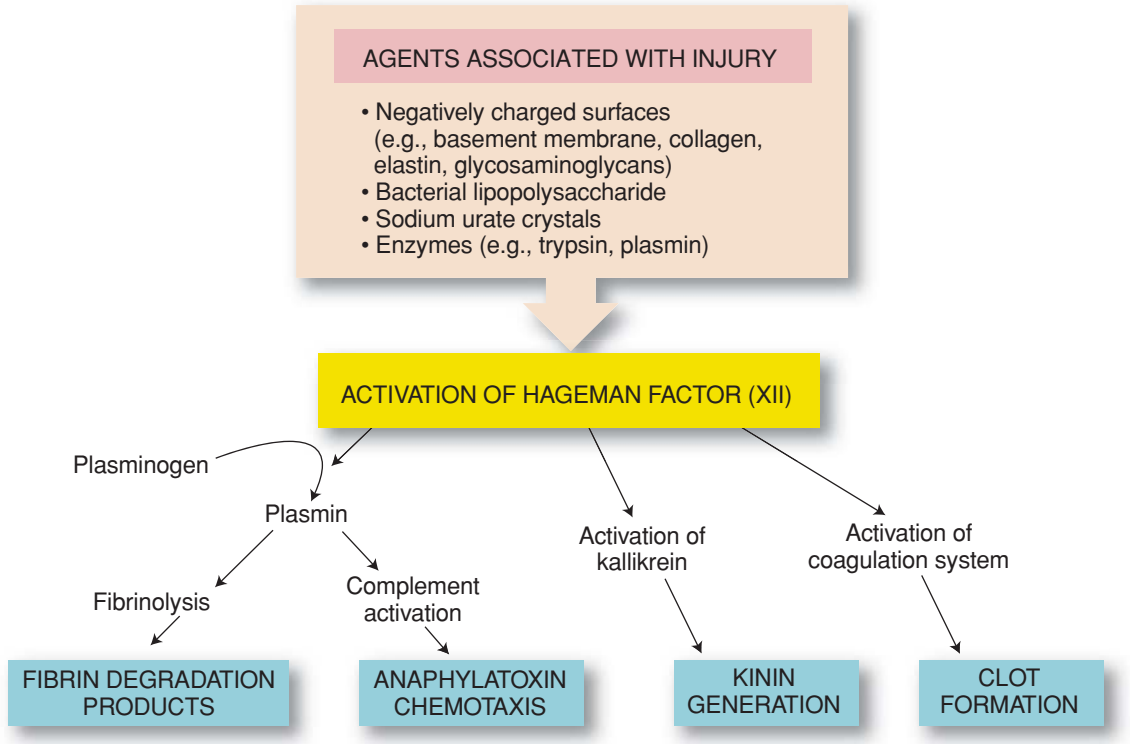

FIGURE 2-7. Hageman factor activation and inflammatory mediator production. Hageman factor activation is a key event leading to conversion of plasminogen to plasmin, resulting in generation of fibrin split products and active complement products. Activation of kallikrein produces kinins and activation of the coagulation system results in clot formation.

Several definitions help in the understanding of the consequences of inflammation:

- **Edema** is accumulation of fluid in the extravascular space and interstitial tissues.
- An **effusion** is excess fluid in body cavities (e.g., peritoneum or pleura).
- A **transudate** is edema fluid with a low protein content (specific gravity <1.015).
- An **exudate** is edema fluid with a high protein concentration (specific gravity >1.015), which frequently contains inflammatory cells. Exudates are seen early in acute inflammation and are produced by mild injuries, such as sunburn or traumatic blisters.
- A **serous exudate,** or **effusion,** is characterized by the absence of a prominent cellular response and has a yellow, straw-like color.
- **Serosanguineous** refers to a serous exudate, or effusion, that contains red blood cells and has a reddish tinge.
- A **fibrinous exudate** has large amounts of fibrin, due to activation of the coagulation system. When a fibrinous exudate occurs on a serosal surface, such as the pleura or pericardium, it is termed "fibrinous pleuritis" or "fibrinous pericarditis."
- **A purulent exudate or effusion** contains prominent cellular components. Purulent exudates and effusions are often associated with pathologic conditions, such as pyogenic bacterial infections, in which polymorphonuclear neutrophils (PMNs) predominate.
- In **suppurative inflammation,** a purulent exudate is accompanied by significant liquefactive necrosis; **it is the equivalent of pus.**

PLASMA-DERIVED MEDIATORS OF INFLAMMATION

Many chemical mediators help to trigger, amplify and terminate inflammatory processes (Fig. 2-6). Cell- and plasma-derived mediators work in concert to activate cells by binding specific receptors, activating cells, recruiting cells to sites of injury and stimulating release of additional soluble mediators. These mediators themselves are short-lived or are inhibited by intrinsic mechanisms, effectively turning off the response and allowing the process to resolve. Thus, these are important "on" and "off" control mechanisms of inflammation. Cell-derived mediators are considered below.

Plasma contains the elements of three major enzyme cascades, each composed of a series of proteases. Sequential activation of proteases results in release of important chemical mediators. These interrelated systems include (1) the **coagulation cascade,** (2) **kinins** and (3) the **complement system** (Fig. 2-7). The coagulation cascade is discussed in Chapters 16 and 26; the kinin and complement systems are presented here.

Hageman Factor Is a Key Initiator of Vasoactive Responses

Hageman factor (clotting factor XII), generated within the plasma, is activated by exposure to negatively charged surfaces, such as basement membranes, proteolytic enzymes, bacterial lipopolysaccharides and foreign materials. It

triggers activation of additional plasma proteases (Fig. 2-7), leading to:

- **Conversion of plasminogen to plasmin:** Plasmin generated by activated Hageman factor induces clot dissolution (fibrinolysis). Products of fibrin degradation (fibrin split products) increase vascular permeability in the skin and lung. Plasmin also cleaves complement components, generating biologically active products, including anaphylatoxins, C3a and C5a.
- **Conversion of prekallikrein to kallikrein:** Plasma kallikrein, also generated by activated factor XII, cleaves high–molecular-weight kininogen to produce several vasoactive low–molecular-weight peptides, collectively called **kinins**.
- **Activation of the alternative complement pathway.**
- **Activation of the coagulation system** (see Chapters 16 and 26).

Kinins Amplify the Inflammatory Response

Kinins are potent inflammatory agents formed in plasma and tissue by the action of serine protease kallikreins on specific plasma glycoproteins, called **kininogens**. Bradykinin and related peptides regulate multiple physiologic processes, including blood pressure, contraction and relaxation of smooth muscle, plasma extravasation, cell migration, inflammatory cell activation and inflammatory-mediated pain responses. The immediate effects of kinins are mediated by B_1 and B_2 receptors. The former are induced by inflammatory mediators and selectively activated by bradykinin metabolites. B_2 receptors are expressed constitutively and widely.

Kinins act quickly and then are rapidly inactivated by kininases. Perhaps the most significant function of kinins is their ability to amplify inflammatory responses by stimulating local tissue cells and inflammatory cells to generate additional mediators, such as prostanoids, cytokines (e.g., tumor necrosis factor-α [TNF-α] and interleukins), NO and tachykinins.

Complement Is Activated through Three Pathways to Form the Membrane Attack Complex

The complement system is a group of proteins found in plasma and on cell surfaces. Its main function is defense against microbes. First identified as a heat-labile serum factor that kills bacteria and "complements" antibodies, the complement system has over 30 proteins, including plasma enzymes, regulatory proteins and cell lysis proteins. They are mainly made in the liver and are activated in sequence.

Physiologic activities of the complement system include (1) defense against pyogenic bacterial infection by opsonization, chemotaxis, activation of leukocytes and lysis of bacteria and cells; (2) bridging innate and adaptive immunity to defend against microbial agents by augmenting antibody responses and enhancing immune memory; and (3) disposal of immune products and products of inflammatory injury by clearing immune complexes from tissues and removing apoptotic cells. Certain complement components, **anaphylatoxins,** are vasoactive mediators. Others fix opsonins to cell surfaces. Still others lyse cells by generating a lytic complex, C5b-9 **(membrane attack complex [MAC])**. Proteins that activate complement are themselves activated by 3 convergent routes: the **classical, mannose-binding lectin (MBL)** and **alternative** pathways.

The Classical Complement Pathway

Activators of the classical pathway include antigen–antibody (Ag–Ab) complexes, products of bacteria and viruses, proteases, urate crystals, apoptotic cells and polyanions (polynucleotides). This pathway includes C1 through C9, the nomenclature following historical order of discovery. Ag–Ab complexes activate C1, triggering a cascade that leads to formation of the MAC and proceeding as follows (Fig. 2-8):

1. **Antibodies bound to antigens on bacterial cell surfaces bind the C1 complex.** The C1 complex consists of C1q, 2 molecules of C1r and 2 molecules of C1s. Antibodies in immune complexes bind C1q, eliciting activation of C1r and C1s.

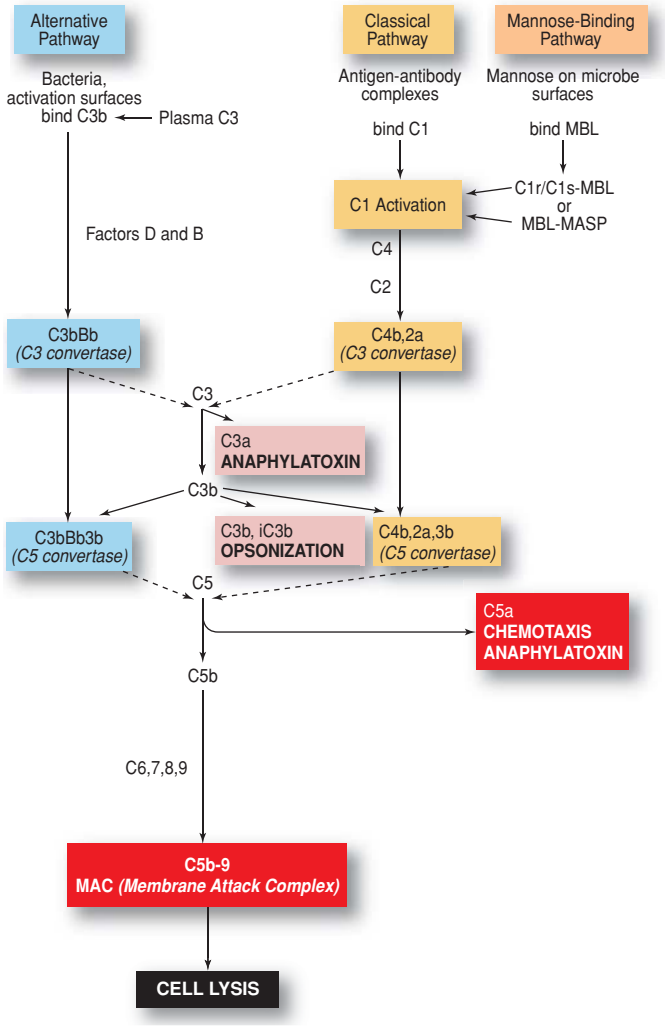

FIGURE 2-8. Complement activation. The alternative, classical and mannose-binding pathways lead to generation of the complement cascade of inflammatory mediators and to cell lysis by the membrane attack complex (MAC). *MBL* = mannose-binding lectin; *MBL-MASP* = *M*BL-*a*ssociated *s*erine *p*rotease.

2. **C1s cleaves C4, which binds the bacterial surface, then cleaves C2.** Resulting split molecules form the C4b2a enzyme complex, also called **C3 convertase,** which remains covalently bound to the bacterial surface. This effect anchors the complement system at specific tissue sites. If a covalent bond is not formed, the complex is inactivated, thus aborting the cascade in normal host cells or tissues.
3. **C3 convertase cleaves C3 into C3a and C3b.** This is a critical step. C3a is released as an **anaphylatoxin**. C3b reacts with cell proteins to localize, or "fix," on the cell surface. C3b and its degradation products, especially iC3b, on the surface of pathogens, enhance phagocytosis. This process of coating a pathogen with a molecule that enhances phagocytosis is called **opsonization,** and the molecule that does this is an **opsonin**.
4. **The complex of C4b, C2a and C3b (termed C5 convertase) cleaves C5 into C5a and C5b.** C5a also is an anaphylatoxin, and C5b acts as the nidus for subsequent sequential binding of C6, C7 and C8 to form the MAC.
5. **The MAC assembles on target cells.** The MAC directly inserts into the plasma membrane by hydrophobic binding of C7 to the lipid bilayer. The resulting cylindrical transmembrane channel disrupts the barrier function of the plasma membrane and leads to cell lysis.

The Mannose-Binding Pathway

The mannose- or lectin-binding pathway shares some elements with the classical pathway. It begins when microbes with terminal mannose groups bind MBL, one of the family of calcium-dependent lectins, or **collectins**. This multifunctional acute phase protein resembles immunoglobulin M (IgM) (it binds many oligosaccharide structures), IgG (it interacts with phagocytic receptors) and C1q. This last property enables it to interact with C1r-C1s or with a serine protease called MASP (*M*BL-*a*ssociated *s*erine *p*rotease) to activate complement (Fig. 2-8):

1. **MBL interacts with C1r and C1s to elicit C1 esterase activity.** Alternatively and preferentially, MBL forms a complex with a precursor of the serine protease, MASP. MBL and MASP bind to mannose groups on glycoproteins or carbohydrates on bacterial cell surfaces. After MBL binds a substrate, the MASP proenzyme is cleaved into two chains and expresses a C1-esterase activity.
2. **C1-esterase activity, either from C1r/C1s–MBL interaction or MBL–MASP, cleaves C4 and C2, leading to assembly of the classical pathway C3 convertase.** The complement cascade then continues as described for the classical pathway.

The Alternative Pathway

This pathway is initiated by derivative products of microorganisms, like endotoxin (from bacterial cell surfaces), zymosan (yeast cell walls), polysaccharides, cobra venom factor, viruses, tumor cells and foreign materials. Alternative pathway members are "factors," followed by a letter. Activation of this pathway proceeds as follows (Fig. 2-8):

1. **A small amount of C3 in plasma cleaves to C3a and C3b.** This C3b is covalently bound to carbohydrates and proteins on microbial cell surfaces. It binds factor B and factor D to form the alternative pathway C3 convertase, C3bBb. This C3 convertase is stabilized by **properdin**.
2. **C3 convertase generates additional C3b and C3a.** Binding of a second C3b molecule to C3 convertase converts it to a C5 convertase, C3bBb3b.
3. **As in the classical pathway, cleavage of C5 by C5 convertase generates C5b and C5a and leads to assembly of the MAC.**

The Complement System Is Tightly Regulated to Generate Proinflammatory Molecules

Biological Activities of Complement Components

The endpoint of complement activation is MAC formation and cell lysis. Cleavage products generated at each step both catalyze the next step in the cascade and have supporting roles as important inflammatory molecules (Fig. 2-9):

- **Anaphylatoxins** (C3a, C4a, C5a): These proinflammatory molecules mediate smooth muscle contraction and increase vascular permeability.
- **Opsonins** (C3b, iC3b): In bacterial opsonization, a specific molecule (e.g., IgG or C3b) binds the surface of a bacterium. The process enhances phagocytosis by allowing receptors on phagocytic cell membranes (e.g., Fc receptor or C3b receptor) to recognize and bind the opsonized bacterium. Viruses, parasites and transformed cells also activate complement similarly, which leads to their inactivation or death.
- **Proinflammatory molecules** (MAC, C5a): These chemotactic factors also activate leukocytes and tissue cells to generate oxidants and cytokines and induce mast cell and basophil degranulation.
- **Lysis** (MAC): C5b binds C6 and C7, and subsequently C8 to the target cell; C9 polymerization is catalyzed to lyse the cell membrane.

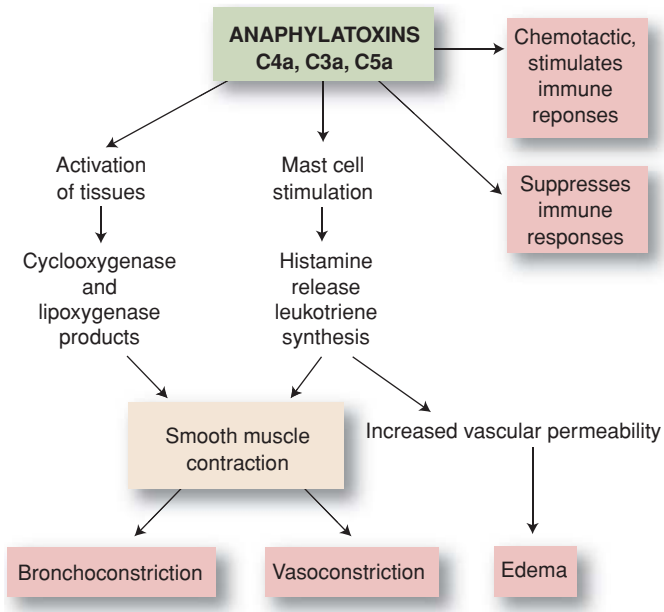

FIGURE 2-9. Biological activity of the anaphylatoxins. Complement activation products, generated during activation of the complement cascade, regulate vascular permeability, cell recruitment and smooth muscle contraction.

Regulation of the Complement System

Proteins in serum and on cell surfaces protect the host from indiscriminate injury by regulating complement activation. Four major mechanisms mediate this effect:

- **Spontaneous decay:** C4b2a and C3bBb and their cleavage products, C3b and C4b, decrease by decay.
- **Proteolytic inactivation:** Plasma inhibitors include factor I (an inhibitor of C3b and C4b) and serum carboxypeptidase N (SCPN). SCPN removes a carboxy-terminal arginine from anaphylatoxins C4a, C3a and C5a. Deleting this single amino acid markedly decreases their biological activities.
- **Binding active components:** C1 esterase inhibitor (C1 INA) binds C1r and C1s to form an irreversibly inactive complex. Other binding proteins in the plasma include factor H– and C4b-binding protein. These complex with C3b and C4b, respectively, increasing their susceptibility to proteolytic cleavage by factor I.
- **Cell membrane–associated molecules:** Two proteins linked to the cell membrane by glycophosphoinositol (GPI) anchors are decay-accelerating factor (DAF) and protectin (CD59). DAF breaks down the alternative pathway C3 convertase; CD59 (membrane cofactor protein, protectin) binds membrane-associated C4b and C3b, promotes its inactivation by factor I and prevents formation of the MAC.

The Complement System Is Finely Focused to Target Microorganisms and Avoid Normal Cells and Tissues

When the mechanisms regulating this balance malfunction or are deficient because of mutation, resulting imbalances in complement activity can cause tissue injury. Uncontrolled systemic activation of complement may occur in sepsis (see Chapter 19), playing a central role in the development of septic shock.

Immune Complexes

Immune complexes (Ag–Ab complexes) form on bacterial surfaces and associate with C1q, activating the classical pathway. Complement then promotes physiologic clearance of circulating immune complexes. However, if these complexes are made continuously and in excess (e.g., in chronic immune responses), relentless activation consumes, and therefore depletes, complement. Complement inefficiency, whether due to complement depletion, deficient complement binding or defects in complement activation, results in immune deposition and inflammation, which in turn may trigger autoimmunity.

Infectious Disease

Defense against infection is a key role of complement. If the system functions poorly, the person is overly susceptible to infection.

- Defects in antibody production, complement proteins or phagocyte function increase susceptibility to pyogenic infections with organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*.
- Deficiencies in MAC formation lead to increased infections, particularly with meningococci.
- Deficiency of complement MBL results in recurrent infections in young children.

Thick capsules may protect some bacteria from lysis by complement. Some bacterial enzymes can also inhibit the effects of complement components, especially C5a. Or, they can also increase catabolism of components, such as C3b, thus reducing formation of C3 convertase. Viruses, on the other hand, may use cell-bound components and receptors to facilitate cell entry. *Mycobacterium tuberculosis*, Epstein-Barr virus, measles virus, picornaviruses, HIV and flaviviruses use complement components to target inflammatory or epithelial cells.

Inflammation and Necrosis

The complement system amplifies the inflammatory response. Anaphylatoxins C5a and C3a activate leukocytes, and C5a and MAC stimulate endothelial cells, thus inducing excess generation of oxidants and cytokines that injure tissues (see Chapter 1). Nonviable or damaged tissues cannot regulate complement normally.

Complement Deficiencies

The importance of an intact and appropriately regulated complement system is exemplified in people with acquired or congenital deficiencies of specific complement components or regulatory proteins (Table 2-1). The most common congenital defect is a C2 deficiency, inherited as an autosomal codominant trait.

Acquired deficiencies of early complement components occur in patients with some autoimmune diseases, especially those associated with circulating immune complexes. These include certain forms of membranous glomerulonephritis and systemic lupus erythematosus (SLE). Deficiencies in early components of complement (e.g., C1q, C1r, C1s, C4) are strongly associated with susceptibility to SLE.

Patients lacking the middle (C3, C5) components are prone to recurrent pyogenic infections, membranoproliferative

TABLE 2-1
HEREDITARY COMPLEMENT DEFICIENCIES

Complement Deficiency	Clinical Association
C3b, iC3b, C5, MBL	Pyogenic bacterial infections Membranoproliferative glomerulonephritis
C3, properdin, MAC proteins	Neisserial infection
C1 inhibitor	Hereditary angioedema
CD59	Hemolysis, thrombosis
C1q, C1r and C1s, C4, C2	Systemic lupus erythematosus
Factor H and factor I	Hemolytic–uremic syndrome Membranoproliferative glomerulonephritis

MAC = membrane attack complex; MBL = mannose-binding lectin.

glomerulonephritis and rashes. Those who lack terminal complement components (C6, C7 or C8) are vulnerable to infections with *Neisseria* species. Such differences in susceptibility underscore the roles of individual complement components in protecting from specific bacteria. Congenital defects in proteins that regulate the complement system (e.g., C1 inhibitor, SCPN) lead to chronic complement activation. Lack of C1 inhibitor is associated with hereditary angioedema.

CELL-DERIVED INFLAMMATORY MEDIATORS

Platelets, basophils, PMNs, endothelial cells, monocyte/macrophages, tissue mast cells and the injured tissue itself may all potentially generate vasoactive and inflammatory mediators. These molecules are (1) derived from metabolism of phospholipids and arachidonic acid (e.g., prostaglandins, thromboxanes, leukotrienes, lipoxins, platelet-activating factor [PAF]), (2) preformed and stored in cytoplasmic granules (e.g., histamine, serotonin, lysosomal hydrolases) or (3) derived from altered production of normal regulators of vascular function (e.g., nitric oxide and neurokinins).

Arachidonic Acid and Platelet-Activating Factor Are Derived from Membrane Phospholipids

Phospholipids and fatty acid derivatives released from plasma membranes are metabolized into mediators and homeostatic regulators by inflammatory cells and injured tissues (Fig. 2-10). As part of a complex regulatory network, prostanoids, leukotrienes and lipoxins, which are derivatives of arachidonic acid, both promote and inhibit inflammation (Table 2-2). The net impact depends on several factors, including levels and profiles of prostanoid production, both of which change during an inflammatory response.

Arachidonic Acid

Depending on the specific inflammatory cell and nature of the stimulus, activated cells generate arachidonic acid by one of two routes (Fig. 2-10). In one pathway, arachidonic acid is liberated from the glycerol of cell membrane phospholipids

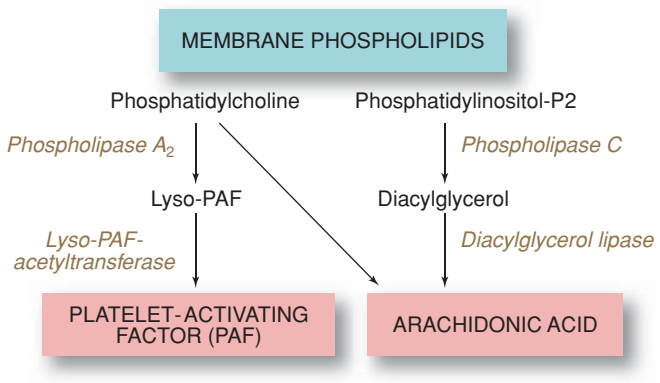

FIGURE 2-10. Cell membrane–derived mediators. Platelet-activating factor (PAF) is derived from choline-containing glycerophospholipids in the membrane. Arachidonic acid derives from phosphatidylinositol phosphates and from phosphatidyl choline.

TABLE 2-2
BIOLOGICAL ACTIVITIES OF ARACHIDONIC ACID METABOLITES

Metabolite	Biological Activity
PGE_2, PDG_2	Induce vasodilation, bronchodilation; inhibit inflammatory cell function
PGI_2	Induces vasodilation, bronchodilation; inhibits inflammatory cell function
$PGF_{2\alpha}$	Induces vasodilation, bronchoconstriction
TXA_2	Induces vasoconstriction, bronchoconstriction; enhances inflammatory cell functions (esp. platelets)
LTB_4	Chemotactic for phagocytic cells; stimulates phagocytic cell adherence; enhances microvascular permeability
LTC_4, LTD_4, LTE_4	Induce smooth muscle contraction; constrict pulmonary airways; increase microvascular permeability

PG . . . = prostaglandin; LT . . . = leukotriene; TXA_2 = thromboxane A_2.

(in particular, phosphatidylcholine) by stimulus-induced activation of phospholipase A_2 (PLA_2). The pathway is phospholipase C cleavage of phosphatidylinositol phosphates to diacylglycerol and inositol phosphates. Diacylglycerol lipase then cleaves arachidonic acid from diacylglycerol. This arachidonic acid is further metabolized by either (1) **cyclooxygenation,** to produce prostaglandins and thromboxanes, or (2) **lipoxygenation,** to leukotrienes and lipoxins (Fig. 2-11).

Corticosteroids are widely used to suppress tissue destruction associated with many inflammatory diseases, including allergic responses, rheumatoid arthritis and SLE. They induce synthesis of an inhibitor of PLA_2 and block arachidonic acid release by inflammatory cells. However, prolonged corticosteroid use can be quite harmful and lead to increased risk of infection and damage to connective tissue.

Platelet-Activating Factor

PAF is another potent inflammatory mediator derived from membrane phospholipids. It is synthesized by virtually all activated inflammatory cells, endothelial cells and injured tissue cells. During inflammatory and allergic responses, PAF is derived from choline-containing glycerophospholipids in the cell membrane, initially by the catalytic action of PLA_2, followed by acetylation by an acetyltransferase (Fig. 2-10). In plasma, PAF-acetylhydrolase regulates PAF activity.

PAF has many functions. It stimulates platelets, monocyte/macrophages, neutrophils, endothelial cells and vascular smooth muscle cells. It also induces platelet aggregation and degranulation at sites of tissue injury and enhances release of serotonin, thereby altering vascular permeability. Since PAF primes leukocytes, it promotes functional responses (e.g., O_2 production, degranulation) to a second stimulus and induces adhesion molecule expression, specifically of integrins. It is also a very potent vasodilator, augmenting permeability of microvasculature at sites of tissue

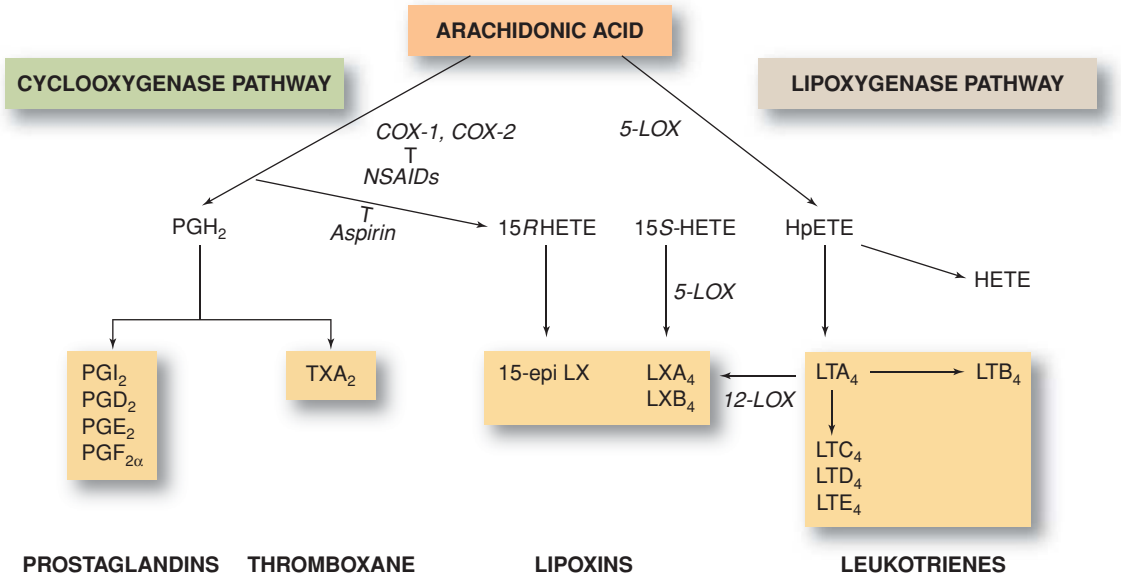

FIGURE 2-11. Biologically active arachidonic acid metabolites. The cyclooxygenase (COX) pathway of arachidonic acid metabolism generates prostaglandins (PG…) and thromboxane (TXA_2). The lipoxygenase (LOX) pathway forms lipoxins (LX…) and leukotrienes (LT…). Aspirin (acetylsalicylic acid) blocks the formation of 5-HETE (*HETE* = hydroxyicosatetraenoic acid). NSAIDs (nonsteroidal anti-inflammatory drugs) block COX-1 and COX-2. *HpETE* = 5-hydroperoxyeicosatetraenoic acid.

injury. PAF generated by endothelial cells cooperates with P-selectin. When P-selectin lightly tethers a leukocyte to an endothelial cell, PAF from the endothelial cell binds its receptor on the leukocyte and induces intracellular signaling.

Prostanoids, Leukotrienes and Lipoxins Are Biologically Active Metabolites of Arachidonic Acid

Prostanoids

Arachidonic acid is further metabolized by cyclooxygenases 1 and 2 (COX-1, COX-2) to generate prostanoids (Fig. 2-11). **COX-1** is constitutively expressed by most cells and increases upon cell activation. It is a key enzyme in the synthesis of prostaglandins, which in turn (1) protect the gut mucosa, (2) regulate water/electrolyte balance, (3) stimulate platelet aggregation to maintain normal hemostasis and (4) maintain resistance to thrombosis on vascular endothelial cell surfaces. **COX-2** expression is generally low or undetectable but increases substantially upon stimulation to yield metabolites that are important in inducing pain and inflammation.

The early inflammatory prostanoid response is COX-1 dependent. As inflammation proceeds, COX-2 takes over as the major source of prostanoids. Both COX isoforms generate prostaglandin H_2 (PGH_2), which is the substrate for production of prostacyclin (PGI_2), PGD_2, PGE_2, $PGF_{2\alpha}$ and TXA_2 (thromboxane). The quantity and variety of prostaglandins produced during inflammation depends in part on the cells present and their state of activation. Thus, mast cells make mostly PGD_2; macrophages generate PGE_2 and TXA_2; platelets are the major source of TXA_2; and endothelial cells secrete PGI_2. Prostanoids affect immune cell function by binding G-protein–coupled cell surface receptors, triggering many intracellular signaling pathways in immune cells and resident tissue cells. The repertoire of prostanoid receptors on various immune cells differs, so the functional responses of these cells may be different, according to the prostanoids present.

Inhibition of COX is one mechanism by which nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, indomethacin and ibuprofen, exert potent analgesic and anti-inflammatory effects. NSAIDs block COX-2–induced formation of prostaglandins, and so mitigate pain and inflammation. However, they also affect COX-1, decreasing homeostatic functions and affecting the stomach and kidneys adversely. This complication has led to the development of COX-2–specific inhibitors.

Leukotrienes

Slow-reacting substance of anaphylaxis (SRS-A) is a smooth muscle stimulant and mediator of hypersensitivity reactions. It is, in fact, a mixture of leukotrienes, the second major family of derivatives of arachidonic acid (Fig. 2-11). The enzyme 5-lipoxygenase (5-LOX) promotes the synthesis of 5-hydroperoxyeicosatetraenoic acid (5-HpETE) and leukotriene A_4 (LTA_4) from arachidonic acid; the latter is a precursor for other leukotrienes. In neutrophils and some macrophage populations, LTA_4 is metabolized to LTB_4, a potent chemotactic agent for neutrophils, monocytes and macrophages. In other cells, especially mast cells, basophils and macrophages, LTA_4 is converted to LTC_4 and thence to LTD_4 and LTE_4. These three cysteinyl-leukotrienes (1) stimulate smooth muscle contraction, (2) enhance vascular permeability and (3) are responsible for many of the clinical symptoms associated with allergic-type reactions. Thus, they play a pivotal role in the development of asthma. Leukotrienes exert their action through high-affinity specific receptors that may prove to be important targets of drug therapy.

Interleukins	Growth Factors	Chemokines	Interferons	Pro-Inflammatory Cytokines
IL-1 IL-6 IL-8 IL-13 IL-10	GM-CSF M-CSF	CC CXC XC CX3C	IFNα IFNβ IFNγ	TNFα
• Inflammatory cell activation	• Macrophage • Bactericidal activity • NK and dendritic cell function	• Leukocyte chemotaxis • Leukocyte activation	• Antiviral • Leukocyte activation	• Fever • Anorexia • Shock • Cytotoxicity • Cytokine induction • Activation of endothelial cells and tissue cells

FIGURE 2-12. Cytokines important in inflammation. *GM-CSF* = granulocyte–macrophage colony-stimulating factor; *IL* = interleukin; *NK* = natural killer; *IFN* = interferon; *TNF* = tumor necrosis factor.

Lipoxins

Lipoxins, the third class of arachidonic acid products, are made in the vascular lumen by cell–cell interactions (Fig. 2-11). They are proinflammatory, trihydroxytetraene-containing eicosanoids, generated during inflammation, atherosclerosis and thrombosis. Several cell types synthesize lipoxins from leukotrienes. LTA_4, released by activated leukocytes, is available for transcellular enzymatic conversion by nearby cells. When platelets adhere to neutrophils, LTA_4 from neutrophils is converted by platelet 12-lipoxygenase to lipoxin A_4 and B_4 (LXA_4 and LXB_4). Monocytes, eosinophils and airway epithelial cells generate 15*S*-hydroxyeicosatetraenoic acid (15*S*-HETE), which is taken up by neutrophils and converted to lipoxins via 5-LOX. Activation of this pathway can also inhibit leukotriene biosynthesis, thus regulating the whole process.

Aspirin initiates transcellular biosynthesis of a group of lipoxins termed "aspirin-triggered lipoxins," or 15-epimeric-lipoxins (15-epi-LXs). When aspirin is given in the presence of inflammatory mediators, 15*R*-HETE is generated by COX-2. Activated neutrophils convert 15*R*-HETE to 15-epi-LXs, which are anti-inflammatory lipid mediators. Thus, this is another pathway in which aspirin exerts a beneficial effect.

Cytokines Are Low–Molecular-Weight Proteins Secreted by Cells

Many different cytokines, including interleukins, growth factors, colony-stimulating factors, interferons and chemokines, are produced at sites of inflammation (Fig. 2-12).

Cytokines

Cytokines are low–molecular-weight proteins secreted by activated cells. They are produced at sites of tissue injury and regulate inflammatory responses from initial changes in vascular permeability to resolution and restoration of tissue integrity. Cytokines are inflammatory hormones that act in several modes (Fig. 2-13): **autocrine,** affecting cells that make them; **paracrine,** affecting neighboring cells; and **endocrine,**

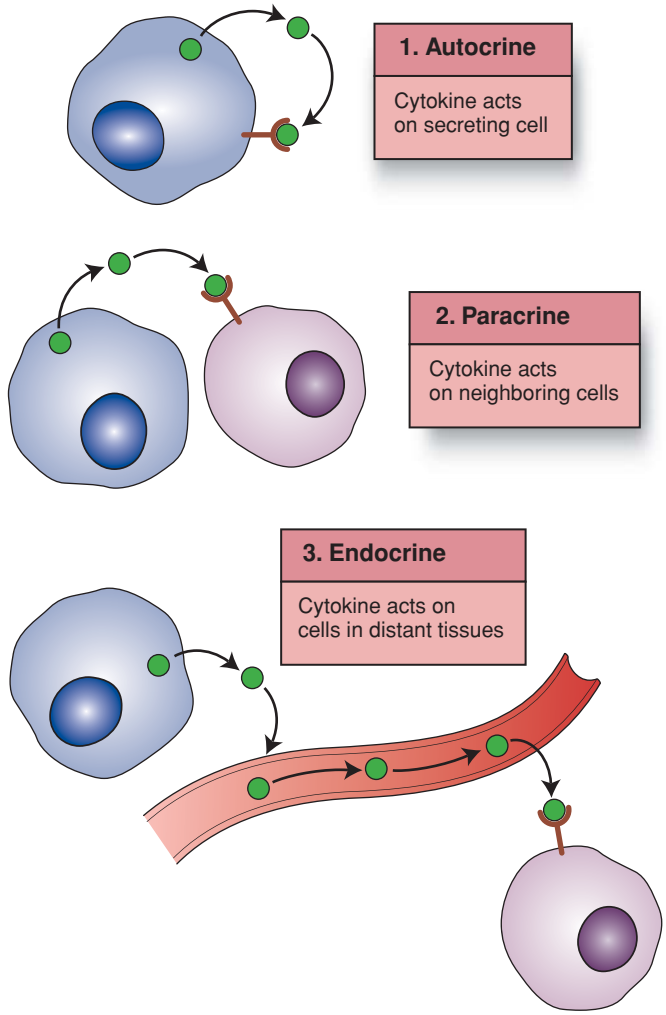

FIGURE 2-13. Types of cytokine signaling. 1. Autocrine signaling occurs when secreted products act through receptors on the secreting cell. **2.** Paracrine signaling occurs when secreted products act on nearby cells. **3.** In endocrine signaling, products are carried in the vascular system to act on distant cells.

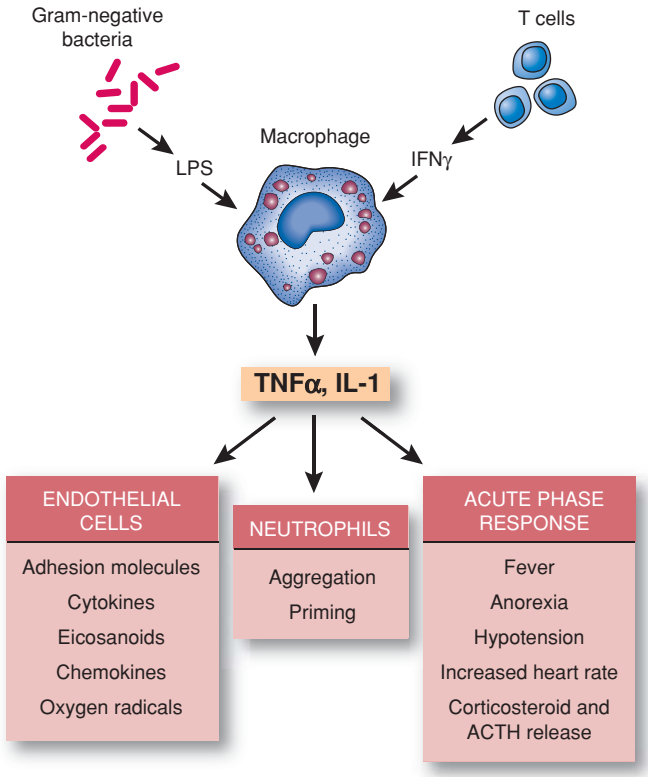

FIGURE 2-14. Central role of interleukin (IL)-1 and tumor necrosis factor (TNF)-α in inflammation. Lipopolysaccharide (LPS) and interferon-γ (IFN-γ) activate macrophages to release inflammatory cytokines, principally IL-1 and TNF-α, responsible for directing local and systemic inflammatory responses. *ACTH* = adrenocorticotrophic hormone.

acting via the bloodstream on distant cells. Most cells produce cytokines but differ in their cytokine repertoires.

Macrophages orchestrate tissue inflammatory responses via cytokine production. **Lipopolysaccharide** (LPS), a constituent of gram-negative bacterial outer membranes, is a highly potent activator of macrophages, as well as of endothelial cells and leukocytes (Fig. 2-14). LPS binds specific cellular receptors directly, or after binding a serum LPS-binding protein (LBP). It triggers macrophage synthesis of TNF-α and interleukins (IL-1, IL-6, IL-8, IL-12 and others). Macrophage-derived cytokines modulate endothelial cell–leukocyte adhesion (TNF-α), leukocyte recruitment (IL-8), acute phase responses (IL-6, IL-1) and immune functions (IL-1, IL-6, IL-12).

IL-1 and TNF-α, produced by macrophages and other cells, are central to development and amplification of inflammatory responses. These cytokines activate endothelial cells to express adhesion molecules and then release cytokines, chemokines and reactive oxygen species (ROS). TNF-α causes priming and aggregation of neutrophils. IL-1 and TNF-α are also among the mediators of fever, catabolism of muscle, shifts in protein synthesis and hemodynamic effects associated with inflammatory states (Fig. 2-14).

Interferon-γ (IFN-γ), another potent stimulus for macrophage activation and cytokine production, is produced by a subset of T lymphocytes as part of the immune response (see Chapter 4). It is also synthesized by natural killer (NK) cells in the primary host response to intracellular pathogens (e.g., *Listeria monocytogenes*) and certain viruses. NK cells migrate to tissues at sites of injury where, when exposed to IL-12 and TNF-α, they produce IFN-γ. Thus, there is an amplification pathway by which activated tissue macrophages produce TNF-α and IL-12, stimulating IFN-γ production by NK cells, with subsequent activation of additional macrophages.

Chemokines Regulate Cell Trafficking and Activation

There are more than 50 known cytokines that participate in inflammation and immunity. Chemotactic cytokines, or chemokines, stimulate cell activation, hematopoiesis and angiogenesis. Accumulation of inflammatory cells at sites of tissue injury requires their migration from vascular spaces into extravascular tissue. The most important chemotactic factors for PMNs are:

- C5a, derived from complement
- Bacterial and mitochondrial products, particularly low–molecular-weight N-formylated peptides (e.g., *N*-formyl-methionyl-leucyl-phenylalanine [FMLP])
- Products of arachidonic acid metabolism, especially LTB_4
- Chemokines

Chemokines are small secreted molecules that bind G-protein–coupled receptors on target cells. They are produced by a variety of cell types, either constitutively or after induction, and differ widely in biological action. This diversity is based on specific cell types targeted, specific receptor activation and differences in intracellular signaling.

There are two functional classes of chemokines: **inflammatory chemokines** and **homing chemokines**. Inflammatory chemokines are elicited by bacterial toxins and inflammatory cytokines (especially IL-1, TNF-α and IFN-γ) by a variety of tissue cells and by leukocytes themselves. They recruit leukocytes during host inflammatory responses. Homing chemokines are constitutively expressed and upregulated in disease. They direct trafficking and homing of lymphocytes and dendritic cells to lymphoid tissues during an immune response (see Chapter 4).

Structure and Nomenclature of Chemokines

Chemokines are synthesized as secretory proteins, consisting of 70–130 amino acids, with four conserved cysteines linked by disulfide bonds. The two major subpopulations, termed CXC or CC chemokines (formerly called α and β chemokines), are distinguished by the position of the first two cysteines, which are either separated by one amino acid (CXC) or are adjacent (CC). Two additional classes of chemokines, each with a single member, have been identified. Lymphotactin has two, instead of four, conserved cysteines (XC), and fractaline (or neurotactin) has three amino acids between the first two cysteines (CX_3C). Chemokines are named according to their structure, followed by "L" and the number of their gene (CCL1, CXCL1, etc.). However, many of the traditional names for chemokines persist in current usage. Chemokine receptors are named according to their structure, "R," and a number (CCR1, CXCR1, etc.); most receptors recognize more than one chemokine and most chemokines bind more than one receptor. Receptor binding by chemokines may lead to agonistic or antagonistic activity. In fact, the same chemokine

may act as an agonist at one receptor and an antagonist at another. Combinations of these agonistic and antagonistic activities and the profile of chemokines at a site dictate the attraction and activation of specific resident and inflammatory cell types.

Anchoring and Activity of Chemokines

Chemokines may be either immobilized or soluble molecules, controlling leukocyte motility and localization within extravascular tissues by establishing a chemotactic gradient. They generate this gradient by binding ECM proteoglycans or cell surfaces. As a result, high concentrations of chemokines persist at sites of tissue injury. Specific receptors on the surface of migrating leukocytes recognize matrix-bound chemokines and associated adhesion molecules, causing cells to move along the chemotactic gradient to a site of injury. The process of responding to matrix-bound chemoattractants is **haptotaxis**. During this migration, the cell extends a pseudopod toward increasing chemokine concentrations. At the leading front of the pseudopod, marked changes in levels of intracellular calcium are associated with assembly and contraction of cytoskeleton proteins. This pulls the rest of the cell along the chemical gradient. Chemokines are also displayed on cytokine-activated vascular endothelial cells. This process can augment very late antigen-4 (VLA-4) integrin-dependent adhesion of leukocytes, resulting in their firm arrest. The variety and combinations of chemokine receptors on cells allow for diverse biological functions. Neutrophils, monocytes, eosinophils and basophils share some receptors but express other receptors exclusively. Thus, specific chemokine combinations can recruit selective cell populations.

Chemokines in Disease

Chemokines are implicated in many acute and chronic diseases. In disorders with a pronounced inflammatory component, multiple chemokines are expressed in inflamed tissues. Examples are rheumatoid arthritis, ulcerative colitis, Crohn disease, pulmonary inflammation (chronic bronchitis, asthma), autoimmune diseases (multiple sclerosis, rheumatoid arthritis, SLE) and vascular diseases, including atherosclerosis.

Reactive Oxygen Species Are Signal-Transducing, Bactericidal and Cytotoxic Molecules

ROS are chemically reactive molecules derived from oxygen. Normally, they are rapidly inactivated, but they can be toxic to cells if generated inappropriately (see Chapters 1 and 5). ROS activate signal transduction pathways and combine with proteins, lipids and DNA, which can impair cell function and kill cells. Leukocyte-derived ROS, released within phagosomes, are bactericidal. Key ROS in inflammation include superoxide (O_2^-), nitric oxide (NO, or NO•), hydrogen peroxide (H_2O_2) and hydroxyl radical (OH•) (Fig. 2-15).

Superoxide

Molecular oxygen is converted to superoxide anion (O_2^-) (1) within cells, where O_2^- is generated spontaneously by the inner mitochondrial membrane; (2) in vascular endothelium, when it is produced by flavoenzymes, such as xanthine oxidase, lipoxygenase and cyclooxygenase; and (3) during inflammation, by leukocytes as well as endothelial cells using a nicotinamide adenine dinucleotide phosphate (NADPH) oxidase to produce O_2^-.

In endothelial cells, xanthine oxidase, a purine-metabolizing enzyme, converts xanthine and hypoxanthine to uric acid, thus generating O_2^-. This pathway is a major intracellular source of O_2^- in neutrophil-mediated cell injury. Proinflammatory mediators, including leukocyte elastase and several cytokines, convert xanthine dehydrogenase to the active xanthine oxidase. Intracellular O_2^- interacts with nuclear factor-κB (NFκB), activating protein-1 (AP-1) and other molecules during signal transduction. It is converted to other free radicals, particularly OH•, which contribute to inflammation-related cell injury.

NADPH oxidase in phagocytic cells, neutrophils and macrophages is a multicomponent enzyme complex that generates high concentrations of extracellular and intracellular O_2^-, mainly for bactericidal and cytotoxic functions. This oxidase uses nicotinamide adenine dinucleotide (NADH) and NADPH to transfer electrons to molecular oxygen. A similar enzyme complex in endothelial cells generates significant, albeit lower, concentrations of O_2^-.

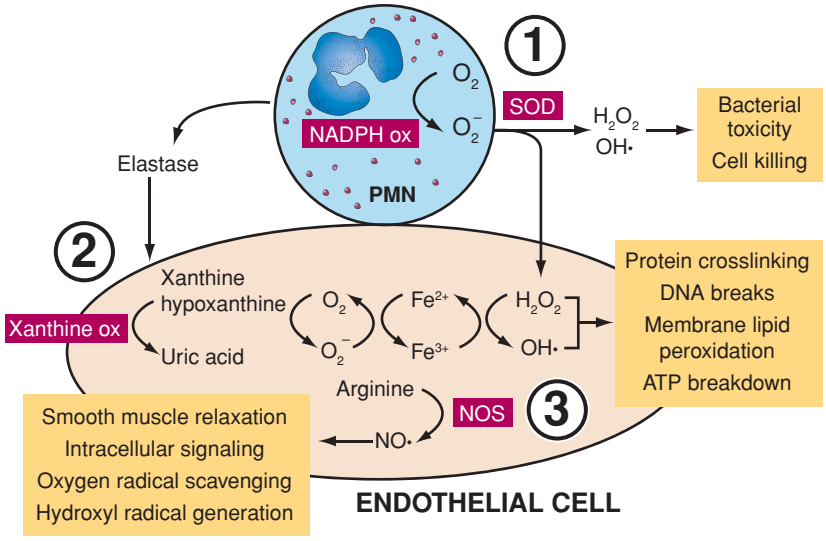

FIGURE 2-15. Biochemical events in neutrophil–endothelial cell interactions. When neutrophils are in firm contact with endothelial cells, oxygen radicals and other active molecules generated by both cells interact. **1.** Superoxide (O_2^-) generated by the neutrophil nicotinamide adenine dinucleotide phosphate oxidase (NADPHox) is converted to toxic hydrogen peroxide (H_2O_2) and hydroxyl radical (OH•). **2.** Within the endothelial cell xanthine oxidase (xanthine ox) converts xanthine to uric acid, ultimately generating O_2^- from molecular oxygen. **3.** Nitric oxide synthase (NOS) generates nitric oxide (NO•) from arginine. Reactive oxygen species contribute to numerous cellular events. *ATP* = adenosine triphosphate; Fe^{2+} = ferrous iron; Fe^{3+} = ferric iron; *PMN* = polymorphonuclear neutrophil.

Nitric Oxide

NO is produced by nitric oxide synthase (NOS), which oxides the guanidino nitrogen of L-arginine in the presence of O_2. There are three main NOS isoforms: constitutively expressed **neuronal** (nNOS) and **endothelial** (eNOS) forms and **inducible NOS** (iNOS). Inflammatory cytokines increase expression of iNOS, generating intracellular and extracellular NO, which has many roles in vascular physiology and pathophysiology:

- NO generated by eNOS is **endothelium-derived relaxing factor** (EDRF), mediating vascular smooth muscle relaxation.
- In physiologic concentrations, it—alone and in balance with O_2^-—is an intracellular messenger.
- NO prevents platelet adherence and aggregation at sites of vascular injury, reduces leukocyte recruitment and scavenges oxygen radicals.
- Excessive NO production, especially in parallel with O_2^-, generates the highly reactive and cytotoxic species, peroxynitrite ($ONOO^-$).

Stress Proteins Protect from Inflammatory Injury

When cells are stressed, many suffer irreversible injury and die. Others may be severely damaged. However, mild heat treatment prior to potentially lethal injury provides tolerance to subsequent injury (see Chapter 1). This phenomenon reflects increased expression of the heat shock family of stress proteins (HSPs). Stress proteins belong to multigene families and are named according to molecular size (e.g., Hsp27, Hsp70, Hsp90). They are upregulated by diverse threats, such as oxidative/ischemic stress and inflammation, and are associated with protection during sepsis and metabolic stress. Protein damage and misfolded proteins are common denominators in injury and disease (see Chapter 1). Protection from many kinds of nonlethal stresses is mediated by HSPs, which are molecular chaperones, increasing protein expression by guiding folding of nascent proteins and preventing misfolding. Potential functions of stress proteins include suppression of proinflammatory cytokines and NADPH oxidase, increased nitric oxide–mediated cytoprotection and enhanced collagen synthesis.

Neurokinins Link the Endocrine, Nervous and Immune Systems

The neurokinin family of peptides includes substance P (SP) and neurokinins A (NKA) and B (NKB). These peptides are distributed throughout the central and peripheral nervous systems and link the endocrine, nervous and immune systems. Diverse biological processes are associated with these peptides, including extravasation of plasma proteins and edema, vasodilation, smooth muscle contraction and relaxation, salivary secretion, airway contraction and transmission of nociceptive responses. As early as 1876, Stricker noted an association between sensory afferent nerves and inflammation. ***Injury to nerve terminals during inflammation evokes an increase in neurokinins that in turn stimulate production of inflammatory mediators, such as histamine, NO and kinins***. The actions of neurokinins are mediated by activation of at least three classes of receptors—NK1, NK2 and NK3—which are widely distributed in the body. The neurokinin system is linked to inflammation in the following settings:

- **Edema formation:** SP, NKA and NKB induce edema by promoting release of histamine and serotonin from mast cells.
- **Thermal injury:** SP and NKA cause edema right after thermal injury.
- **Arthritis:** SP is widespread in nerves in joints and increases vascular permeability. SP and NKA modulate tasks of inflammatory and immune cells.
- **Airway inflammation:** SP and NKA mediate bronchoconstriction, mucosal edema, leukocyte adhesion and activation and vascular permeability.

EXTRACELLULAR MATRIX MEDIATORS

Interactions of cells and ECM regulate tissue responses to inflammation. The extracellular environment consists of macromolecular matrices specific for each tissue. During injury, resident inflammatory cells interact with the ECM, using this scaffolding for migration along a chemokine gradient. Collagen, elastic fibers, basement membrane proteins, glycoproteins and proteoglycans are among the ECM components (see Chapter 3). Matricellular proteins are secreted macromolecules that link cells to the ECM or that disrupt cell–ECM interactions. Cytokines and growth factors influence associations among cells, the ECM and matricellular proteins (Fig. 2-16). Matricellular proteins include:

- **SPARC (secreted protein acidic and rich in cysteine)** is a multifunctional glycoprotein that organizes ECM components and modulates growth factor activity. It affects cell proliferation, migration and differentiation and is counteradhesive, especially for endothelial cells.
- **Thrombospondins** are secreted glycoproteins that affect cell–matrix interactions, influence platelet aggregation and support neutrophil chemotaxis and adhesion.
- **Tenascins C, X and R** are counteradhesive proteins expressed during development, tissue injury and wound healing.
- **Syndecans** are heparan sulfate proteoglycans implicated in coagulation, growth factor signaling, cell adhesion to the ECM and tumorigenesis.
- **Osteopontin** is a phosphorylated glycoprotein important in bone mineralization. It also (1) mediates cell–matrix

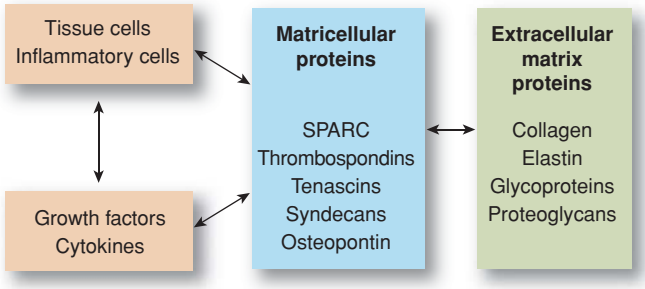

FIGURE 2-16. Dynamic relationship associates cells, soluble mediators and matricellular proteins with the extracellular matrix. *SPARC* = secreted protein acidic and rich in cysteine.

interactions, (2) activates cell signaling (mainly in T cells), (3) is chemotactic for and supports adhesion of leukocytes and (4) has anti-inflammatory effects via regulation of macrophage function.

CELLS OF INFLAMMATION

Leukocytes are the major cellular participants in inflammation and include neutrophils, T and B lymphocytes, monocytes, macrophages, eosinophils, mast cells and basophils. Each cell type has specific functions, but they overlap and change as inflammation progresses. ***Inflammatory cells and resident tissue cells interact with each other in a continuous response during inflammation.***

Neutrophils

PMNs predominate in acute inflammation. They are stored in bone marrow, circulate in the blood and rapidly accumulate at sites of injury or infection (Figs. 2-17A and 2-18). PMNs have granulated cytoplasm and a 2- to 4-lobed nucleus. Neutrophil receptors recognize the Fc portion of IgG and IgM; complement components C5a, C3b and iC3b; arachidonic acid metabolites; chemotactic factors; and cytokines. In tissues, PMNs phagocytose, invading microbes and

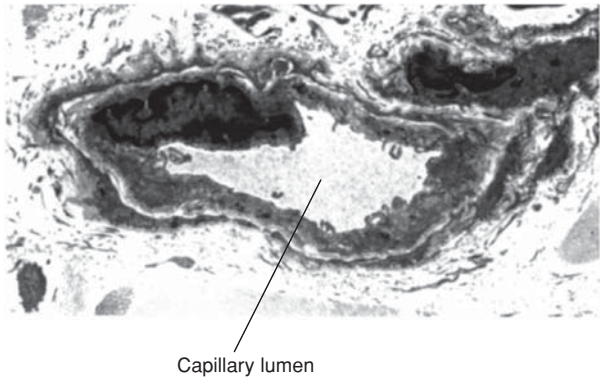
POLYMORPHONUCLEAR LEUKOCYTE

CHARACTERISTICS AND FUNCTIONS
- Central to acute inflammation
- Phagocytosis of microorganisms and tissue debris
- Mediates tissue injury

PRIMARY INFLAMMATORY MEDIATORS
- Reactive oxygen metabolites
- Lysosomal granule contents

Primary granules	Secondary granules
Myeloperoxidase	Lysozyme
Lysozyme	Lactoferrin
Defensins	Collagenase
Bactericidal/permeability increasing protein	Complement activator
Elastase	Phospholipase A_2
Cathepsins protease 3	CD11b/CD18
Glucuronidase	CD11c/CD18
Mannosidase	Laminin
Phospholipase A_2	**Tertiary granules**
	Gelatinase
	Plasminogen activator
	Cathepsins
	Glucuronidase
	Mannosidase

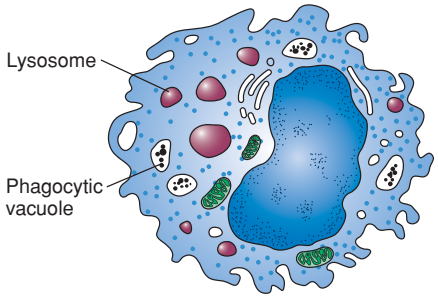


B

ENDOTHELIAL CELL

CHARACTERISTICS AND FUNCTIONS
- Maintains vascular integrity
- Regulates platelet aggregation
- Regulates vascular contraction and relaxation
- Mediates leukocyte recruitment in inflammation

PRIMARY INFLAMMATORY MEDIATORS
- von Willebrand factor
- Nitric oxide
- Endothelins
- Prostanoids



C

MONOCYTE/MACROPHAGE

CHARACTERISTICS AND FUNCTIONS
- Regulates acute and chronic inflammatory response
- Regulates coagulation/fibrinolytic pathway
- Regulates immune response (see Chapter 4)

PRIMARY INFLAMMATORY MEDIATORS
- Enzymes
- Proteins
- Complement proteins
- Chemokines
- Cytokines
- Reactive oxygen species
- Antioxidants
- Coagulation factors
- Bioactive lipids

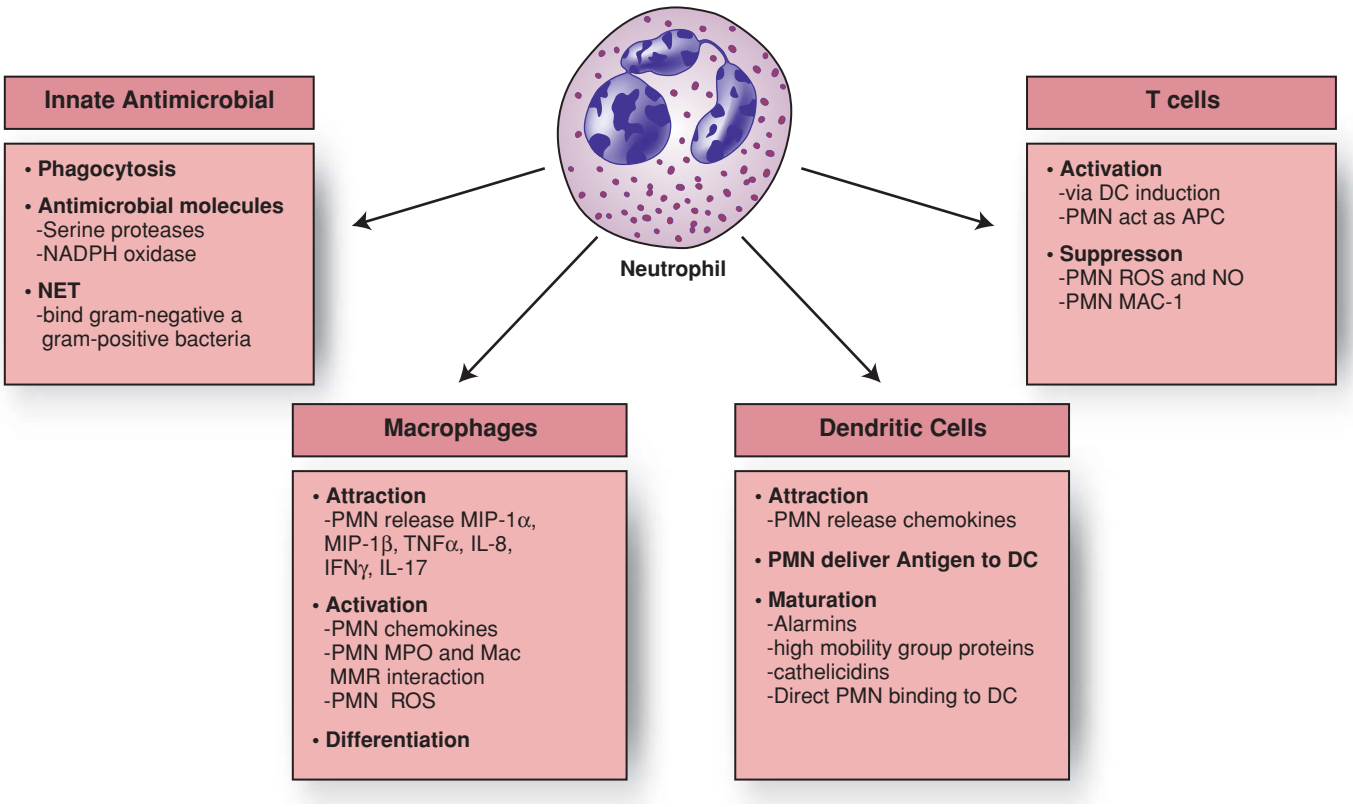

FIGURE 2-18. Effector functions of neutrophils.

dead tissue, then undergo apoptosis, largely during the resolution phase of acute inflammation. They exhibit NETosis (see Chapter 1), a unique mechanism of trapping and killing microbial invaders, while at the same time dying themselves. In addition to microbicidal and proinflammatory properties, PMNs affect dendritic cells, T cells and macrophages.

Endothelial Cells

Endothelial cells line blood vessels as a monolayer and help separate intravascular and extravascular spaces. They produce antiplatelet and antithrombotic agents that maintain blood vessel patency and secrete vasodilators and vasoconstrictors that regulate vascular tone. Injury to a vessel wall interrupts the endothelial barrier and exposes local procoagulant signals (Fig. 2-17B).

Endothelial cells are gatekeepers in inflammatory cell recruitment; they may promote or inhibit tissue perfusion and inflammatory cell influx. Inflammatory agents such as bradykinin and histamine, endotoxins and cytokines induce endothelial cells to show adhesion molecules that anchor and activate leukocytes, causing them to present major histocompatibility complex (MHC) class I and II molecules, and generate key vasoactive and inflammatory mediators. These mediators include:

- **NO:** Nitric oxide is a low–molecular-weight vasodilator that inhibits platelet aggregation, regulates vascular tone by stimulating smooth muscle relaxation and reacts with ROS to create highly reactive radical species (see above).
- **Endothelins:** Endothelins-1, -2 and -3 are low–molecular-weight peptides made by endothelial cells. They are potent vasoconstrictor and pressor agents, which induce prolonged vasoconstriction of vascular smooth muscle.
- **Arachidonic acid–derived contraction factors:** Oxygen radicals generated by the hydroperoxidase activity of cyclooxygenase and prostanoids, such as TXA_2 and PGH_2, induce smooth muscle contraction.
- **Arachidonic acid–derived relaxing factors:** The biological opponent of TXA_2, PGI_2 inhibits platelet aggregation and causes vasodilation.
- **Cytokines:** IL-1, IL-6, TNF-α and other inflammatory cytokines are generated by activated endothelial cells.
- **Anticoagulants:** Heparin-like molecules and thrombomodulin inactivate the coagulation cascade (see Chapters 16 and 26).
- **Fibrinolytic factors:** Tissue-type plasminogen activator (t-PA) promotes fibrinolytic activity.
- **Prothrombotic agents:** von Willebrand factor facilitates adhesion of platelets, and tissue factor activates the extrinsic clotting cascade.

Monocyte/Macrophages

Circulating monocytes (Fig. 2-17C) are bone marrow–derived cells that have a single lobed or kidney-shaped nucleus. They may exit the circulation to migrate into tissue and become resident macrophages that accumulate at sites of acute inflammation and clear pathogens, cell debris and apoptotic cells. Monocytes/macrophages produce potent phlogistic mediators, influencing initiation, progression and resolution of acute inflammatory responses. They also have a central role in regulating progression to, and maintenance of, chronic inflammation. Macrophages respond to inflammatory stimuli by phagocytosis of cell debris and microorganisms, chemotaxis, antigen processing and presentation, and secretion immunomodulatory factors. A large repertoire of surface receptors mediate these various macrophage functions; some immune receptors are macrophage specific, but others are shared with PMNs and lymphocytes.

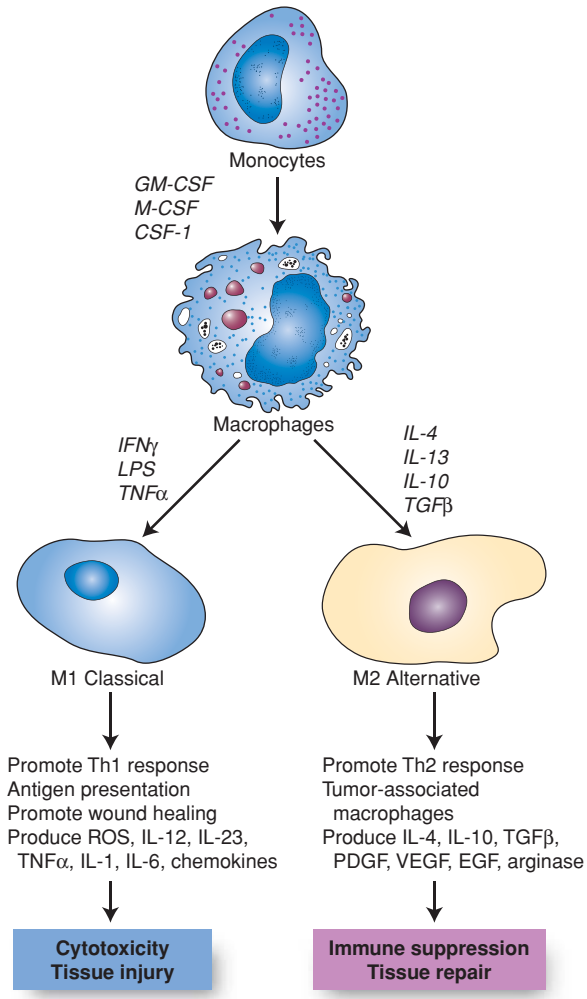

FIGURE 2-19. Macrophage activation states.

Classically activated macrophages (Figs. 2-19 and 2-20) are driven by IFN-γ, TNF-α and LPS to promote proinflammatory responses and release ROS and immune defense cytokines. Alternatively, activated macrophages respond to IL-4 and IL-13 to help clear parasitic infections. Macrophages also respond to cytokines such as IL-10 and transforming growth factor-β (TGF-β) to promote resolution of inflammation or switch acute to chronic inflammatory responses.

Like PMNs, macrophages are phagocytes and, like dendritic cells, are crucial in antigen processing and presentation. Members of this mononuclear phagocyte system are functionally diverse and include bone marrow macrophages, alveolar macrophages (lung), Kupffer cells (liver), microglial cells (CNS), Langerhans cells (skin), mesangial cells (kidney) and tissue macrophages throughout the body. Tumor-associated macrophages (TAMs) can recognize and lyse tumor cells.

Dendritic Cells

Dendritic cells are derived from bone marrow progenitors, circulate in the blood as immature precursors, then settle widely in tissues, where they differentiate. They are highly efficient, antigen-presenting cells and stimulate naive T cells. Antigens bind to MHC class II on dendritic cells and are presented to lymphocytes, which are subsequently activated (see Chapter 4).

Mast Cells and Basophils

Basophils (Fig. 2-21A) are the least common leukocyte in the blood and can migrate into tissue to participate in immunologic responses. Functionally similar mast cells are long-lived and reside in all supporting tissues. They are important in regulating vascular permeability and bronchial smooth muscle tone, especially in hypersensitivity reactions (see Chapter 4). Mast cells are seen in connective tissues and

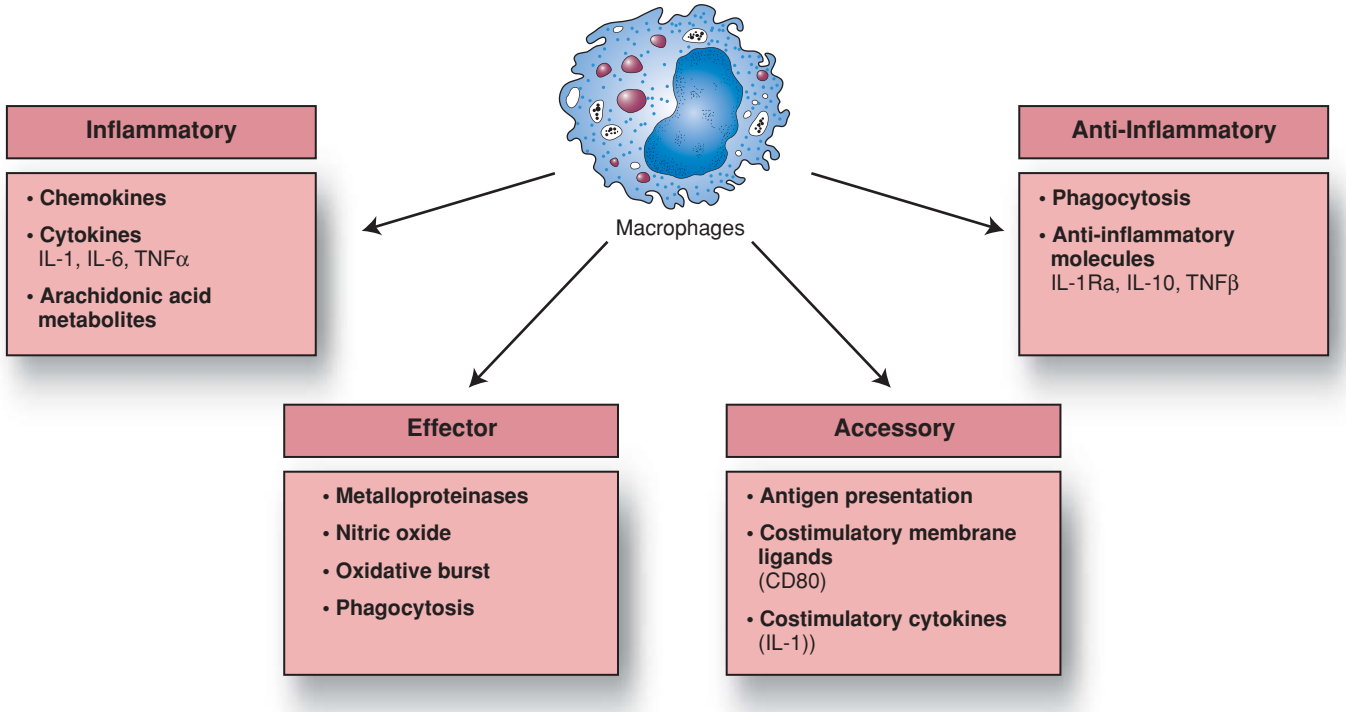

FIGURE 2-20. Effector functions of macrophages.

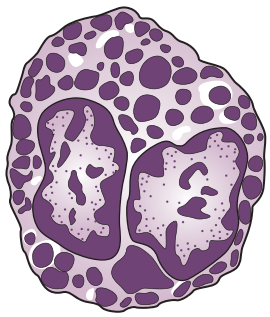
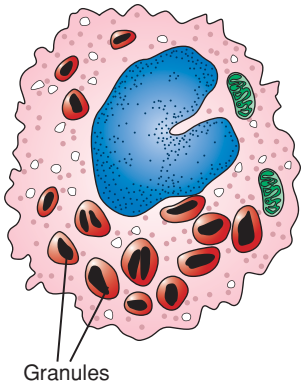


A

MAST CELL (BASOPHIL)

CHARACTERISTICS AND FUNCTIONS
- Binds IgE molecules
- Contains electron-dense granules

PRIMARY INFLAMMATORY MEDIATORS
- Histamine
- Leukotrienes (LTC, LTD, LTE)
- Platelet-activating factor
- Eosinophil chemotactic factors
- Cytokines (e.g., TNF-α IL-4)

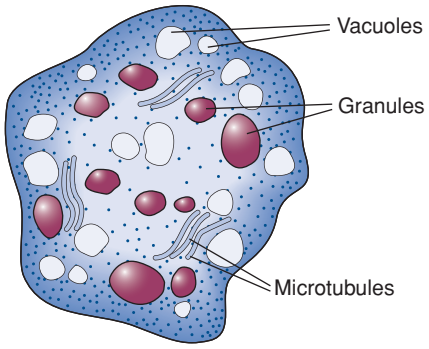


B

EOSINOPHIL

CHARACTERISTICS AND FUNCTIONS
- Associated with:
  - -Allergic reactions
  - -Parasite-associated inflammatory reactions
  - -Chronic inflammation
- Modulates mast cell-mediated reactions

PRIMARY INFLAMMATORY MEDIATORS
- Reactive oxygen metabolites
- Lysosomal granule enzymes (primary crystalloid granules)
  - -Major basic protein
  - -Eosinophil cationic protein
  - -Eosinophil peroxidase
  - -Acid phosphatase
  - -β-glucuronidase
  - -Arylsulfatase B
  - -Histaminase
- Phospholipase D
- Prostaglandins of E series
- Cytokines



C

PLATELET

CHARACTERISTICS AND FUNCTIONS
- Thrombosis; promotes clot formation
- Regulates permeability
- Regulates proliferative response of mesenchymal cells

PRIMARY INFLAMMATORY MEDIATORS
- Dense granules
  - -Serotonin
  - -Ca^{2+}
  - -ADP
- α-granules
  - -Cationic proteins
  - -Fibrinogen and coagulation proteins
  - -Platelet-derived growth factor (PDGF)
- Lysosomes
  - -Acid hydrolases
- Thromboxane A_2

FIGURE 2-21. More cells of inflammation: morphology and function. A. Mast cell/basophil. **B.** Eosinophil. **C.** Platelet. *ADP* = adenosine diphosphate.

especially on lung and gastrointestinal mucosal surfaces, in the dermis and in the microvasculature.

Granulated mast cells and basophils have cell surface receptors for IgE. When IgE-sensitized mast cells or basophils are stimulated by antigens, physical agonists (cold, trauma) or cationic proteins, inflammatory mediators in dense cytoplasmic granules are secreted into extracellular tissues. These granules contain acid mucopolysaccharides (including heparin), serine proteases, chemotactic mediators for neutrophils and eosinophils, and histamine, a primary mediator of early increased vascular permeability. Histamine binds specific H_1 receptors in the vascular wall, inducing endothelial cell contraction, gap formation and edema, which can be blocked pharmacologically by H_1-receptor antagonists. Stimulation of mast cells and basophils also leads to release of products of arachidonic acid metabolism (LTC_4, LTD_4 and LTE_4) and cytokines, such as TNF-α and IL-4.

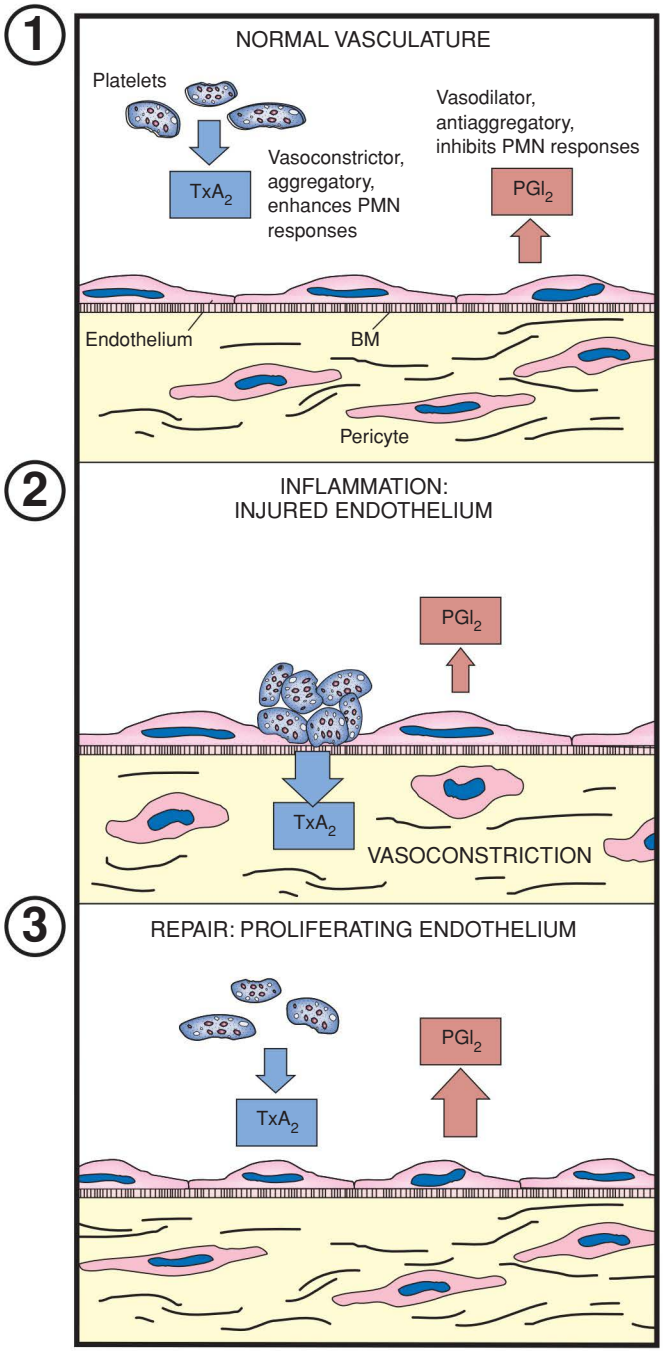
Eosinophils

Eosinophils (Fig. 2-21B) circulate in blood and are recruited to tissue similarly to PMNs. They are often seen in settings of IgE-mediated reactions, such as allergy and asthma. Eosinophils contain leukotrienes and PAF, acid phosphatase and peroxidase. They express IgA receptors and exhibit large granules that contain eosinophil major basic protein, both of which are involved in defense against parasites (see Chapter 4).

Platelets

Platelets (Fig. 2-21C) play a primary role in normal homeostasis and in initiating and regulating clotting (see Chapter 26). They produce inflammatory mediators, such as potent vasoactive substances and growth factors that modulate mesenchymal cell proliferation. Platelets are small (about 2 mm), lack nuclei and have three types of inclusions: (1) **dense granules,** rich in serotonin, histamine, calcium and adenosine diphosphate (ADP); (2) **α-granules,** containing fibrinogen, coagulation proteins, platelet-derived growth factor (PDGF) and other peptides and proteins; and (3) **lysosomes,** which sequester acid hydrolases.

Platelets adhere, aggregate and degranulate when they contact fibrillar collagen (e.g., after vascular injury that exposes interstitial matrix proteins) or thrombin (after activation of the coagulation system) (Fig. 2-22). Degranulation releases serotonin (5-hydroxytryptamine), which, like histamine, directly increases vascular permeability. In addition, the platelet arachidonic acid metabolite TXA_2 plays a key



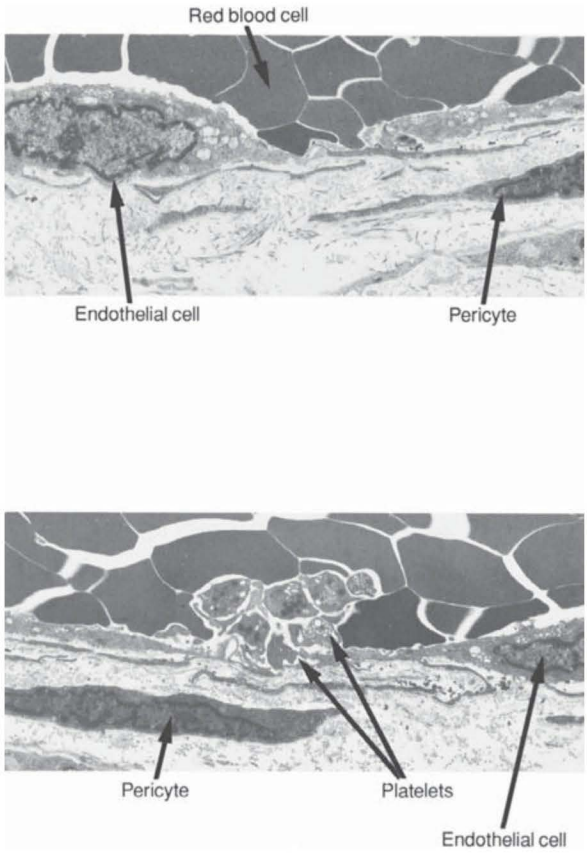


FIGURE 2-22. Regulation of platelet and endothelial cell interactions by thromboxane A_2 (TXA_2) and prostaglandin I_2 (PGI_2). 1. Platelet-derived TXA_2 and endothelial-derived PGI_2 maintain vasodilation and vasoconstriction in balance. **2.** During inflammation, the normal balance is shifted to vasoconstriction, increased vascular permeability, platelet aggregation and polymorphonuclear neutrophil (PMN) responses. **3.** During repair, the prostaglandin effects predominate, inhibiting PMN responses and promoting normal blood flow. *BM* = basement membrane.

role in the second wave of platelet aggregation and mediates smooth muscle constriction. On activation, platelets, as well as phagocytic cells, secrete cationic proteins that neutralize the negative charges on endothelium and promote increased permeability.

LEUKOCYTE RECRUITMENT IN ACUTE INFLAMMATION

An essential feature of inflammation is leukocyte accumulation, especially PMNs, in affected tissues. Swift recruitment requires a response orchestrated by chemoattractants that induce directed cell migration. In several models of neutrophil recruitment, lipid mediators, eicosanoids (such as LTB_4 interacting with neutrophil receptor BLT1), serum proteins (complement products C3a, C5a, cytokines) and chemokines function sequentially for optimal responses (Fig. 2-23). A variety of inflammatory stimuli, including proinflammatory cytokines, bacterial endotoxins and viral proteins, stimulate endothelial cells, resulting in loss of barrier function and recruitment of leukocytes. Leukocytes adhere to activated endothelium and are themselves activated in the process. They then flatten and migrate from the vascular space, through the vessel wall and into surrounding tissue. In the extravascular tissue, PMNs ingest foreign material, microbes and dead tissue (Fig. 2-24).

Leukocyte Adhesion to Endothelium Reflects Interaction of Complementary Adhesion Molecules

Leukocyte recruitment in postcapillary venules is a multistep process that begins with altered expression of endothelial cell adhesion molecules. Then leukocytes bind to endothelial cell selectins, which redistribute to endothelial cell surfaces during activation. This process, called **tethering,** slows leukocytes in the bloodstream (Figs. 2-25 and 2-26). Leukocytes then move along the vascular endothelial cell surface with a saltatory movement, called **rolling.** PMNs become activated by proximity to the endothelium and by inflammatory mediators and adhere strongly to intercellular adhesion molecules (ICAMs) on the endothelium **(leukocyte arrest)**. As endothelial cells separate, leukocytes **transmigrate** through the vessel wall and, under the influence of chemotactic factors, migrate to the site of injury.

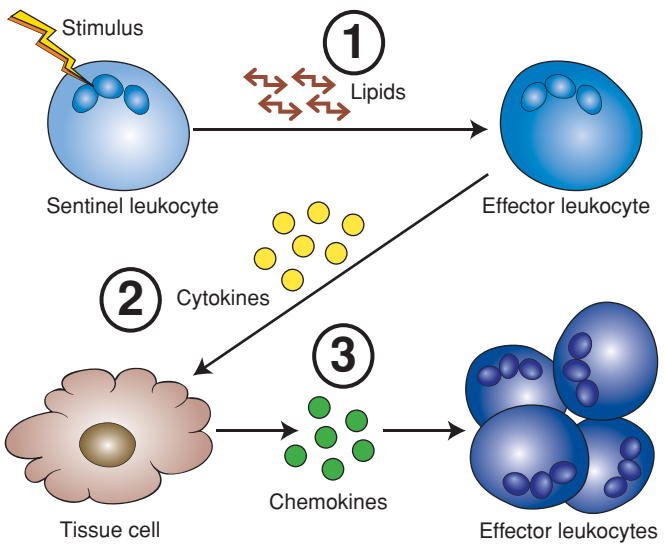

FIGURE 2-23. A schema of orchestrated initiation of inflammatory responses. 1. Lipid mediators (eicosanoids) are released from activated cells, resulting in early recruitment of inflammatory cells from bone marrow into the vascular system. **2.** Proinflammatory cytokines activate resident tissue cells, which in turn **(3)** release chemokines to amplify inflammatory cell recruitment.

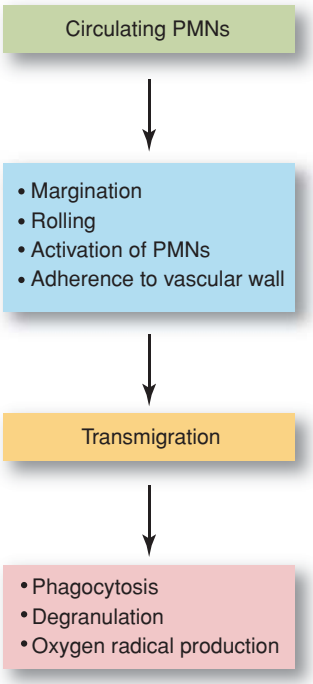

FIGURE 2-24. Leukocyte recruitment and activation. *PMNs* = polymorphonuclear neutrophils.

Events in leukocyte recruitment are regulated by a temporal and spatial distribution of forces. Pro- and anti-inflammatory effects of healthy and diseased tissue microenvironments include:

1. Inflammatory mediators that stimulate resident tissue cells in sequence, including vascular endothelial cells; proinflammatory cytokines that upregulate endothelial cell adhesion molecules; and anti-inflammatory cytokines such as TGF-β that downregulate these same adhesion molecules as well as proinflammatory cytokines.
2. Chemotactic factors, which attract leukocytes along a chemical gradient to the site of injury (Fig. 2-25).
3. Expression of adhesion molecules on vascular endothelial cell surfaces, which bind to reciprocal molecules on the surfaces of circulating leukocytes. Endothelial cells are activated by exposure to proinflammatory cytokines and vasoactive peptides and by blood flow patterns, such as turbulent flow or oscillatory shear stress. NFκB and c-Jun N-terminal kinase-AP-1 (JNK-AP-1) signaling pathways induce a proadhesive phenotype, with increased transcription of proinflammatory genes and augmented expression of cell adhesion molecules. Counteracting antiadhesive forces include physiologic laminar shear stress and expression of peroxisome proliferator-activated receptors (PPARs). These forces trigger production of

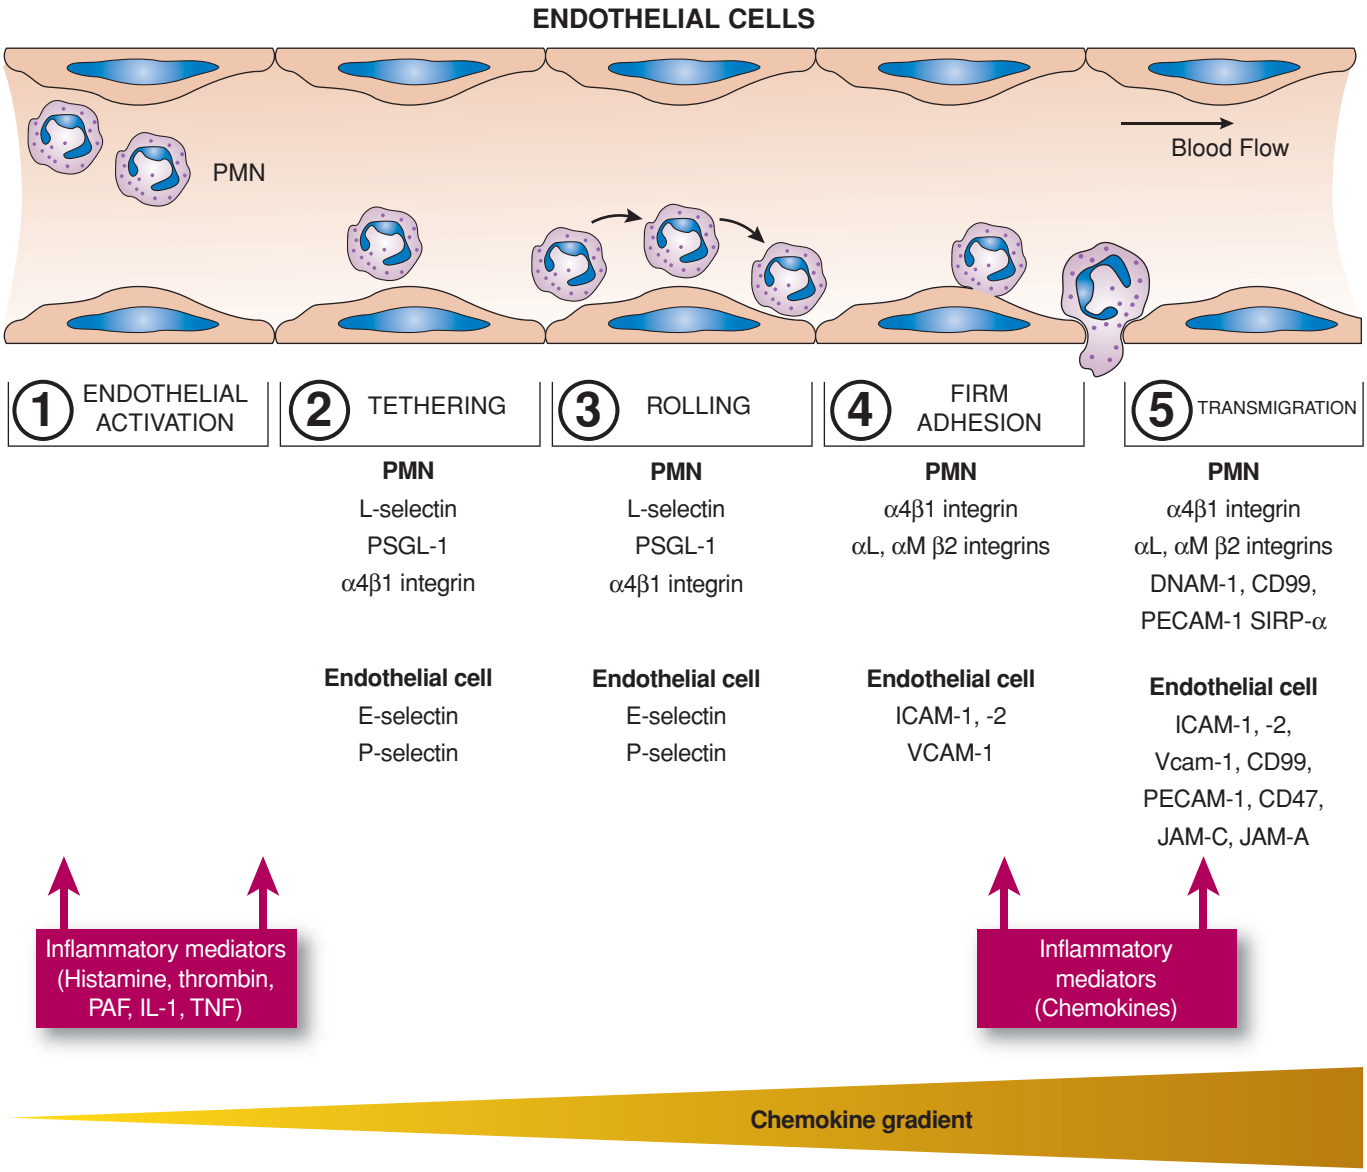

FIGURE 2-25. Neutrophil adhesion and extravasation. 1. Inflammatory mediators activate endothelial cells to increase expression of adhesion molecules. Sialyl-Lewis X on neutrophil P-selectin glycoprotein-1 (PSGL-1) and E-selectin ligand (ESL-1) binds to P- and E-selectins to facilitate **(2)** tethering and **(3)** rolling of neutrophils. Increased integrins on activated neutrophils bind to intercellular adhesion molecule-1 (ICAM-1) on endothelial cells to form **(4)** a firm attachment. **5.** Endothelial cell attachments to one another are released and neutrophils then pass between separated cells to enter the tissue. *EC* = endothelial cell; *IL* = interleukin; *PAF* = platelet-activating factor; *PMN* = polymorphonuclear neutrophil; *TNF* = tumor necrosis factor.

superoxide dismutase (SOD) and NO, thus reducing O_2^- and oxidative stress, inhibiting proinflammatory cytokine expression and suppressing formation of specific adhesion molecules (Fig. 2-26).

Adhesion Molecules

Four molecular families of adhesion molecules are involved in leukocyte recruitment: selectins, addressins, integrins and immunoglobulins (Fig. 2-27).

Selectins

The selectin family includes P-selectin, E-selectin and L-selectin. They are expressed respectively on platelets and endothelial and leukocyte surfaces. Selectins share a similar molecular structure: a chain of transmembrane glycoproteins with an extracellular lectin-binding domain. This calcium-dependent, or C-type, lectin binds sialylated oligosaccharides, specifically the sialyl-Lewis X moiety, on addressins, which allows rapid cell attachment and rolling.

P-selectin (CD62P, GMP-140, PADGEM) is preformed and stored in Weibel-Palade bodies of endothelial cells and α-granules of platelets. On stimulation with histamine, thrombin or specific inflammatory cytokines, P-selectin moves rapidly to the cell surface, where it binds sialyl-Lewis X on leukocyte surfaces. Preformed P-selectin can be delivered quickly to the cell surface, allowing rapid adhesive interaction between endothelial cells and leukocytes.

E-selectin (CD62E, ELAM-1) is not normally expressed on endothelial cell surfaces but is induced by inflammatory

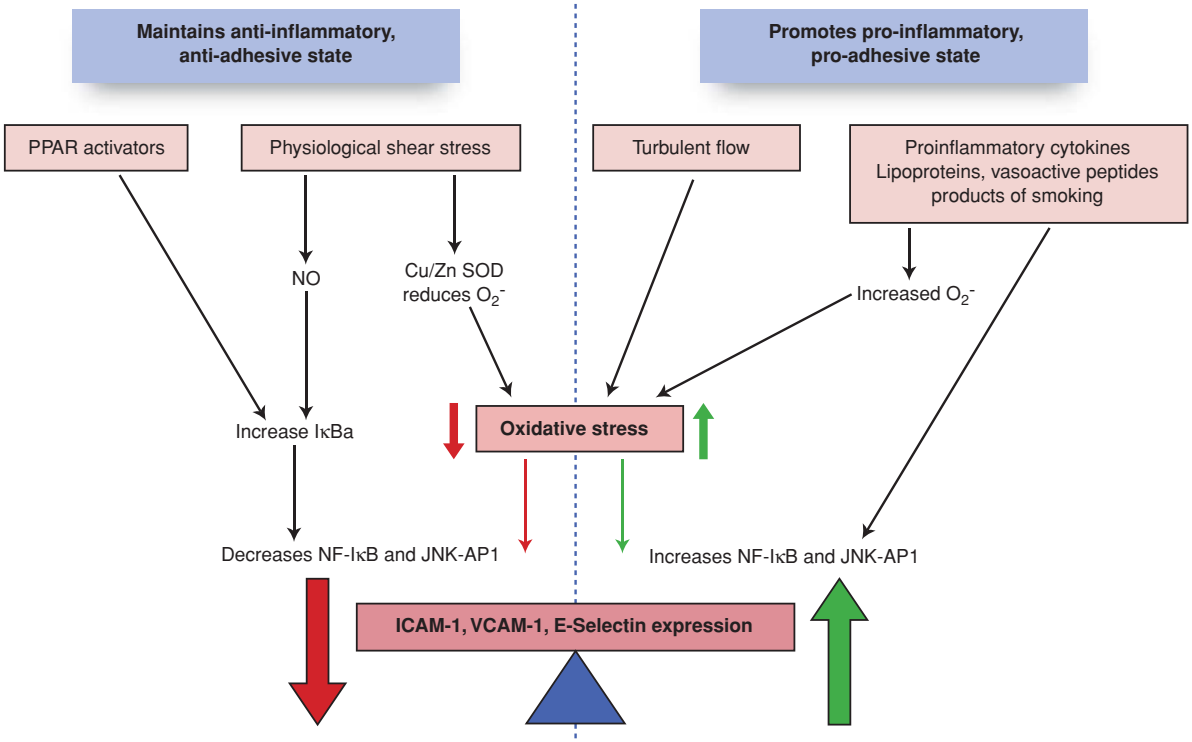

FIGURE 2-26. Balance of pro- and antiadhesive forces in vascular endothelial cells. Under physiologic conditions of vascular flow and expression of peroxisome proliferator-activated receptors (PPARs), oxidative stress and adhesion molecule expression are held in check. In the presence of proinflammatory mediators and turbulent flow or oscillatory shear stress, oxidative stress increases, followed by increased transcription of proinflammatory genes and enhanced expression of adhesion molecules.

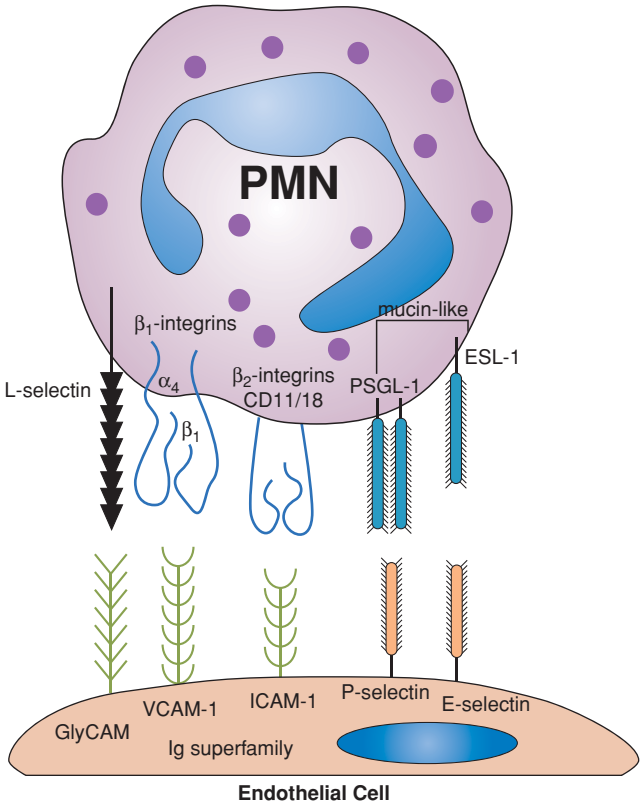

FIGURE 2-27. Leukocyte and endothelial cell adhesion molecules. *GlyCAM* = glycan-bearing cell adhesion molecule; *ICAM-1* = intercellular adhesion molecule-1; *VCAM* = vascular cell adhesion molecule.

mediators, such as cytokines or bacterial LPSs. E-selectin mediates adhesion of neutrophils, monocytes and certain lymphocytes by binding to Lewis X or Lewis A.

L-selectin (CD62L, LAM-1, Leu-8) is a "homing" molecule found on many types of leukocytes. It binds lymphocytes to high endothelial venules (HEVs) in lymphoid tissues, thus regulating trafficking. It also binds glycan-bearing cell adhesion molecule-1 (GlyCAM-1), mucosal addressin cell adhesion molecule-1 (MadCAM-1) and CD34.

This selectin-mediated interaction of PMNs and endothelial cells in turn enhances G-protein–mediated activation by endothelial chemokines. The chemokine-induced adhesion involves actin reorganization and α-integrins on neutrophil surfaces.

Addressins

Vascular addressins are mucin-like glycoproteins including GlyCAM-1, P-selectin glycoprotein-1 (PSGL-1), E-selectin ligand (ESL-1) and CD34. They possess sialyl-Lewis X, which binds the lectin domain of selectins. Addressins are expressed at leukocyte and endothelium surfaces. They regulate localization of leukocyte subpopulations and are involved in lymphocyte activation.

Integrins

Chemokines, lipid mediators and proinflammatory molecules activate cells to express integrin adhesion molecules (see Chapter 3). Integrins have transmembrane α- and β-chains arranged as heterodimers. They participate in cell–cell interactions, cell–ECM binding and leukocyte recruitment. *V*ery *l*ate *a*ctivation (VLA) molecules include VLA-4 ($\alpha_4\beta_1$) on leukocytes and lymphocytes, which bind

vascular cell adhesion molecule-1 (VCAM-1) on endothelial cells. The β2 (CD18) integrins form molecules by association with α-integrin chains: $\alpha_1\beta_2$ and $\alpha_m\beta_2$ (CD11b/CD18 or Mac-1) bind ICAM-1 and ICAM-2, respectively. Leukocyte integrins exist in a low-affinity state but are converted to a high-affinity state via a G-protein–mediated conformational change when these cells are activated. This results in a transition from leukocyte rolling to firm adhesion.

Immunoglobulins

Adhesion molecules of the Ig superfamily include ICAM-1, ICAM-2 and VCAM-1, all of which interact with integrins on leukocytes to mediate recruitment. They are expressed at the surfaces of cytokine-stimulated endothelial cells and some leukocytes, as well as certain epithelial cells, such as pulmonary alveolar cells.

Junctional adhesion molecules (JAMs) are also proteins of the Ig superfamily. JAM-A, JAM-B and JAM-C are found on endothelial cells, leukocytes and platelets. JAM-A binds the integrin LFA-1; VLA-4 binds to JAM-B; MAC1 connects with JAM-C.

Adhesion Molecules Mediating Endothelial Barrier Function and Leukocyte Recruitment

Endothelial cells adhere to one another to seal off the vascular space from adjacent tissue. The vascular endothelial–cadherin complex forms adherens junctions, and occludin, claudins and JAMs, PECAM-1 (platelet endothelial cell adhesion molecule) and CD99, each adherent to homologous molecules on adjacent endothelial cells, form tight junctions. Together, these molecules create a barrier to transmigration of cells from the vascular space (Fig. 2-28A).

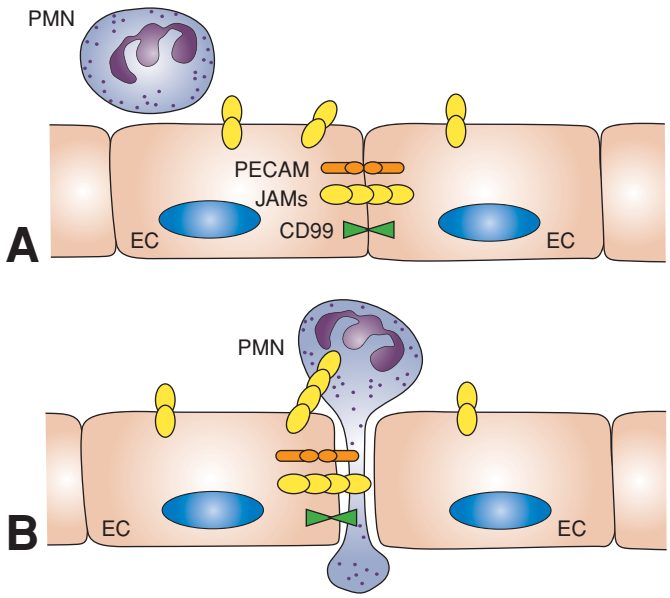

FIGURE 2-28. Endothelial cell junctional molecules participate in leukocyte recruitment. A. Junctional molecules contribute to cell–cell adhesion and maintenance of endothelial barrier function. **B.** These same molecules regulate paracellular transmigration of leukocytes. *PMN* = polymorphonuclear neutrophil; *EC* = endothelial cell; *PECAM* = platelet endothelial cell adhesion molecule, CD31; *JAMs* = junctional adhesion molecules.

Tethering, Rolling and Firm Adhesion Are Prerequisites for Leukocyte Recruitment into Tissues

Endothelial cells are activated by blood flow patterns and exposure to proinflammatory cytokines and vasoactive peptides. These trigger NFκB and JNK-AP-1 signaling to elicit a proadhesive phenotype, with increased surface cell adhesion molecules (Fig. 2-26). Cytokines or chemokines specific to the inflammatory process induce adhesion molecules on endothelium and leukocytes and change their affinity for their ligands.

For a rolling cell to adhere, there is a selectin-dependent reduction in rolling velocity. Early increases in rolling depend on P-selectin, whereas cytokine-induced E-selectin initiates early adhesion. Integrin family members function cooperatively with selectins to facilitate rolling and subsequent firm adhesion of leukocytes. Leukocyte β_1 and β_2 integrins bind their counterreceptors, the Ig superfamily of ligands (VCAM-1, ICAM-1, ICAM-2, JAMs), on endothelium. This process further slows leukocytes and increases the exposure time for each leukocyte to endothelium. Simultaneously, engagement of adhesion molecules activates intracellular signal transduction. As a result, leukocytes and endothelial cells are further activated, with subsequent upregulation of L-selectin and integrin binding. The net result is firm adhesion.

Recruitment of specific subsets of leukocytes to areas of inflammation results from unique patterns or relative densities of adhesion molecules on cell surfaces. For subsets of leukocytes, each cell type can express specific adhesion molecules. Leukocyte adherence to arterioles and capillaries also has different requirements, as hydrodynamic forces in these vessels differ. Regional recruitment is also influenced by vascular flow conditions, which alter expression of adhesion molecules and leukocyte transmigration.

Chemotactic Molecules Direct Neutrophils to Sites of Injury

Leukocytes must be accurately positioned at sites of inflammatory injury to function correctly. For the right subsets of leukocytes to arrive in a timely fashion, they must get very specific directions. ***Leukocytes are guided through vascular and extravascular spaces by a complex interaction of attractants, repellants and adhesion molecules.*** **Chemotaxis** is a dynamic and energy-dependent process of directed cell migration. Blood leukocytes are recruited by chemoattractants released by endothelial cells. They migrate from the endothelium toward the target tissue, down a gradient of one chemoattractant in response to a second, more distal chemoattractant gradient.

PMNs must integrate the various signals to arrive at the correct site at the correct time for their assigned tasks. Their most important chemotactic factors are C5a, bacterial and mitochondrial products (particularly low–molecular-weight N-formylated peptides such as FMLP), products of arachidonic acid metabolism (especially LTB_4), products of ECM degradation and chemokines. The latter represent a key mechanism of leukocyte recruitment because they generate a chemotactic gradient by binding to ECM proteoglycans. As a result, high concentrations of chemokines persist at sites of tissue injury. In turn, specific receptors on migrating

leukocytes bind matrix-bound chemokines, moving cells along the chemotactic gradient to the site of injury.

Chemotactic factors for other cell types, including lymphocytes, basophils and eosinophils, are also produced at sites of tissue injury and may be secreted by activated endothelial cells, tissue parenchymal cells or other inflammatory cells. They include PAF, TGF-β, neutrophilic cationic proteins and lymphokines. ***The cocktail of chemokines within a tissue largely determines the types of leukocytes that come to the site.*** When cells arrive at their destination, they must then be able to stop there. Contact guidance, regulated adhesion molecules or inhibitory signals determine the final arrest of specific cells in specific tissue locations.

Leukocytes Traverse the Endothelium to Gain Access to Tissues

Leukocytes adherent to the endothelium emigrate by **paracellular diapedesis** (i.e., passing between adjacent endothelial cells). Responding to chemokine gradients, neutrophils extend pseudopods and insinuate themselves between the endothelial cells, then out of the intravascular space.

Several adhesion molecules, expressed intercellularly, contribute to tight adhesion between endothelial cells. However, they may also release during leukocyte transmigration or redistribute to cell surfaces to facilitate leukocyte recruitment (Fig. 2-28). JAMs are proteins of the immunoglobulin superfamily. JAM-A, JAM-B and JAM-C are expressed on endothelial cells, leukocytes and platelets. JAMs, CD99 and PECAM-1 (CD31, platelet endothelial cell adhesion molecule) on endothelial cell surfaces bind to each other to keep cells together. These junctions separate under the influence of inflammatory mediators, intracellular signals generated by adhesion molecule engagement and signals from the adherent neutrophils. Neutrophils mobilize elastase to their pseudopod membranes, inducing endothelial cells to retract and separate at the advancing edge of the neutrophil, a process facilitated by PMN-elicited increases in endothelial cell intracellular calcium. At the same time, JAMs and particularly CD99 and PECAM are integral to neutrophil adhesion to endothelial cells during this process of transmigration.

A little-understood method of migration of neutrophils through endothelial cells is **transcellular diapedesis**. In tissues with fenestrated microvessels, such as gut mucosa and secretory glands, PMNs may traverse thin regions of endothelium, called **fenestrae,** without damaging endothelial cells. In nonfenestrated microvessels, PMNs may cross the endothelium using endothelial cell caveolae or pinocytotic vesicles, which form small, membrane-bound passageways across the cell.

INFLAMMATORY CELL FUNCTIONS IN ACUTE INFLAMMATION

Phagocytosis of Microorganisms and Tissue Debris

Many inflammatory cells—including monocytes, tissue macrophages, dendritic cells and neutrophils—recognize, internalize and digest foreign material, microorganisms or cellular debris by **phagocytosis**. This term, first used over a century ago by Élie Metchnikoff, is now defined as ingestion by eukaryotic cells of large (usually >0.5 μm) insoluble particles and microorganisms. **Phagocytes** are effector cells. The

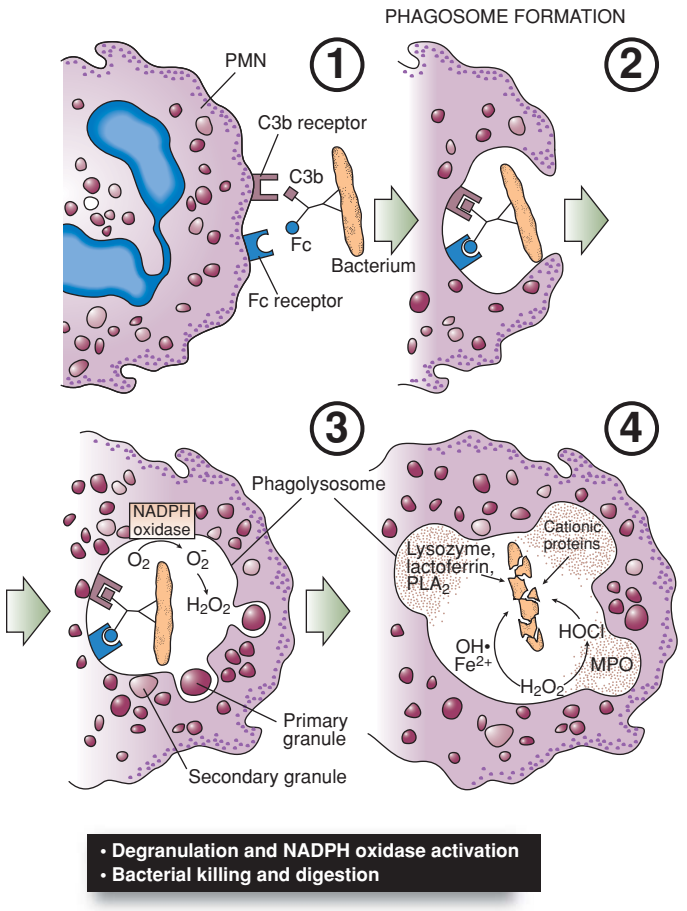

FIGURE 2-29. Mechanisms of neutrophil bacterial phagocytosis and cell killing. 1. Opsonins such as C3b coat the surface of microbes, allowing recognition by the neutrophil C3b receptor. **2.** Receptor clustering triggers intracellular signaling and actin assembly within the neutrophil. Pseudopods form around the microbe to enclose it within a phagosome. **3.** Lysosomal granules fuse with the phagosome to form a phagolysosome, into which the lysosomal enzymes and oxygen radicals are released to **(4)** kill and degrade the microbe. *Fe^{2+} = ferrous iron; HOCl* = hypochlorous acid; *MPO* = myeloperoxidase; *PLA_2* = phospholipase A_2; *PMN* = polymorphonuclear neutrophil.

complex process involves a sequence of transmembrane and intracellular signaling events:

1. **Recognition:** Phagocytosis is initiated when specific receptors on the surface of phagocytic cells recognize their targets (Fig. 2-29). Phagocytosis of most biological agents is enhanced by, if not dependent on, their coating (**opsonization**) with plasma components **(opsonins)**, particularly immunoglobulins or C3b. Phagocytic cells have specific opsonic receptors, including those for Ig Fcγ (FcRs) and complement components. Many pathogens have evolved mechanisms to evade phagocytosis by leukocytes. Polysaccharide capsules, protein A, protein M or peptidoglycans around bacteria can prevent complement deposition or antigen recognition and receptor binding.
2. **Signaling:** Clumping of opsonins at bacterial surfaces causes phagocyte plasma membrane Fcγ receptors to cluster. Subsequent phosphorylation of immunoreceptor, tyrosine-based, activation motifs (ITAMs), in the cytosolic domain or γ subunit of the receptor, triggers intracellular

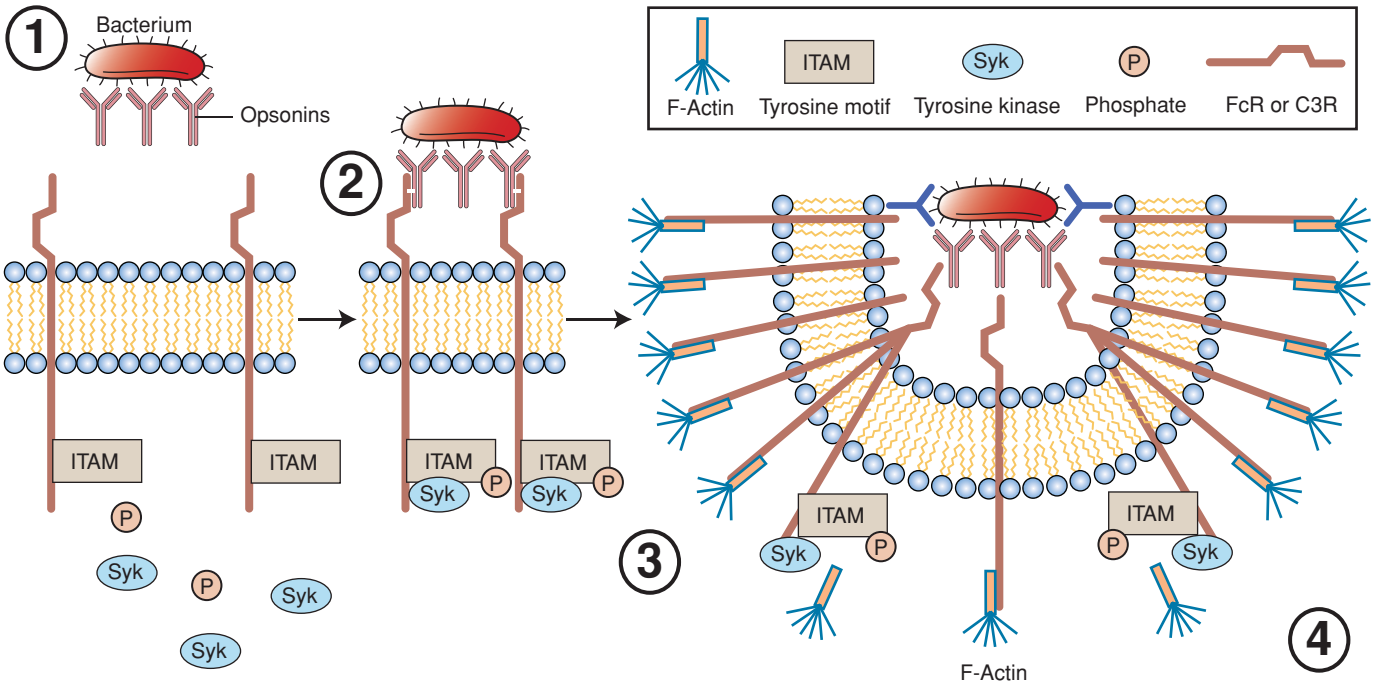

FIGURE 2-30. Intracellular signaling during leukocyte phagocytosis. 1. Opsonins coating the surface of microbes or foreign material are recognized by the neutrophil C3b receptor. **2.** Receptor clustering triggers **(3)** phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) on the receptor, and tyrosine kinases initiate intracellular signaling. **4.** Polymerized actin filament aggregates beneath the plasma membrane to form a pseudopod to enclose the foreign agent.

signaling via tyrosine kinases that associate with the Fcγ receptor (Fig. 2-30).

3. **Internalization:** For Fcγ receptor or CR3, actin assembly occurs directly under the phagocytosed target. Polymerized actin filaments push the plasma membrane forward. The plasma membrane remodels to increase surface area and to form pseudopods surrounding the foreign material. The resulting phagocytic cup engulfs the foreign agent. The membrane then "zippers" around the opsonized particle to enclose it in a vacuole called a **phagosome** (Fig. 2-29).
4. **Digestion:** The phagosome with the foreign material fuses to cytoplasmic lysosomes to form a **phagolysosome,** into which lysosomal enzymes are released. The acid pH in the phagolysosome activates these hydrolytic enzymes, which then degrade the phagocytosed material. Some microorganisms have evolved mechanisms for evading killing by neutrophils by preventing lysosomal degranulation or inhibiting neutrophil enzymes.

Inflammatory Cell Enzymes Provide Antimicrobial Defense and Debridement

PMNs and macrophages are critical for degrading microbes and cell debris but may also cause tissue injury (Fig. 2-31): release of PMN granule contents at sites of injury is a double-edged sword. On the one hand, debridement of damaged tissue by proteolytic breakdown facilitates tissue repair. On the other hand, degradative enzymes can damage endothelial and epithelial cells and degrade connective tissue.

Inflammatory cells possess the armamentarium of enzymes used to degrade microbes and tissue. Neutrophil primary, secondary and tertiary granules are morphologically and biochemically distinct; each has unique activities (Fig. 2-17).

- **Primary granules (azurophilic granules):** Antimicrobial and proteinase activity of these granules can directly activate other inflammatory cells. Potent acid hydrolases and

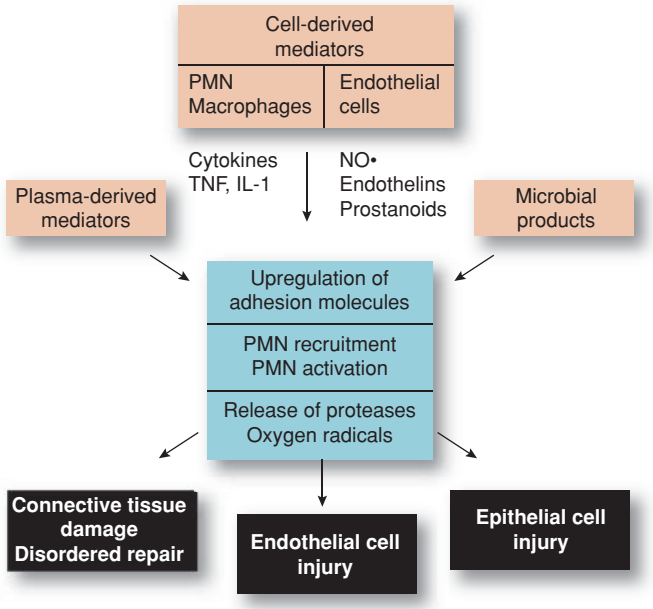

FIGURE 2-31. Mechanisms of cell and tissue damage. *IL* = interleukin; *LPS* = lipopolysaccharide; *NO•* = nitric oxide; *PMN* = polymorphonuclear neutrophil; *TNF* = tumor necrosis factor.

neutral serine proteases digest diverse macromolecules. Lysozyme and PLA_2 degrade bacterial cell walls and biological membranes and are important in killing bacteria. Myeloperoxidase, a key enzyme in the metabolism of hydrogen peroxide, generates toxic ROS.

- **Secondary granules (specific granules):** These contain PLA_2, lysozyme and proteins that initiate killing of specific cells. In addition, their contents include the cationic lactoferrin, a vitamin B_{12}–binding protein and matrix metalloproteinase (collagenase) specific for type IV collagen.
- **Tertiary granules (small storage granules, C granules):** These granules are released at the leading front of neutrophils during chemotaxis. They are the source of enzymes that promote migration of cells through basement membranes and tissues, including proteinases, cathepsin, gelatinase and urokinase-type plasminogen activator (u-PA).

In the macrophage, the specific array of agents released varies, depending on the role of the macrophage as pro- or anti-inflammatory (Figs. 2-17C and 2-20).

Proteinases

Proteolytic enzymes (proteinases) are stored in cytoplasmic granules and secretory vesicles of neutrophils. They cleave peptide bonds in polypeptides. As PMNs leave the circulation, they release proteinases that enable them to penetrate the ECM and migrate to sites of injury, there to degrade matrix, cell debris and pathogens. Neutrophils are not the only source of proteinases, however. Monocytes, eosinophils, basophils, mast cells, lymphocytes and tissue cells, including endothelium, also produce proteinases.

Proteinases are grouped by their catalytic activity: serine proteinases and metalloproteinases are neutral enzymes that work in extracellular spaces; cysteine proteinases and aspartic proteinases are acidic and act in the acidic milieu of lysosomes (Table 2-3). These enzymes target many intracellular and extracellular proteins, such as (1) inflammatory products; (2) debris from damaged cells, microbial proteins and matrix proteins; (3) microorganisms; (4) plasma proteins, including complement and clotting proteins, immunoglobulins and cytokines; (5) matrix macromolecules (e.g., collagen, elastin, fibronectin and laminin); and (6) lymphocytes and platelets.

Serine Proteinases

Serine proteinases degrade extracellular proteins, cell debris and bacteria. Human leukocyte elastase is primarily responsible for degrading fibronectin. Cathepsin G converts angiotensin I to angiotensin II, thereby mediating smooth muscle contraction and vascular permeability. u-PA dissolves fibrin clots to generate plasmin at wound sites, degrades ECM proteins and activates procollagenases to create a path for leukocyte migration. Although serine proteinases are most important in digesting ECM molecules, they modify cytokine activity; they solubilize membrane-bound cytokines and receptors by cleaving active cytokines from inactive precursors as well. They also detach cytokine receptors from cell surfaces, thereby regulating cytokine activity.

Metalloproteinases

At least 25 metalloproteinases are known (see Chapter 3). Matrix metalloproteinases (**MMPs,** matrixins) degrade all ECM components, including basement membranes. They are subgrouped by substrate specificity into interstitial collagenases, gelatinases, stromelysins, metalloelastases and matrilysin. Proteins with metalloproteinase and disintegrin domains (ADAMs) regulate neutrophil infiltration by targeting disintegrins, polypeptides that disrupt integrin-mediated binding of cells to each other and to the ECM.

TABLE 2-3
PROTEINASES IN INFLAMMATION

Enzyme Class	Examples
Neutral Proteinases	
Serine proteinases	Human leukocyte elastase Cathepsin G Proteinase 3 Urokinase-type plasminogen Activator
Metalloproteinase	Collagenases (MMP-1, MMP-8, MMP-13) Gelatinases (MMP-7, MMP-9) Stromelysins (MMP-3, MMP-10, MMP-11) Matrilysin (MMP-7) Metalloelastase (MMP-12) ADAMs-7, -9, -15, -17
Acidic Proteinases	
Cysteine proteinases	Cathepsins, S, L, B, H
Aspartic proteinases	Cathepsin D

MMP = matrix metalloproteinase; ADAM = *A* protein with *di*sintegrin *a*nd *m*etalloproteinase domains.

Cysteine Proteinases and Aspartic Proteinases

These acid proteinases function primarily within lysosomes of leukocytes to degrade intracellular proteins.

Proteinase Inhibitors

The proteolytic environment is regulated by a battery of inhibitors. During wound healing, these antiproteases protect from tissue damage by limiting protease activity. ECM remodeling entails a balance between enzymes and their inhibitors. In chronic wounds, ongoing influx of neutrophils, with their proteases and ROS, may overwhelm and inactivate these inhibitors, allowing continuation of proteolysis (see Chapter 3). Known proteinase inhibitors include:

- **α_2-Macroglobulin:** Nonspecific inhibitor of all classes of proteinases, primarily found in plasma
- **Serpins:** The major inhibitors of serine proteinases
- **α_1-Antiproteases (α_1-antitrypsin, α_1-antichymotrypsin):** Inhibit human leukocyte elastase and cathepsin G
- **Secretory leukocyte proteinase inhibitor (SLPI), Elafin:** Inhibit proteinase 3
- **Plasminogen activator inhibitors (PAIs):** Inhibit u-PA
- **Tissue inhibitors of metalloproteinases (TIMP-1s):** Specific for tissue matrix metalloproteinases

Inflammatory Cells Kill Bacteria by ROS- and Non-ROS-Mediated Mechanisms

Bacterial Killing by Oxygen Species

Phagocytosis is accompanied by metabolic reactions in inflammatory cells that lead to production of oxygen metabolites (see Chapter 1). These ROS are more reactive than oxygen itself and contribute to the killing of ingested bacteria (Fig. 2-29).

- **Superoxide anion** (O_2^-): Phagocytosis activates an NADPH oxidase in PMN cell membranes. NADPH oxidase is a multicomponent electron transport complex that reduces molecular oxygen to O_2^-. Activation of this enzyme is enhanced by prior exposure of cells to a chemotactic stimulus or LPS. NADPH oxidase increases oxygen consumption and stimulates the hexose monophosphate shunt. Together, these cell responses are the **respiratory burst**.
- **Hydrogen peroxide** (H_2O_2): O_2^- is rapidly converted to H_2O_2 at the cell surface and in phagolysosomes by SOD. H_2O_2 is stable and is a source for generating additional reactive oxidants.
- **Hypochlorous acid** (HOCl): Myeloperoxidase (MPO), a neutrophil product with a very strong cationic charge, is secreted from granules during exocytosis. In the presence of a halide, usually chlorine, MPO catalyzes conversion of H_2O_2 to HOCl. This powerful oxidant is a major bactericidal agent made by phagocytic cells. It also helps activate neutrophil-derived collagenase and gelatinase, both of which are secreted as latent enzymes. HOCl also inactivates α_1-antitrypsin.
- **Hydroxyl radical** (OH•): Reduction of H_2O_2 via the Haber-Weiss reaction, forms the highly reactive OH•. This occurs slowly at physiologic pH, but if ferrous iron (Fe^{2+}) is present, the Fenton reaction rapidly converts H_2O_2 to OH•, which is a potent bactericidal agent. Further reduction of OH• yields H_2O (see Chapter 1).
- **Nitric oxide** (NO•): Phagocytes and endothelial cells produce NO• and its derivatives, which have many physiologic and nonphysiologic effects. NO• and other free radicals interact with one another to balance their cytotoxic and cytoprotective effects. NO• can react with oxygen radicals to form toxic molecules such as peroxynitrite and *S*-nitrosothiols, or it can scavenge O_2^-, thus reducing the amount of toxic radicals.

Monocytes, macrophages and eosinophils also make oxygen radicals, depending on their state of activation and the stimulus to which they are exposed. Production of ROS by these cells contributes to their bactericidal and fungicidal activity and to their ability to kill certain parasites. The importance of oxygen-dependent bacterial killing is exemplified in **chronic granulomatous disease** of childhood, a hereditary deficiency of NADPH oxidase. Affected patients fail to produce O_2^- and H_2O_2 during phagocytosis and so are prone to recurrent infections, especially with gram-positive cocci. Patients with a related genetic deficiency in MPO cannot produce HOCl and are excessively susceptible to fungal infections with *Candida* (Table 2-4).

TABLE 2-4
CONGENITAL DISEASES OF DEFECTIVE PHAGOCYTIC CELL FUNCTION CHARACTERIZED BY RECURRENT BACTERIAL INFECTIONS

Disease	Defect
Leukocyte adhesion deficiency (LAD)	LAD-1 (defective β_2-integrin expression or function [CD11/CD18]) LAD-2 (defective fucosylation, selectin binding)
Hyper-IgE-recurrent infection, (Job) syndrome	Poor chemotaxis
Chediak-Higashi syndrome	Defective lysosomal granules, poor chemotaxis
Neutrophil-specific granule deficiency	Absent neutrophil granules
Chronic granulomatous disease	Deficient NADPH oxidase, with absent H_2O_2 production
Myeloperoxidase deficiency	Deficient HOCl production

H_2O_2 = hydrogen peroxide; HOCl = hypochlorous acid; Ig = immunoglobulin; NADPH = nicotinamide adenine dinucleotide phosphate.

Nonoxidative Bacterial Killing

Phagocytes, particularly PMNs and monocytes/macrophages, have substantial oxygen-independent antimicrobial activity. This activity mainly involves bactericidal proteins in cytoplasmic granules, such as lysosomal acid hydrolases and specialized noncatalytic proteins unique to inflammatory cells.

- **Lysosomal hydrolases:** Primary and secondary granules in PMNs and lysosomes of mononuclear phagocytes contain hydrolases, such as sulfatases, phosphatases and other enzymes that can digest polysaccharides and DNA.
- **Bactericidal/permeability-increasing protein (BPI):** This cationic protein in PMN primary granules can kill many gram-negative bacteria but is not toxic to gram-positive bacteria or eukaryotic cells. BPI inserts into bacterial envelope outer membranes and increases their permeability. Activation of certain phospholipases and enzymes then degrades bacterial peptidylglycans.
- **Defensins:** Primary granules of PMNs and lysosomes of some mononuclear phagocytes contain these cationic proteins, which kill many gram-positive and gram-negative bacteria, fungi and some enveloped viruses. Some also kill host cells. Defensins are chemotactic for phagocytes, immature dendritic cells and lymphocytes and so help mobilize and amplify antimicrobial immunity.
- **Lactoferrin:** Lactoferrin is an iron-binding glycoprotein in neutrophil secondary granules and in most body secretory fluids. It chelates iron and so competes with bacteria for iron. It may help generate OH• for oxidative killing of bacteria.
- **Lysozyme:** This bactericidal enzyme is found in many tissues and body fluids, in primary and secondary granules of PMNs and in lysosomes of mononuclear phagocytes. Peptidoglycans of gram-positive bacterial cell walls are sensitive to degradation by lysozyme; gram-negative bacteria are usually resistant to it.
- **Eosinophils' bactericidal proteins:** Eosinophils have several granule-bound cationic proteins, the most important

of which are major basic protein (MBP) and eosinophilic cationic protein. Both are potent killers of many parasites, though not bacteria. MBP accounts for half of the total protein of eosinophil granules.

Defects in Leukocyte Function

The importance of acute inflammatory cells in protection from infection is underscored by the frequency and severity of infections when PMNs are depleted or defective. ***The most common such deficit is iatrogenic neutropenia due to cancer chemotherapy.*** Functional impairment of phagocytes may occur at any step in the sequence: adherence, emigration, chemotaxis, phagocytosis or killing. These disorders may be acquired or congenital. Acquired diseases, such as leukemia, diabetes, malnutrition, viral infections and sepsis, often entail defects in inflammatory cell function. Table 2-4 shows representative examples of congenital diseases linked to defective phagocytic function.

REGULATION OF THE ACUTE INFLAMMATORY RESPONSE

Infection, foreign agents and injured tissue are triggers for acute inflammation. The specificity and intensity of inflammatory mediators, both humoral and cellular, affect tissue responses to the offending agents. Left unchecked, acute inflammation can cause serious tissue injury and death. However, genetic and biochemical regulation mitigates "bystander" effects of acute inflammation, thus allowing resolution and repair. Positive and negative regulation and modulation of these responses occurs at several levels, including (1) release of pro- or anti-inflammatory mediators, (2) expression of surface molecules, (3) intracellular signaling pathways with positive and negative feedback loops and (4) gene expression of molecules involved in the inflammatory process.

Soluble Mediators Activate Common Intracellular Pathways

Plasma- and cell-derived proinflammatory mediators amplify tissue responses in a positive feedback loop, with progressive amplification and resultant tissue injury. Complement, proinflammatory cytokines and, in some cases, immune complexes activate signal transduction pathways that control expression of proinflammatory mediators, including TNF-α, IL-1, chemokines and adhesion molecules. Secreted cytokines then propagate responses by activating other cell types via these and similar pathways. The process by which diverse stimuli lead to functional inflammatory responses is **stimulus–response coupling**. Stimuli include microbial products and the many plasma- or cell-derived inflammatory mediators described in this chapter. Although intracellular signaling pathways are complex and vary with cell type and stimulus, some common intracellular pathways are associated with inflammatory cell activation by soluble mediators, including G-protein, TNF receptor (TNFR) and JAK-STAT pathways (Janus kinase–signal transducer and activator of transcription) (Figs. 2-32, 2-33, and 2-34, respectively).

The inflammatory response is also regulated so as to contain the cascade described above and to limit tissue damage.

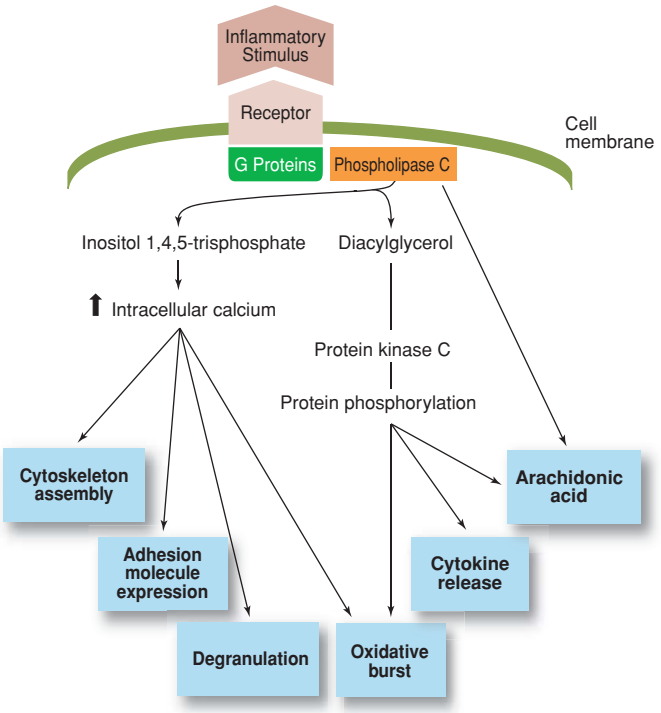

FIGURE 2-32. G-protein–mediated intracellular signal transduction pathway common to many inflammatory stimuli.

Inducible cytokines, like IL-4, IL-10 and IL-12, block NFκB activation by stabilizing its inhibitor, Iκb, thus reducing the response. Protease inhibitors, such as secreted leukocyte protease inhibitor (SLPI); inhibitors of metalloproteases (e.g., tissue inhibitor of MMPs [TIMPs]); antioxidant enzymes (e.g., peroxide dismutase); lipoxins; glucocorticoids and phosphatases; and transcriptional regulatory factors, including suppressor of cytokine signaling (SOC), inhibit the activation of proinflammatory factors, oxidants and signaling pathways.

G-Protein Pathways

Many chemokines, hormones, neurotransmitters and other mediators signal via G-binding proteins (Fig. 2-32). G proteins

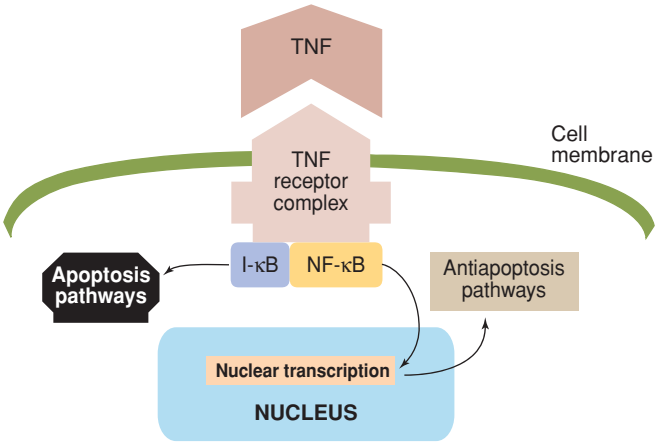

FIGURE 2-33. Tumor necrosis factor (TNF) receptor–mediated intracellular signal transduction pathway.

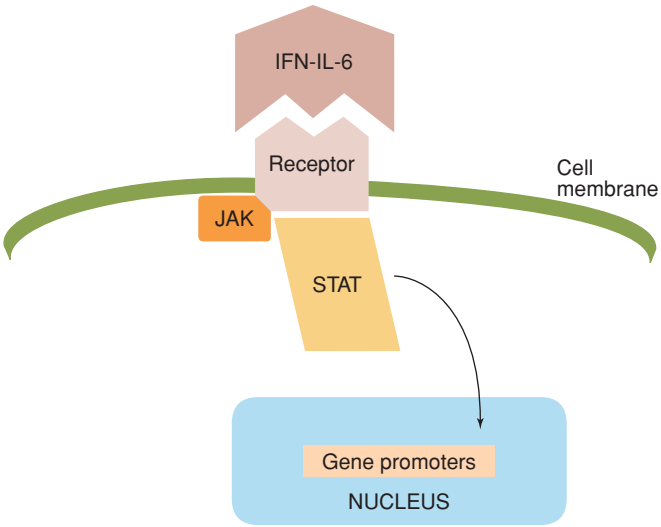

FIGURE 2-34. JAK-STAT–mediated intracellular transduction pathway. *IFN* = interferon; *IL* = interleukin.

vary in downstream intracellular signaling pathways, but common activities include:

- **Ligand–receptor binding:** Binding of a stimulatory factor to a specific cell membrane receptor creates a ligand–receptor complex. Exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) activates the G protein, which dissociates into subunits that, in turn, activate phospholipase C (PLC) and phosphatidylinositol-3-kinase (PI3K).
- **Phospholipid metabolism of cell membranes:** PLC hydrolyzes a plasma membrane phosphoinositide (phosphatidylinositol bisphosphate [PIP_2]) to generate diacylglycerol and inositol trisphosphate (IP_3).
- **Elevated cytosolic free calcium:** IP_3 induces release of stored intracellular Ca^{2+}. Together with influx of Ca^{2+} from the extracellular fluid, IP_3 increases cytosolic free calcium, a key event in inflammatory cell activation.
- **Protein phosphorylation and dephosphorylation:** Specific tyrosine kinases bind the ligand–receptor complex and initiate a series of protein phosphorylations.
- **Protein kinase C activation:** Protein kinase C (PKC) and other protein kinases activate intracellular signaling pathways, often activating gene transcription.

Tumor Necrosis Factor Receptor Pathways

TNF-α is central to the development of inflammation and its symptoms. It induces tumor cell apoptosis and regulates immune functions (Fig. 2-33). TNF-α and related proteins bind two cell surface receptors to form a multiprotein-signaling complex at the cell membrane. This complex can trigger (1) apoptosis-related enzymes (i.e., **caspases**) (see Chapter 1), (2) inhibitors of apoptosis or (3) the transcription factor **NFκB**. NFκB activity is regulated by association with, and disassociation from, the NFκB inhibitor, IκB. If IκB is bound to NFκB, the latter cannot translocate to the nucleus, where it can act as a transcriptional activator. This latter pathway is critical to regulation of TNF-mediated events during inflammation.

JAK-STAT Pathway

This pathway provides a direct route from extracellular polypeptides (e.g., growth factors) or cytokines (e.g., interferons or interleukins) through cell receptors to gene promoters in the nucleus. Ligand–receptor interactions elicit transcription complexes of JAK-STAT. STAT proteins translocate to the nucleus, where they regulate gene promoters (Fig. 2-34).

Pathogens and Damaged Cells Regulate Gene Expression

Four phases of gene expression in inflammation are shown in Fig. 2-35.

1. **Initiation** of an inflammatory response, often by microbial products
2. **Gene activation** to induce proinflammatory mediators
3. **Reprogramming** to silence acute proinflammatory genes and activate anti-inflammatory mediators
4. **Gene silencing** to promote resolution of inflammatory responses and allow tissue to recover its integrity

Initiation of Inflammation

Infectious agents or damaged cells trigger signaling pathways, leading to an innate or adaptive immune response. In the setting of infection, **pathogen-associated microbial patterns** (PAMPs) of microorganisms are recognized by membrane-bound or endosomal families of **pattern-recognition receptors** (PRRs). **Danger (damage)-associated molecular patterns** (DAMPs) derived from damaged cells are released extracellularly after tissue injury and are also recognized by PRRs located on cell surfaces and intracellularly. Together, they activate intracellular cascades to drive a coordinated immune response (Figs. 2-36 and 2-37).

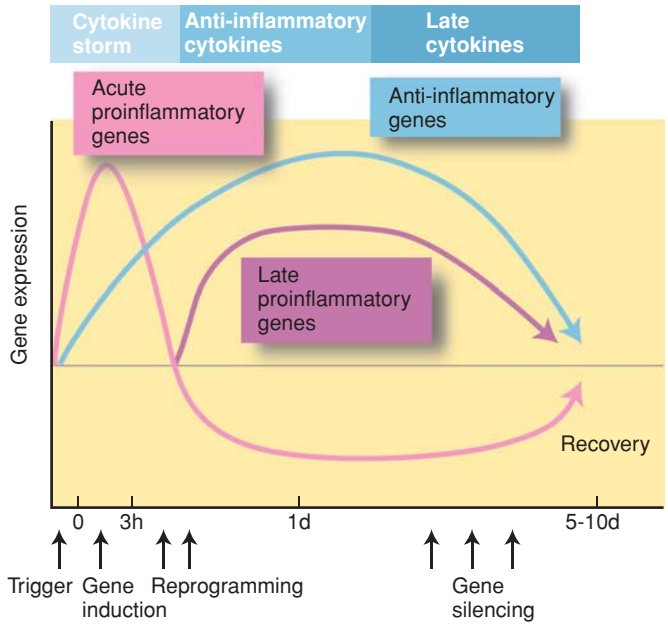

FIGURE 2-35. Time course of gene expression in the activation and regulation phases of the acute inflammatory response.

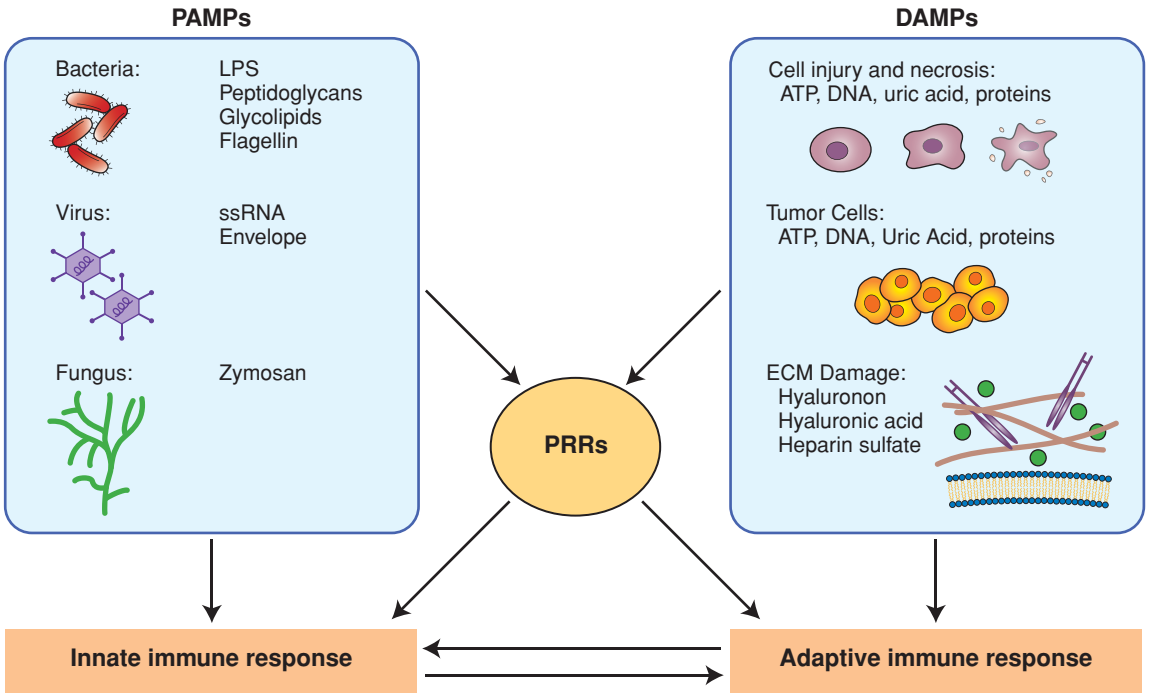

FIGURE 2-36. Pathogen-associated molecular pattern molecules (PAMPS) and damage-associated molecular pattern molecules (DAMPS) initiate adaptive and innate immune responses. Microbes release PAMPs. Damaged cells and tissue release DAMPS. Binding to receptors belonging to the family of pattern recognition receptors (PRRs) mediates innate and adaptive immune responses.

With activation, the multifaceted inflammatory response commences and is amplified by (1) release of cytokines and chemokines, (2) activation of coagulation and complement cascades and (3) release of free radical products (Fig. 2-37).

Pattern-Recognition Receptors

Four families of PRRs are found on inflammatory and immune cells: (1) Toll-like receptors, (2) nucleotide oligomerization domain leucine-rich repeat proteins (NOD-like receptors), (3) cytoplasmic caspase activation and recruitment domain helicases and (4) C-type lectin receptors.

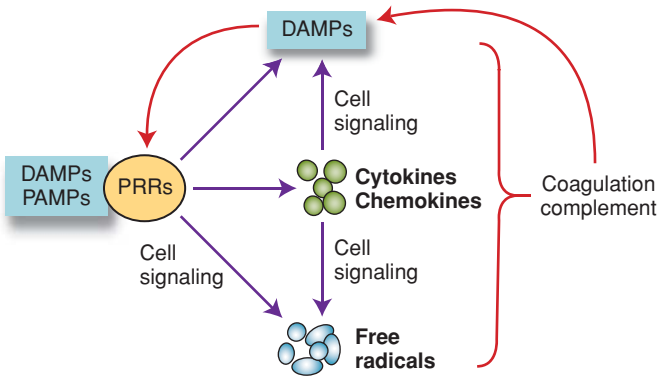

FIGURE 2-37. Damage-associated molecular pattern molecules (DAMPs) and pathogen-associated molecular pattern molecules (PAMPs) drive the multifaceted inflammatory response. Interaction of PAMPs and DAMPS with pattern recognition receptors (PRRs) initiates cell signaling, leading to enhanced activation of inflammatory mediators. These inflammatory signals can lead to further release of DAMPs and maintenance of the inflammatory response.

Toll-like Receptors

Toll-like receptors (TLRs) are a major class of PRRs found on immune, inflammatory and tissue cells, including macrophages, endothelial cells and epithelial cells (Table 2-5). TLRs on the cell surface recognize bacterial cell wall components and viruses. Genetic polymorphisms of TLRs are related to specific cellular responses. Thus, specific TLRs recognize lipid and carbohydrates on gram-positive bacteria, fungi, LPS of gram-negative bacteria and viral RNA. Although TLR engagement activates intracellular pathways to defend against microbial organisms, it may lead to excessive activation of cytokine cascades, notably contributing to septic shock (see Chapter 20). Thus, IL-1 and TLR signaling participate in many inflammatory and infectious diseases, which has prompted development of TLR antagonists.

NOD-like Receptors

These intracellular soluble proteins are sensors for microbes (PAMPs) and cell injury (DAMPs). They form large molecular complexes, **inflammasomes,** that are linked to the proteolytic activation of proinflammatory cytokines.

Cytoplasmic Caspase Activation and Recruitment Domain Helicases

This large family includes receptors such as retinoic acid inducible gene-1–like receptors (RIG-1-like receptors) expressed by macrophages, dendritic cells and fibroblasts.

TABLE 2-5
PATHOGEN RECOGNITION RECEPTORS

Toll-like Receptor	Cell Expression	Pathogen Recognized
TLR1	Macrophages Neutrophils	Lipid and carbohydrates from gram-positive bacteria
TLR2	Macrophages Basophils Neutrophils	Lipid and carbohydrates from gram-positive bacteria Fungal organisms
TLR3	Macrophages	Nucleic acid and derivatives Double-stranded RNA (viral DNA)
TLR4	Macrophages Basophils Neutrophils	LPS from gram-negative bacteria
TLR5	Macrophages Neutrophils	Bacterial flagellin
TLR6	Macrophages Neutrophils	Lipid and carbohydrates from gram-positive bacteria
TLR7	Macrophages Neutrophils	Nucleic acid and derivatives (viral DNA)
TLR8	Macrophages Neutrophils	Nucleic acid and derivatives (viral DNA)
TLR9	Macrophages Neutrophils	Nucleic acid and derivatives Bacterial DNA containing unmethylated CpG motifs
TLR10	Macrophages Neutrophils	Ligand unknown
TLR11 (pseudogene)	Macrophages Neutrophils	Bacterial profilin

LPS = lipopolysaccharide.

They are cytoplasmic RNA helicases that survey for microbes and recognize viral RNA in the cytoplasm.

C-Type Lectin Receptors

Glycosylated proteins have pathogen recognition functions in addition to their role in cell adhesion. Mainly expressed on macrophages and dendritic cells, these receptors participate in fungal recognition and modulation of innate immunity. Members include the mannose receptor, dendritic cell–specific ICAM-3–grabbing nonintegrin (DC-SIGN), dectin-1, dectin-2 and the collectins. When pathogens bind these receptors on epithelial and endothelial cells, additional DAMPS are released. This stimulates inflammatory cells and amplifies activation of coagulation and complement cascades. These, in turn, positively feed back to drive production of inflammatory mediators (i.e., cytokine, chemokines and DAMPS) (Fig. 2-37).

Gene Activation

The primary function of PRRs is to activate three major signaling pathways:

1. NFκB pathway
2. Mitogen-activated protein kinase/activator protein-1 (MAPK/AP-1) pathway
3. Interferon regulatory factor (IRF) pathway

Activation of NFκB promotes induction of proinflammatory cytokines. MAPK activates AP-1, which induces proinflammatory cytokines. IRFs activate type 1 IFNs and proinflammatory mediators. Via these signal transduction pathways, microbial recognition activates transcription factors, which in turn bind specific sequences in gene promoters. TLRs engage microbes and activate immune cells by signaling from the plasma membrane via NFκB and AP-1. TLRs also signal from endosomes via activation of IRFs to induce type 1 interferons. Activation of RIG-1 by binding to cytoplasmic viral RNA activates NFκB and IRF3 to increase interferon transcription. The soluble cytoplasmic retinoic acid inducible gene-1–like receptors (RLRs) activate NFκB, thus increasing IFN and inflammatory cytokine production.

Negative Regulators of Acute Inflammation

The natural resolution of acute inflammation involves removal of the initial stimulus and subsequent apoptosis of inflammatory cells. Decreased proinflammatory mediators and increased anti-inflammatory mediators brake the process. Removal of damaged tissue and cell debris allows proper healing to take place.

The response to injury is, however, variable. Genetics and the sex and age of a patient determine the response to injury, extent of healing and, especially, progression to chronic inflammatory disease. Negative regulators of inflammation include:

- **Gene silencing and reprogramming:** Inflammation is associated with gene reprogramming, which (1) silences acute proinflammatory gene expression, (2) increases anti-inflammatory gene expression and (3) allows the inflammatory process to start to resolve. Notably, TNF-α, IL-1β and other proinflammatory genes are repressed. At the same time, expression of anti-inflammatory factors, like IL-1 receptor antagonist (IL-1RA), TNF-α receptors, IL-6 and IL-10, increases.
- **Cytokines:** Several interleukins (IL-6, IL-10, IL-11, IL-12, IL-13) limit inflammation by reducing production of TNF-α. This may occur by preserving IκB, thus blocking cell activation and release of inflammatory mediators.
- **Protease inhibitors:** Secretory leukocyte proteinase inhibitor (SLPI) and TIMP-2 are important in reducing the responses of a variety of cell types, including macrophages and endothelial cells, and in decreasing connective tissue damage.
- **Lipoxins:** Lipoxins and aspirin-triggered lipoxins are anti-inflammatory lipid mediators that inhibit leukotriene biosynthesis.
- **Glucocorticoids:** Stimulating the hypothalamic–pituitary–adrenal axis increases release of immunosuppressive glucocorticoids. These have transcriptional and posttranscriptional suppressive effects on inflammatory response genes.
- **Kininases:** Kininases in plasma and blood degrade the potent proinflammatory mediator bradykinin.

- **Phosphatases:** A signal transduction mechanism that commonly regulates inflammatory cell signaling is rapid and reversible protein phosphorylation. Phosphatases and associated proteins balance the effect via dephosphorylation.
- **Transforming growth factor-β (TGF-β).** Apoptotic cells, particularly PMNs, induce TGF-β expression. TGF-β suppresses proinflammatory cytokines and chemokines, switches arachidonic acid–derived mediators to favor production of lipoxin and resolvin (resolution phase interaction products; omega-3 unsaturated fatty acid), causes recognition and clearance of apoptotic cells and debris by macrophages and stimulates anti-inflammatory cytokines and fibrosis.

OUTCOMES OF ACUTE INFLAMMATION

A combination of regulatory activities and the short life span of neutrophils limit the duration of acute inflammatory reactions. As the source of tissue injury is eliminated, inflammation recedes and normal tissue architecture and physiologic function are restored. How the inflammation ends depends on the balance between cell recruitment, cell division, cell emigration and cell death. If a tissue is to return to normal, the inflammatory process must be reversed: the stimulus to injury must be removed, proinflammatory signals turned off, acute inflammatory cell influx ended, tissue fluid balance restored, cell and tissue debris removed, normal vascular function restored, epithelial barriers repaired and the ECM regenerated. As signals for acute inflammation wane, apoptosis of PMNs limits the immune response and resolution begins.

However, inflammatory responses can lead to other outcomes (Fig. 2-38):

- **Scar:** Although the body may eliminate the offending agent, if a tissue is irreversibly injured, normal architecture is often replaced by a scar (see Chapter 3).
- **Abscess:** If the area of acute inflammation is walled off by inflammatory cells and fibrosis, PMN products destroy the tissue, leaving an abscess (see Chapter 1).
- **Lymphadenitis:** Localized acute and chronic inflammation may cause secondary inflammation of lymphatic channels **(lymphangitis)** and lymph nodes **(lymphadenitis)**. These inflamed lymphatic channels appear as red streaks, and lymph nodes are enlarged and painful. Affected lymph nodes show lymphoid follicle hyperplasia and proliferation of mononuclear phagocytes in the sinuses **(sinus histiocytosis)**.
- **Persistent inflammation:** If an insulting agent persists or resolution is incomplete, inflammation may persist. This may be a prolonged acute response, with continued influx of neutrophils and tissue destruction, or, more commonly, chronic inflammation.

CHRONIC INFLAMMATION

In chronic inflammation, inflammatory cells persist, the stroma becomes hyperplastic and tissue destruction and scarring may lead to organ dysfunction. The process may be localized, but it often progresses to disabling diseases, such as chronic lung disease, rheumatoid arthritis, ulcerative colitis, granulomatous diseases, autoimmune diseases and chronic dermatitis. Acute and chronic inflammation are ends of a dynamic continuum with overlapping morphologies: (1) inflammation that features continued recruitment of chronic inflammatory cells is followed by (2) tissue injury due to a prolonged inflammatory response and (3) an often

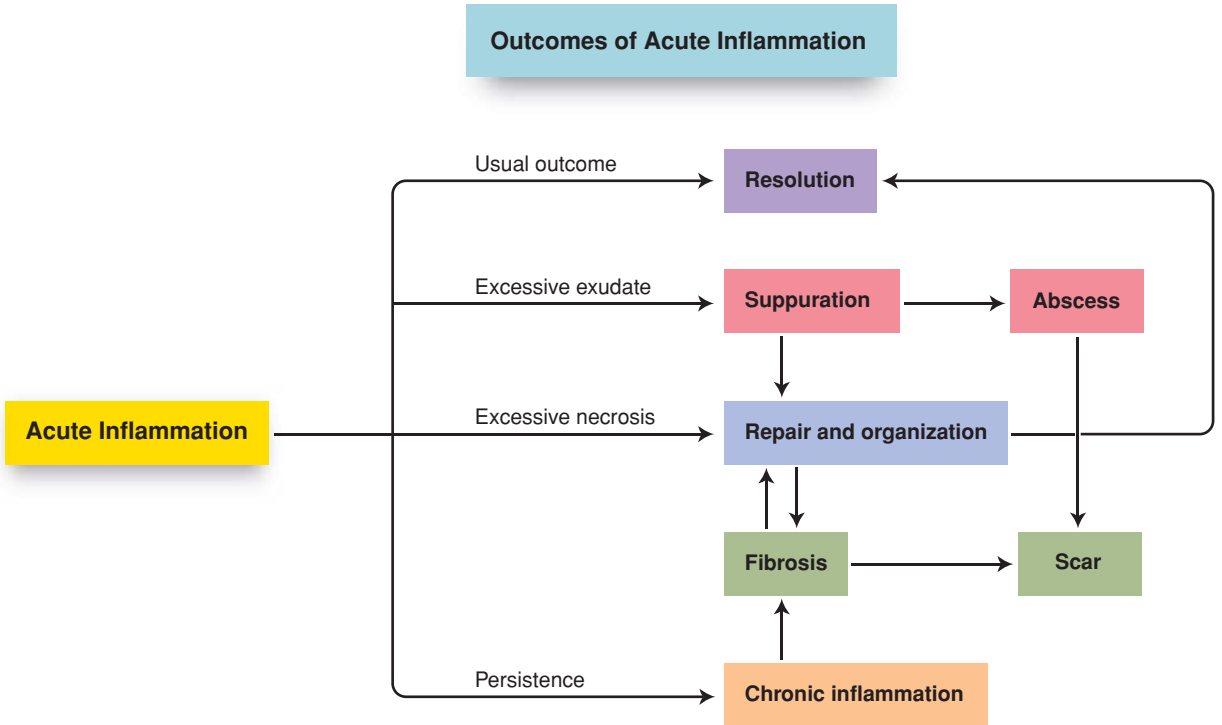

FIGURE 2-38. Outcomes of acute inflammation.

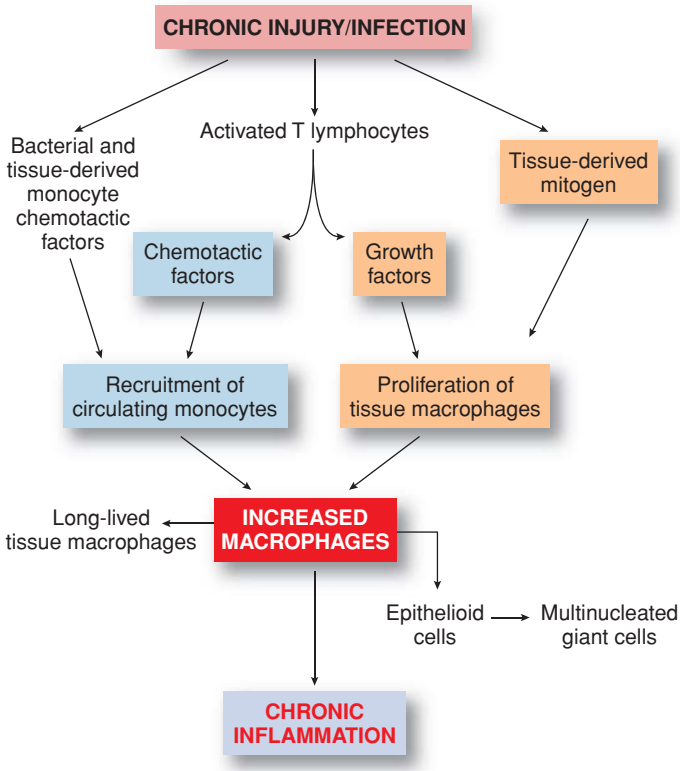

FIGURE 2-39. Accumulation of macrophages is central to development of chronic inflammation.

disordered attempt to restore tissue integrity. Macrophages are key determinants of the outcome (Fig. 2-39).

The events leading to amplified inflammatory responses resemble those of acute inflammation in several ways:

- **Specific triggers,** microbial products or injury, initiate the response.
- **Chemical mediators** direct recruitment, activation and interaction of inflammatory cells. Activation of coagulation and complement generates small peptides that act to prolong the inflammatory response. Cytokines, specifically IL-6 and RANTES, regulate a switch in chemokines, so that mononuclear cells are directed to the site. Other cytokines (e.g., IFN-γ) then promote macrophage proliferation and activation.
- **Inflammatory cells** come in from the blood. Interactions between lymphocytes, macrophages, dendritic cells and fibroblasts generate antigen-specific responses. Macrophages have a central, controlling role, producing inflammatory mediators that activate other macrophages, lymphocytes and tissue fibroblasts (Fig. 2-39) either to promote resolution or to perpetuate injury.
- **DAMPs and PAMPs drive multifaceted inflammatory responses.** Interaction of PAMPs, DAMPS and PRRs increases activation of inflammatory mediators. This can cause more release of DAMPs and subsequent maintenance of the inflammatory response, even after the initial inciting event has passed (Fig. 2-37).
- **Stromal cell activation and extracellular matrix** remodeling occur, both of which affect cellular immune responses. Variable fibrosis may result, depending on the extent of tissue injury and the persistence of injury and inflammation.

Chronic inflammation is not synonymous with chronic infection, but if an inflammatory response does not eliminate an injurious agent, infection may persist. Chronic inflammation does not necessarily require infection: it may follow an acute inflammatory or immune response to a foreign antigen. Signals that lead to an extended response include:

- **Bacteria, viruses and parasites:** These agents can provide signals to support persistent inflammatory responses, which may be directed toward isolating the invader from the host.
- **Apoptosis:** As apoptotic PMNs induce an anti-inflammatory reaction, defects in recognizing or responding to PMN remnants may lead to chronic inflammation.
- **Defective gene silencing:** Delayed or persistent expression of late proinflammatory genes helps to perpetuate the inflammatory environment. In this case, a gene silencing phase does not occur, cytokine onslaught persists and pathologic inflammation develops.
- **Trauma:** Extensive tissue damage releases mediators that prolong the inflammatory environment.
- **Cancer:** Chronic inflammatory cells, especially macrophages and T lymphocytes, may be recruited by tumors to feed and stimulate tumor cell growth (see Chapter 5). Chemotherapy may limit inflammation and increase susceptibility to infection.
- **Immune factors:** In many autoimmune diseases, including rheumatoid arthritis, chronic thyroiditis and primary biliary cirrhosis, chronic inflammatory responses occur in affected tissues. There may be associated activation of antibody-dependent and cell-mediated immunity (see Chapter 4). Such autoimmune abnormalities may lead to persistent injury in affected organs.

Mononuclear Cells Are Mainly Those Involved in Chronic Inflammation

The cellular participants in chronic inflammatory responses are recruited from the circulation (macrophages, lymphocytes, plasma cells, dendritic cells and eosinophils) and affected tissues (fibroblasts, endothelial cells).

Monocytes/Macrophages

Activated macrophages and their cytokines are central to inflammation and prolonging responses that lead to chronic inflammation. Tissue macrophages are stimulated and proliferate as circulating monocytes are recruited and differentiate into tissue macrophages (Fig. 2-39). Under the influence of the microenvironment, resident tissue macrophages become phenotypically polarized into classically activated M1 macrophages and alternatively activated M2 macrophages (Figs. 2-19 and 2-20). Macrophages produce inflammatory and immunologic mediators and regulate reactions leading to chronic inflammation. They also regulate lymphocyte responses to antigens and secrete other mediators that modulate proliferation of fibroblasts and endothelial cell proliferation and their activities.

Within different tissues, resident macrophages differ in their armamentarium of enzymes and responses to local inflammatory signals. Granules of circulating monocytes contain serine proteinases, like those in PMNs. Blood monocytes synthesize additional enzymes, particularly MMPs. When monocytes enter tissue and differentiate into macrophages, they acquire the ability to make additional MMPs and cysteine proteinases

but lose the capacity to produce serine proteinases. The activities of these enzymes are central to the tissue destruction that may occur in chronic inflammation. For example, in the case of emphysema, resident macrophages generate proteinases, particularly MMPs with elastolytic activity, which destroy alveolar walls and recruit blood monocytes into the lung. ***Other macrophage products include oxygen metabolites, chemotactic factors, cytokines and growth factors*** (Fig. 2-17C).

Lymphocytes

Naive lymphocytes home to secondary lymphoid organs, where they encounter antigen-presenting cells and become antigen-specific lymphocytes. Plasma cells and T cells leave secondary lymphoid organs and circulate in the vascular system, from which they are recruited to peripheral tissues.

T cells regulate macrophage activation and recruitment by secreting specific mediators (lymphokines), modulate antibody production and cell-mediated cytotoxicity and maintain immunologic memory (Fig. 2-40A). NK cells, as well as other lymphocyte subtypes, help defend against viral and bacterial infections.

Plasma Cells

Plasma cells are rich in rough endoplasmic reticulum and are the primary source of antibodies (Fig. 2-40B). Production of antibody to specific antigens at sites of chronic inflammation is important in antigen neutralization, clearance of foreign antigens and particles and antibody-dependent cell-mediated cytotoxicity (see Chapter 4).

Dendritic Cells

Dendritic cells are professional antigen-presenting cells that trigger immune responses to antigens (see Chapter 4). They phagocytose antigens and migrate to lymph nodes, where they present those antigens. Recognition of antigen and other costimulatory molecules by T cells results in recruitment of specific cell subsets to the inflammatory process. During chronic inflammation, dendritic cells are present in inflamed tissues, where they help prolong responses.

Acute Inflammatory Cells

Neutrophils characteristically participate in acute inflammation but may also be present during chronic inflammation if there is ongoing infection and tissue damage. Eosinophils are particularly prominent in allergic reactions and parasitic infestations.

Fibroblasts

Fibroblasts are long-lived, ubiquitous cells, whose chief function is to produce components of the ECM (Fig. 2-40C). They

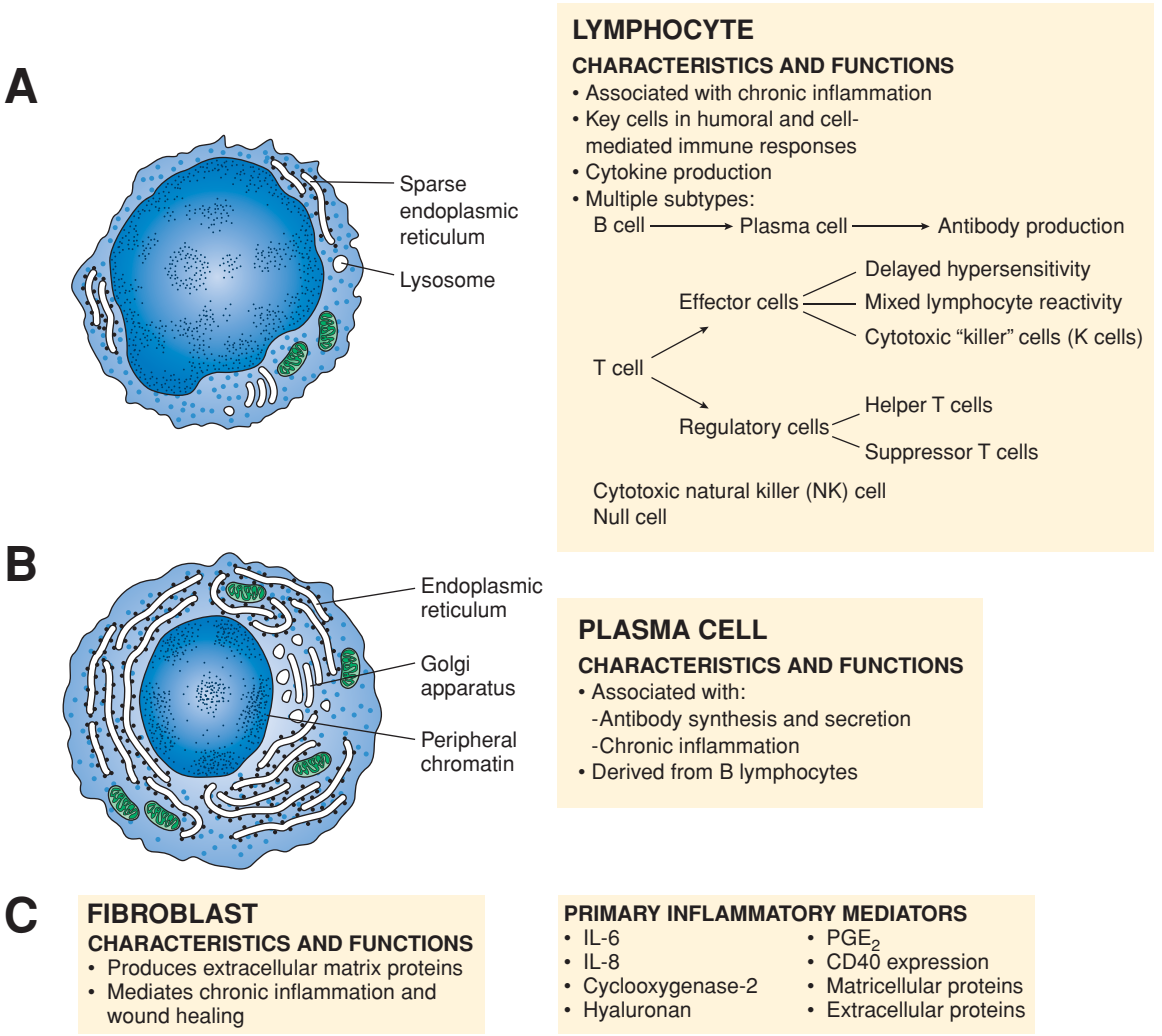

FIGURE 2-40. More cells of inflammation: morphology and function. A. Lymphocyte. **B.** Plasma cell. **C.** Fibroblast.

are derived from mesoderm or neural crest and can differentiate into other connective tissue cells (e.g., chondrocytes, adipocytes, osteocytes and smooth muscle cells). Fibroblasts are the construction workers of tissue, rebuilding the scaffolding of the ECM upon which tissue is re-established.

Fibroblasts not only respond to immune signals that induce their proliferation and activation but also actively function in immune responses. They interact with inflammatory cells, particularly lymphocytes, via surface molecules and receptors on both cells. For example, when CD40 on fibroblasts binds its ligand on lymphocytes, both cells are activated. Activated fibroblasts produce cytokines, chemokines and prostanoids, creating a tissue microenvironment that further regulates the behavior of inflammatory cells in the damaged tissue. This process results in resolution and subsequent wound healing or chronic persistent inflammation (see Chapter 3).

INJURY AND REPAIR IN CHRONIC INFLAMMATION

Chronic inflammation is mediated by immunologic and nonimmunologic mechanisms and often occurs with reparative responses, namely, granulation tissue and fibrosis.

Extended Inflammatory Responses May Lead to Persistent Injury

The primary role of PMNs in inflammation is host defense and debridement of damaged tissue. The neutrophil response, however, is both yin and yang. PMN products protect the host from foreign invaders and help debride damaged tissues, but if they are not well regulated, these same products may prolong tissue damage and promote chronic inflammation. PMN enzymes are beneficial when they digest phagocytosed organisms intracellularly, but these same enzymes can be destructive if they are released extracellularly. Thus, when PMNs accumulate, connective tissue may be digested by their enzymes.

Persistent tissue injury due to inflammatory cells is important in the pathogenesis of several diseases (e.g., emphysema, rheumatoid arthritis, some immune complex diseases, gout and acute respiratory distress syndrome). Phagocytic cell adherence, escape of ROS and release of lysosomal enzymes together enhance cytotoxicity and tissue degradation. Proteinase activity is significantly elevated in chronic wounds, creating a proteolytic environment that prevents healing.

Altered Repair Mechanisms Prevent Resolution

Repair processes initiated as part of inflammation can restore normal architecture and function. However, if inflammation is prolonged or exaggerated, repair may be ineffective, alter tissue architecture and cause tissue dysfunction (Fig. 2-38). Thus:

- Ongoing proliferation of epithelial cells can cause metaplasia (see Chapter 1). Goblet cell metaplasia, for example, is seen in the airways of smokers.
- Fibroblast proliferation and activation lead to increased ECM. Because ECM components such as collagen now occupy space normally devoted to tissue cells, organ function is altered (see Chapter 3).
- The ECM may be altered. Matrix degradation and production change the normal mix of extracellular proteins. Thus, elastin degradation is important in the development of emphysema.
- Altered ECM (e.g., fibronectin) can be a chemoattractant for inflammatory cells and present an altered scaffolding to cells.

GRANULOMATOUS INFLAMMATION

PMNs ordinarily remove agents that incite acute inflammatory responses. However, sometimes these cells cannot digest those substances. Such a situation is potentially dangerous, because it can lead to a vicious circle of (1) phagocytosis, (2) failure of digestion, (3) death of the PMN, (4) release of undigested provoking agents and (5) rephagocytosis by a newly recruited PMN (Fig. 2-41). ***Granuloma formation is a protective response to chronic infection (e.g., some fungi, tuberculosis) or the presence of foreign material (e.g., suture or talc). It isolates a persistent offending agent, preventing it from disseminating and restricting inflammation, thus protecting the host.*** Some autoimmune diseases are also associated with granulomas (e.g., Crohn disease). In some granulomatous disorders such as sarcoidosis, no inciting agent has yet been identified.

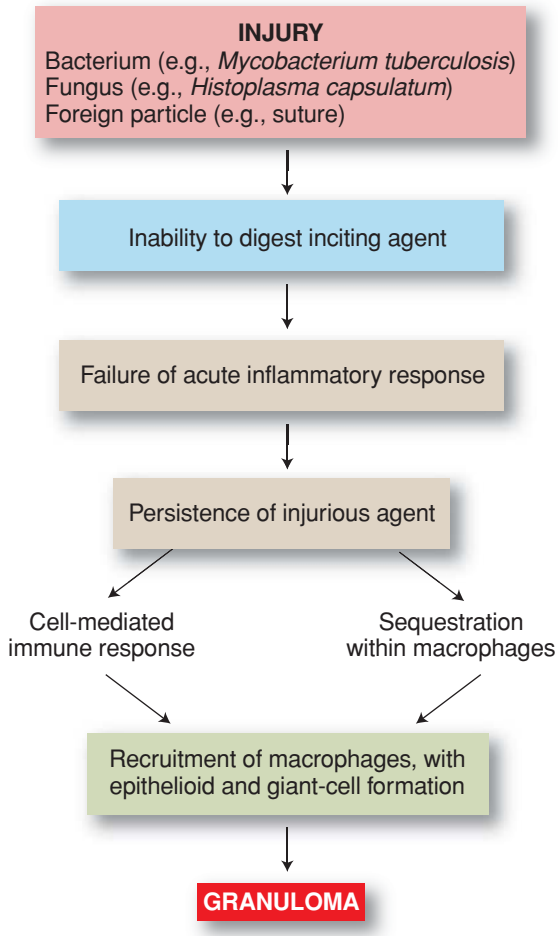

FIGURE 2-41. Mechanism of granuloma formation.

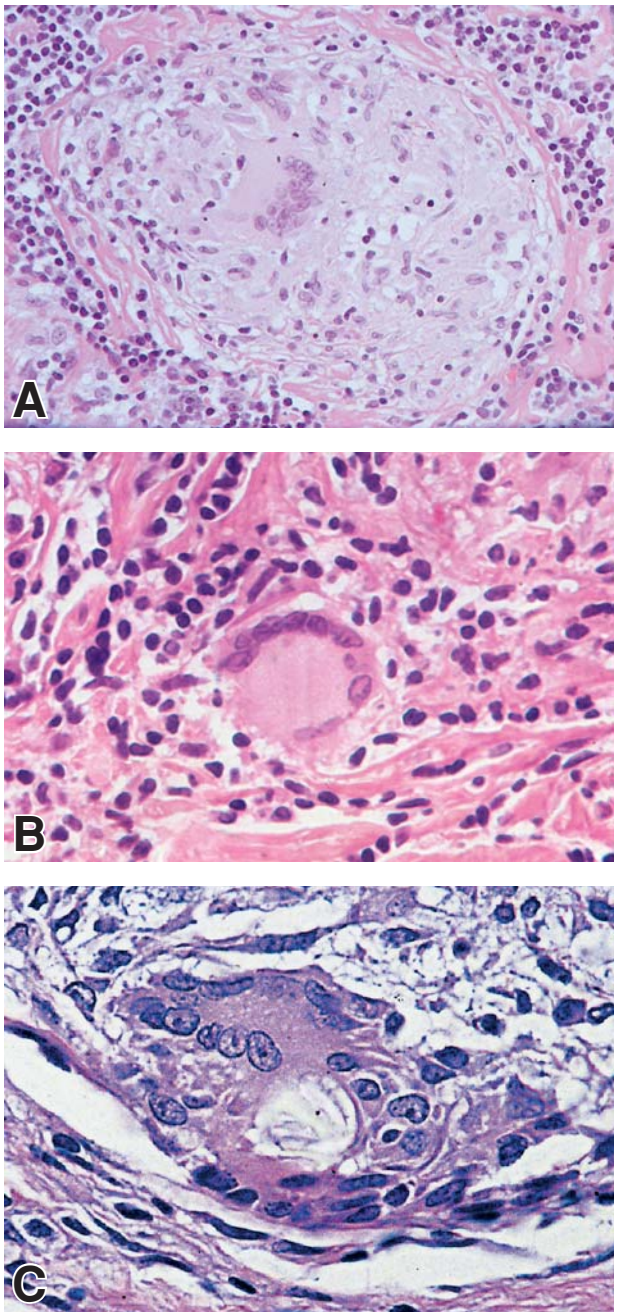

FIGURE 2-42. Types of granulomas. A. Granuloma with a multinucleated giant cell amid numerous pale epithelioid cells. **B.** Langhans giant cell shows nuclei arranged on the periphery of an abundant cytoplasm. **C.** Foreign body giant cell with numerous nuclei randomly arranged in the cytoplasm and foreign material in the center.

The principal cells involved in granulomatous inflammation are macrophages and lymphocytes (Fig. 2-42). Macrophages are mobile cells that continuously migrate through extravascular connective tissues. After amassing substances they cannot digest, macrophages lose their motility and accumulate at the site of injury to form nodular collections of pale, epithelioid cells, **granulomas**. Multinucleated giant cells are formed by cytoplasmic fusion of macrophages. When the nuclei of such giant cells are arranged around the periphery of the cytoplasm in a horseshoe pattern, the cell is called a **Langhans giant cell** (Fig. 2-42B). A foreign agent (e.g., silica or a *Histoplasma* spore) or other indigestible material persists in the cytoplasm of a multinucleated giant cell, in which case the term **foreign body giant cell** is used (Fig. 2-42C). Foreign body giant cells tend to have more central nuclei. Granulomas are further classified by the presence or absence of necrosis. Certain infectious agents, such as *Mycobacterium tuberculosis,* characteristically produce necrotizing granulomas, the centers of which are filled with an amorphous mixture of debris and dead microorganisms and cells. In other diseases, such as sarcoidosis, granulomas characteristically lack necrosis.

Immune granulomas, formed during delayed-type hypersensitivity responses, contain activated T cells and macrophages, which initiate granuloma formation. $CD4^+$ T cells then recruit and organize cells at the site. They use CXCL chemokines to develop Th1-type granulomas and CCL chemokines to develop Th2-type granulomas. Several T-cell cytokines stimulate macrophage function (e.g., IFN-γ), whereas others inhibit macrophage activation (e.g., IL-4, IL-10). Thus, lymphocytes are vital for regulating development and resolution of inflammatory responses.

The outcome of granulomatous reactions depends on the immunogenicity and toxicity of the inciting agent. Cell-mediated immune responses may modify granulomatous reactions by recruiting and activating more macrophages and lymphocytes. Under the influence of T-cell cytokines, such as IL-13 and TGF-β, a granuloma may burn out and become a fibrotic nodule.

CHRONIC INFLAMMATION AND TUMORIGENESIS

Several chronic infectious diseases are associated with development of malignancies such that chronic inflammation may enable tumorigenesis. For example, schistosomiasis in the urinary bladder leads to squamous cell carcinoma of that organ. Inflammation that is not specifically linked to infection may also be a risk factor for cancer. Patients with reflux esophagitis or ulcerative colitis are at higher risk for adenocarcinoma in those organs. An environment created by chronic inflammation promotes malignant transformation by several mechanisms (see Chapter 5):

- **Increased cell proliferation:** Chronically stimulated cell division increases the likelihood of transforming mutations in proliferating cells.
- **Oxygen and NO• metabolites:** Inflammatory metabolites, such as nitrosamines, may cause genomic damage (see Chapter 5).
- **Chronic immune activation:** Chronic antigen exposure alters the cytokine milieu by suppressing cell-mediated immune responses. This creates a more permissive environment for malignant growth.
- **Angiogenesis:** Growth of new vessels is associated with inflammation and wound healing and is important in sustaining cancers.
- **Inhibition of apoptosis:** Chronic inflammation suppresses apoptosis. Increased cell division and decreased apoptosis favor survival and expansion of mutated cell populations.

SYSTEMIC MANIFESTATIONS OF INFLAMMATION

An effective inflammatory response will (1) limit the area of injury, (2) clear the inciting pathologic agent and damaged

tissue and (3) restore tissue function. However, local injury may cause prominent systemic consequences that may themselves be debilitating. These effects may result when a pathogen enters the bloodstream, a separate condition acts synergistically and the combination of a local and a systemic insult directly or indirectly causes both local and systemic effects of inflammation. The symptoms associated with inflammation, including fever, myalgia, arthralgia, anorexia and somnolence, are attributable to these cytokines. The most prominent systemic manifestations of inflammation, termed the **systemic inflammatory response syndrome (SIRS),** are activation of the hypothalamic–pituitary–adrenal axis, leukocytosis and the acute phase response, fever and shock.

Hypothalamic–Pituitary–Adrenal Axis

Many of the systemic effects of inflammation are mediated via the hypothalamic–pituitary–adrenal axis, a key component in the response to chronic inflammation and chronic immune disease. Inflammation results in release of anti-inflammatory glucocorticoids from the adrenal cortex. Thus, loss of adrenal function can increase the severity of inflammation.

Leukocytosis

Leukocytosis is an increase in circulating leukocytes. It commonly accompanies acute inflammation. Immature PMNs ("band" forms) may also be seen in the peripheral blood (see Chapter 26). Leukocytosis is most commonly associated with bacterial infections and tissue injury and is caused by release of specific mediators from macrophages and perhaps other cells. These mediators accelerate release of PMNs, even immature ones, from the bone marrow. Subsequently, macrophages and T lymphocytes are stimulated to produce a group of proteins (colony-stimulating factors) that induce proliferation of bone marrow hematopoietic precursor cells. Occasionally, circulating levels of PMNs and their precursors may be very high, a condition known as a **leukemoid (i.e., leukemia-like) reaction,** which may be confused with leukemia (see Chapter 26).

In contrast to bacterial infections, viral infections (including infectious mononucleosis) are characterized by **lymphocytosis,** an increase in the number of circulating lymphocytes. Parasitic infestations and certain allergic reactions cause eosinophilia (i.e., increased blood eosinophils).

Leukopenia

Leukopenia is an absolute decrease in circulating white cells. It happens occasionally during chronic inflammation, especially in patients who are malnourished or who suffer from a chronic debilitating disease such as disseminated cancer. Leukopenia may also be caused by typhoid fever and certain viral and rickettsial infections.

Acute Phase Response

The acute phase response is a regulated physiologic reaction that occurs in inflammatory conditions. It is characterized clinically by fever, leukocytosis, decreased appetite and altered sleep patterns, and chemically by changes in plasma levels of acute phase proteins. These molecules (Table 2-6) are synthesized primarily by the liver and released in large quantities into the circulation in response to an acute inflammatory challenge. Changes in plasma levels of acute phase proteins are mediated primarily by IL-1, IL-6 and TNF-α. Increased plasma levels of some acute phase proteins increase the **erythrocyte sedimentation rate** (ESR), which is a qualitative index used clinically to monitor the activity of many inflammatory diseases.

TABLE 2-6
ACUTE PHASE PROTEINS

Protein	Function
Mannose-binding protein	Opsonization/complement activation
C-reactive protein	Opsonization
α_1-Antitrypsin	Serine protease inhibitor
Haptoglobin	Binds hemoglobin
Ceruloplasmin	Antioxidant, binds copper
Fibrinogen	Coagulation
Serum amyloid A protein	Apolipoprotein
α_2-Macroglobulin	Antiprotease
Cysteine protease inhibitor	Antiprotease

Fever

Fever is a clinical hallmark of inflammation. Release of **pyrogens** (molecules that cause fever) by bacteria, viruses or injured cells may directly affect hypothalamic thermoregulation. More importantly, they stimulate production of endogenous pyrogens, namely, cytokines (IL-1α, -1β and -6 and TNF-α) and interferons. IL-1 stimulates prostaglandin synthesis in hypothalamic thermoregulatory centers, thus altering the "thermostat" that controls body temperature. Inhibitors of cyclooxygenase (e.g., aspirin) block the fever response by inhibiting IL-1–stimulated PGE_2 synthesis in the hypothalamus. TNF-α and IL-6 also increase body temperature by a direct action on the hypothalamus. Chills (the sensation of cold), rigor (profound chills with shivering and piloerection) and sweats (to allow heat dissipation) are symptoms associated with fever.

Pain

Pain in acute phase reactions is associated with (1) **nociception** (i.e., detection of noxious stimuli and transmission of this information to the brain), (2) pain perception and (3) suffering and pain behavior. Nociception is mainly a neural response initiated in injured tissues by specific nociceptors, which are high-threshold receptors for thermal, chemical and mechanical stimuli. Most chemical mediators of inflammation described in this chapter—including ions, kinins, histamine, NO, prostanoids, cytokines and growth factors—activate peripheral nociceptors directly or indirectly. Kinins, especially bradykinin, are formed after tissue trauma and during inflammation; they activate primary sensory neurons via B_2 receptors to mediate pain transmission. Another kinin, des-arg bradykinin, activates B_1 receptors to produce pain only during inflammation. Cytokines, particularly TNF-α and IL-1, -6 and -8, produce pain hypersensitivity to mechanical and thermal stimuli. Prostaglandins and growth factors may directly activate nociceptors but appear to act mostly by enhancing nociceptor sensitivity. Pain perception

and subsequent behavior arise in response to this enhanced sensitivity to both noxious and normally innocuous stimuli.

Shock

If tissue injury is massive or infection spreads to the blood (sepsis), huge quantities of cytokines, especially TNF-α, and other chemical mediators of inflammation are poured into the circulation. Their persistence affects the heart and peripheral vascular system by causing generalized vasodilation; increasing vascular permeability, intravascular volume loss and myocardial depression; and decreasing cardiac output (SIRS) (see Chapter 7). Cardiac output may then not satisfy the body's need for oxygen and nutrients **(cardiac decompensation)**. In severe cases, activation of coagulation pathways causes microthrombi throughout the body, consuming clotting components and predisposing to bleeding. This condition is **disseminated intravascular coagulation**. The net result is multisystem organ dysfunction syndrome (MODS) and death (see Chapter 20).

Suboptimal Wound Repair

From scarring to regeneration, damaged tissue heals in ways that ensure the immediate survival of the organism. Observations regarding the repair of wounds (i.e., wound healing) date to physicians in ancient Egypt and battle surgeons in classic Greece. The clotting of blood to prevent exsanguination was recognized as the first necessary event in wound healing. With the advent of the microscope, studies of wound infection led to the discovery that inflammatory cells are primary actors in the repair process. The importance of antisepsis to wound healing is now taken for granted. From the 2nd-century Greco-Roman physician Galen to the works of Pasteur and Lister at the end of the 19th century, the presence of pus at a wound site was praised and even referred to as "laudable pus." In 1876, British physician Joseph Lister was invited to serve as president of the Surgical Section of the International Medical Congress in Philadelphia. Five years later, President Garfield died after being shot by an assassin, succumbing not to damage from the bullet but several months later to pus and sepsis, the result of tissue probing by physicians leery of the germ theory and antiseptic methods. The importance of extracellular matrix, specifically collagen, in tissue integrity and wound healing was first recognized through study of scurvy, a disease that claimed the lives of millions (see Chapter 8). In 1747, Dr. James Lind, a surgeon in England's Royal Navy, conducted what is thought to be the first controlled clinical trial. Aboard the HMS Salisbury, he separated scurvy-ridden sailors into six treatment groups and observed that sailors given oranges and lemons derived the greatest benefit by preventing the reopening of wounds and loss of teeth. In 1907, the role of vitamin C began to be clarified when Norwegians Axel Holst and Theodor Frolich discovered that guinea pigs, like humans, were unable to synthesize vitamin C (ascorbic acid). Ascorbate was eventually found necessary for the action of prolyl hydroxylase, an enzyme required for proper folding and stabilization of the collagen triple helix, an important step in establishing tissue integrity and building a strong scar.

The topic of regeneration elicits thoughts of flatworms, starfish and amphibians. However, the regeneration of the human liver was the basis of the Greek myth of Prometheus, whose liver regenerated daily. Modern concepts of regeneration and cell differentiation progressed in the latter half of the 20th century. In the 1950s, Sir John Gurdon determined that even somatic cell nuclei transplanted into a Xenopus egg could form a normal adult organism, and his work was a progenitor of current technologies that yield inducible pluripotent stem cells from many tissues. Current studies on epigenetic control of gene expression, stem and progenitor cell biology and directed control of differentiation patterns in cells are rapidly advancing the fields of regenerative healing and tissue engineering.

The study of wound healing now encompasses a variety of cells, matrix proteins, growth factors and cytokines, which regulate and modulate the repair process. Nearly every stage in the repair process is redundantly controlled, and there is no one rate-limiting factor, except uncontrolled infection. Extracellular matrix will be presented here in some detail as it occupies a central role in both repair and regeneration. Matrix deposition is a key process in tissue repair and fibrosis, and matrix composition is an important functional factor in both the niche environment that maintains stem and progenitor cells in an undifferentiated state during regeneration and in the tissue microenvironments in which these cells differentiate. In the adult, ***successful healing maintains tissue function and repairs tissue barriers, preventing blood loss and infection, but it is usually accomplished through collagen deposition or scarring (fibrosis)***. Advances in our understanding of critical factors—growth factors, extracellular matrix and stem cell biology—are improving healing, and they offer the possibility of restoring injured tissues to their normal architecture and of engineering replacement tissues.

Successful repair relies on a crucial balance between the *yin* of tissue formation and the *yang* of tissue remodeling. ***Regeneration is favored when matrix composition and***

architecture are preserved. Thus, wounds that do not heal may reflect excess proteinase activity, reduced signaling, decreased matrix accumulation or altered matrix assembly. Conversely, fibrosis and scarring may result from inadequate proteinase activity or increased matrix production. Although formation of new collagen during repair is essential for increased strength of the healing site, fibrosis is a major complication of diseases that involve chronic injury.

THE BASIC PROCESSES OF HEALING

Many of the basic cellular and molecular mechanisms required for wound healing participate in other processes that involve dynamic tissue changes, such as development and tumor growth. Three key cellular mechanisms are necessary for wound healing once hemostasis is achieved:

- **Cellular migration**
- **Extracellular matrix organization and remodeling**
- **Cell proliferation**

Migration of Cells Initiates Repair

Cells That Migrate to the Wound

Migration of cells into a wound and activation of local cells are initiated by changes in the mechanical environment and mediators that are either expressed de novo by resident cells or released from preformed reserves stored in granules of **platelets** and **basophils**. These granules contain cytokines, chemoattractants, proteases and mediators of inflammation, which together control vascular supply, degrade damaged tissue and initiate the repair cascade. Platelets are activated when bound to collagen exposed at sites of endothelial damage. Their ensuing aggregation, in combination with fibrin cross-linking, limits blood loss. Activated platelets release platelet-derived growth factor (PDGF) and many other molecules that facilitate adhesion, coagulation, vasoconstriction, cell proliferation and clot resorption. **Mast cells** are bone marrow–derived cells whose granules contain high concentrations of heparin, histamine and proteinases. They reside in connective tissue near small blood vessels and respond to foreign antigens by releasing the contents of their granules, many of which are angiogenic. **Resident macrophages,** tissue-fixed mesenchymal cells and epithelial cells also release mediators that contribute to and perpetuate the early response. The cellularity of wound sites increases through proliferation and recruitment to sites of injury (Fig. 3-1). ***Cell types characteristic of skin wounds are:***

- **Leukocytes** arrive at the wound site early by adherence to activated endothelium, exit from the circulation and rapidly migrate into tissue by forming small focal adhesions with matrix molecules such as fibrin, fibronectin and collagen. A family of small peptide chemoattractants **(chemokines)** mediates both restricted and broad recruitment of particular leukocyte subtypes (see Chapter 2).
- **Polymorphonuclear leukocytes** from the bone marrow invade the wound site within hours. They degrade and destroy nonviable tissue and infectious organisms by releasing their granular contents and generating reactive oxygen species, before undergoing apoptosis and digestion by macrophages.
- **Monocytes/macrophages** maintain a basal resident population in tissues; they are recruited transiently in larger numbers from bone marrow and spleen shortly after neutrophil entry. During their more extended residence time in wounds, macrophages phagocytose debris and orchestrate the developing granulation tissue and healing by releasing cytokines and chemoattractants.
- **Dendritic cells** are resident antigen-presenting cells that regulate innate and adaptive immunity. They can proliferate in some tissues, such as skin, and they are also recruited from bone marrow or differentiated from closely related macrophages.
- **Fibroblasts, myofibroblasts, pericytes and smooth muscle cells** represent a spectrum of mesenchymal cells that are recruited locally and are also populated from mesenchymal progenitors in bone marrow. They migrate and propagate via signals from growth factors and matrix degradation products, populating a skin wound by day 3 or 4. These cells mediate synthesis of connective tissue (fibroplasia), tissue remodeling, vascular integrity, wound contraction and wound strength.
- **Endothelial cells** sprout from existing postcapillary venules and are also seeded by circulating bone marrow progenitors. Nascent capillaries form in response to growth factors and are visible in wound granulation tissue, together with fibroblasts, beyond day 3. Development of capillaries is critical for gas exchange, delivery of nutrients and influx of inflammatory cells.
- **Epidermal cells** move across the surface of a skin wound (Fig. 3-1.5). Reepithelialization is delayed if the migrating epithelial cells must reconstitute a damaged basement membrane. In open wounds, keratinocytes migrate between provisional matrix (see below) and preexisting or newly formed stromal collagen, which is coated with plasma glycoproteins, fibrinogen and fibronectin. The phenotype of the epithelial layer is altered if basement membrane is lacking.
- **Stem cells** from bone marrow, or in the skin, stem cells or **progenitor cells** in the hair follicle and within the basal epidermal layer, provide renewable sources of epidermal and dermal cells capable of differentiation, proliferation and migration. Stem cells for epidermal regeneration reside in the bulge region of the hair follicle and the interfollicular epidermis (Fig. 3-1.4). Dermal progenitors are also associated with the lower hair shaft and the follicular bulb. Marrow-derived, multipotential progenitors of fibroblasts and endothelium are recruited to sites of injury (Fig. 3-1.1) as well, although they appear to play a temporary role in repair. These cells aid in forming new blood vessels and new epithelium and regenerate skin structures, such as hair follicles and sebaceous glands.

Mechanisms of Cell Migration

Cell migration uses the most important mechanisms of wound healing, receptor-mediated responses to chemical signals **(cytokines)** and insoluble substrates of the extracellular matrix. Ameboid locomotion powers the rapidly migrating leukocytes via wave-like membrane extensions called **lamellipodia**. Slower-moving cells, such as fibroblasts, extend narrower, finger-like membrane protrusions called **filopodia**. Growth factors or chemokines bind to specific receptors on cell surfaces to trigger cell polarization and

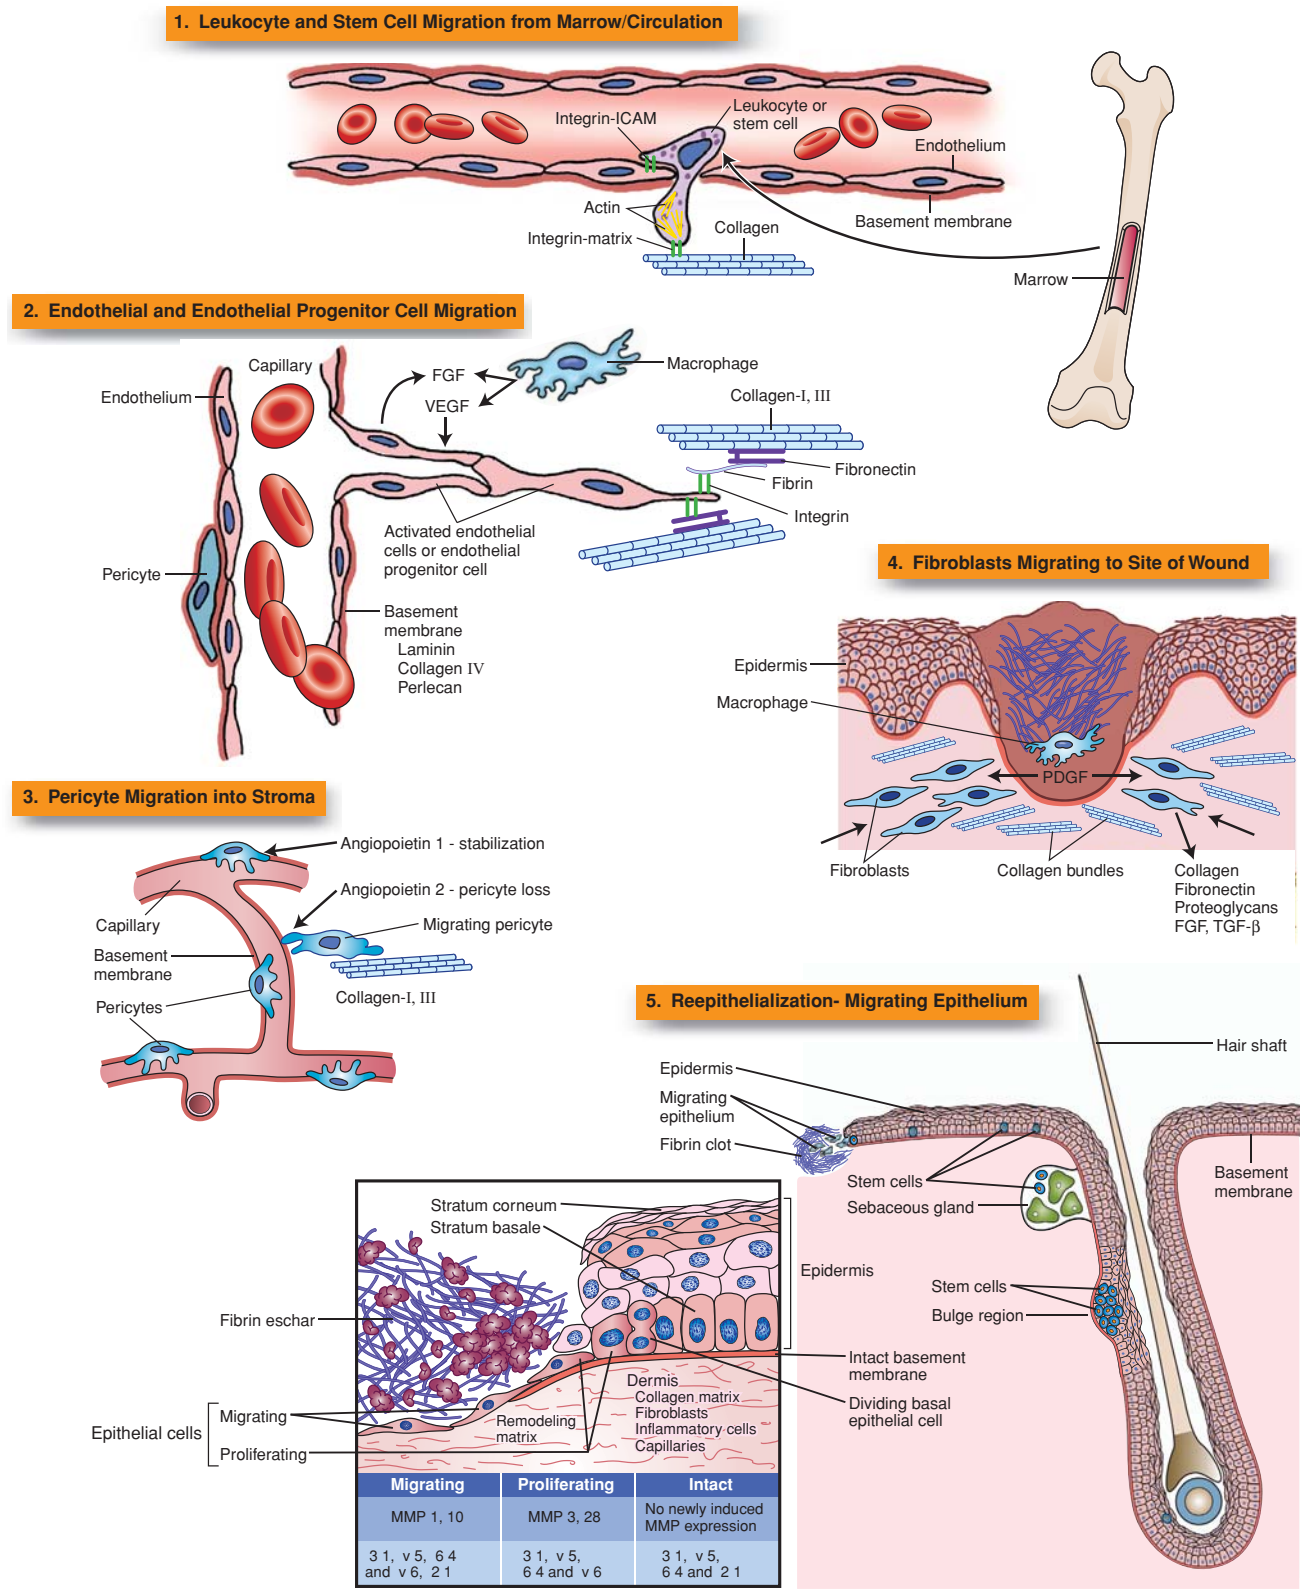

FIGURE 3-1. Resident and migrating cells initiate repair and regeneration. 1. After cytokine activation of capillary endothelium, leukocytes and bone marrow–derived circulating stem cells attach to, and migrate between, capillary endothelial cells; penetrate the basement membrane; and enter the interstitial matrix in response to chemotactic signals. **2.** Under the influence of locally released angiogenic factors, capillary endothelial cells lose their connection with the basement membrane and extend through the provisional matrix to form new capillaries. Pericytes and basement membranes are required to stabilize new and existing capillary structures. **3.** Pericytes detach from capillary endothelial cells and their basement membranes to migrate into the matrix. **4.** Under the influence of growth factors such as platelet-derived growth factor (PDGF), fibroblasts become bipolar and migrate through the matrix to the site of injury where transforming growth factor-β (TGF-β) can cause differentiation into smooth muscle actin-containing myofibroblasts. These then become bipolar and migrate through the matrix to the site of injury. **5.** During reepithelialization, groups of basal keratinocytes at the wound edge release from underlying basement membrane, take on a migratory behavior and penetrate between the fibrin eschar (if present) and the granulation tissue that generates wound dermis. Migrating cells switch to a different display of integrin matrix receptors that recognize provisional matrix and stromal collagen (type I) and to different metalloproteinases that favor migration and matrix remodeling. *FGF* = fibroblast growth factor; *VEGF* = vascular endothelial growth factor.

membrane extensions. **Actin fibrils** polymerize and form a network at the membrane's leading edge, thereby propelling lamellipodia and filopodia forward, with traction achieved by engaging extracellular matrix substrate. Actin-related proteins modulate actin assembly, and numerous actin-binding proteins act like molecular tinkertoys, rapidly constructing, stabilizing and destabilizing actin networks.

The leading edge of the cell membrane impinges upon adjacent extracellular matrix and adheres to it through allosterically activated, transmembrane adhesion receptors called **integrins** (see Chapter 2). These molecules show significant redundancy; many of the 24 known vertebrate integrin heterodimer combinations recognize the same matrix components (e.g., collagen, laminin, fibronectin), yet they show specificity in distinguishing basement membrane, provisional and stromal matrices. Focal contacts develop via adherence of the integrin extracellular domain to the provisional or stromal connective tissue matrix. In vitro, focal adhesions form under the cell body, while smaller focal contacts form at the leading edges of migrating cells. The focal contact anchors actin stress fibers, against which myosins pull to extend or contract the cell body. As cells move forward, older adhesions at the rear are weakened or destabilized, allowing the trailing edge to retract.

Hundreds of proteins have been associated with formation of adhesion plaques. Cytoplasmic domains of integrins trigger a protein cascade that anchors actin stress fibers. The Rho family of guanosine triphosphatases (GTPases; Rho, Rac, Cdc42) are molecular switches that interact with surface receptors to regulate matrix assembly, generate focal adhesions and organize the actin cytoskeleton.

Integrins transmit intracellular signals that also regulate cellular survival, proliferation and differentiation. Integrin functions are affected by additional matrix receptors, such as collagen-binding discoidin domain receptors (DDRs), tetraspanins and other cell activators (e.g., growth factors and chemokines). These molecules allosterically alter the binding avidity of the extracellular portion of integrins by signaling through activation of their cytoplasmic tails (inside-out signaling). Thus, cytokines can also influence organization and tension in matrix and tissue. Integrin binding is also essential for many growth factor receptor signaling processes. Growth factors and integrins share several common signaling pathways, but integrins are unique in their ability to organize and anchor cytoskeleton. Cytoskeletal connections are regulated by the interplay between cell–cell and cell–matrix connections and determine the shape and differentiation of epithelial, endothelial and other cells. Not surprisingly, these same cytoskeletal connections are foci of change during epithelial-to-mesenchymal transitions that occur during reepithelialization of the wound surface.

Extracellular Matrix Sustains the Repair Process

Extracellular matrix is presented in some depth since it is critical for repair and regeneration by providing the key components of scar tissue and the stem cell niche. Three types of extracellular matrix contribute to the organization, physical properties and function of tissue:

- **Basement membrane**
- **Provisional matrix**
- **Connective tissue (interstitial matrix or stroma)**

Basement Membrane

Basement membrane, also called **basal lamina,** is a thin, well-defined layer of specialized extracellular matrix that separates cells that synthesize it from adjacent interstitial connective tissue (Fig. 3-2). It is a supportive and biological boundary important in development, healing and regeneration, providing key signals for cell differentiation and polarity and contributing to tissue organization. Basement membrane is also a key structural and functional feature of the neuromuscular synapse. It appears as a thin lamina that stains by the periodic acid–Schiff (PAS) stain, owing to its high glycoprotein content. Unique basement membranes form under different epithelial layers and around epithelial ducts and tubules of skin and organs and around adipocytes, cover smooth and skeletal muscle cells and peripheral nerve Schwann cells and surround capillary endothelium and associated pericytes.

- Basement membranes are made from special extracellular matrix molecules, including isoforms of collagen IV, isoforms of the glycoprotein laminin, entactin/nidogen and perlecan, a heparan sulfate proteoglycan (Table 3-1). They self-assemble into a sandwich-like structure with a covalently associated type IV collagen lattice built upon the noncovalently associated laminin network.
- Within different tissues and during development, expression of unique members or isoforms of the collagen IV and laminin families imparts diversity to the basement membrane and the many structures and _functions it supports.
- Basement membranes support cellular differentiation and act as filters, cellular anchors and a surface for migrating epidermal cells after injury. They also help re-form neuromuscular junctions after nerve damage. Basement membranes determine cell shape, contribute to developmental

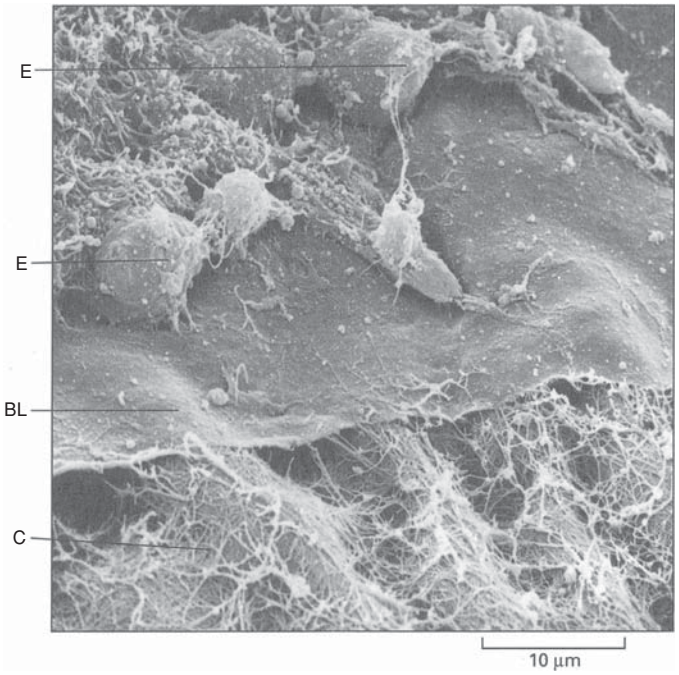

FIGURE 3-2. Scanning electron micrographs of basement membrane. The basement membrane (BL, basal lamina) separates chick embryo corneal epithelial cells (E) from underlying stromal connective tissue with collagen fibrils.

TABLE 3-1
BASEMENT MEMBRANE CONSTITUENTS AND ORGANIZATION

Basement Membrane Components	Chains	Molecular Structure	Molecular Associations	Basement Membrane Aggregate Form
Perlecan (heparan sulfate proteoglycan)	1 protein core 3 heparan sulfate GAG chains		Laminin, collagen IV, fibronectin, growth factors (VEGF, FGF), chemokines	Laminin	16 isoforms Heterotrimers with α-, β-, γ-chains 5 α-chains, 3 β-chains, 3 γ-chains		Integrin, dystroglycan and other receptors on a variety of cells (epithelium, endothelium, muscle, Schwann cells, adipocytes) Forms self-associated noncovalent network that organizes basement membranes Laminin, nidogen/entactin, perlecan, agrin, fibulin	
Nidogen/ entactin	2-member family monomeric		Collagen IV, laminin, perlecan, fibulin Stabilizes basement membrane through association of laminin and collagen IV networks	
Collagen IV	≥3-member family Heterotrimers Chains selected from 2 or 3 of 6 unique α-chains	3 single chains form α-helical tail of collagenous regions and association of the 3 globular regions 	Integrin receptors on many cells Forms covalent self-associated network Collagen IV, perlecan nidogen/entactin, SPARC	
FGF = fibroblast growth factor; GAG = glycosaminoglycan; SPARC = secreted protein acidic and rich and cysteine; VEGF = vascular endothelial growth factor.

morphogenesis and, notably, provide a repository for growth factors and chemotactic peptides.

Provisional Matrix

Provisional matrix is the temporary extracellular organization of plasma-derived matrix proteins and tissue-derived components that accumulate at sites of injury (e.g., hyaluronan, tenascin and fibronectin). These molecules associate with preexisting stromal matrix and serve to stop blood or fluid loss. Provisional matrix supports migration of leukocytes, endothelial cells and fibroblasts to the wound site. ***Plasma-derived provisional matrix proteins include fibrinogen, fibronectin, thrombospondin and vitronectin.*** The platelet thrombus also contains several growth factors, most prominently PDGF. Insoluble fibrin is generated through the clotting cascade, and the provisional matrix is internally stabilized and bound to the adjacent stromal matrix by transglutaminase (factor XIII)-generated cross-links. In addition to factor XIII stabilization of the fibrin clot, tissue transglutaminases 1 and 2 are also active in wound remodeling and cutaneous regeneration.

Stromal (Interstitial Connective Tissue) Matrix

Connective tissue forms a continuum between tissue elements such as epithelia, nerves and blood vessels and

provides physical protection by conferring resistance to compression or tension. Connective tissue stroma is also important for cell migration and as a medium for storage and exchange of bioactive proteins.

Connective tissue contains both extracellular matrix elements and individual cells that synthesize the matrix. The cells are primarily of mesenchymal origin and include fibroblasts, myofibroblasts, adipocytes, chondrocytes, osteocytes and endothelial cells. Bone marrow–derived cells (e.g., mast cells, macrophages, transient leukocytes) are also present.

The extracellular matrix of connective tissue, also called **stroma** or **interstitium,** is defined by fibers formed from a large family of collagen molecules (Table 3-2). Of the fibrillar collagens, type I collagen is the major constituent of bone. Type I and type III collagens are prominent in skin; type II collagen is predominant in cartilage. Elastic fibers, which impart elasticity to skin, large blood vessels and lungs, are composite structures consisting of elastin and microfibrillar scaffolding proteins such as fibrillin and fibulin. The so-called **ground substance** represents a number of molecules, including glycosaminoglycans (GAGs), proteoglycans, matricellular proteins and fibronectin. These components are important in many biological functions of connective tissue and in the support and modulation of cell attachment.

Collagens

Collagen is the most abundant protein in the animal kingdom; it is essential for the structural integrity of tissues and organs. If its synthesis is reduced, delayed or abnormal, wounds fail to heal, as in scurvy or **nonhealing wounds**. Excess collagen deposition leads to **fibrosis**. Fibrosis is the basis of connective tissue diseases such as scleroderma and keloids and of compromised tissue function seen in chronic damage to many organs, including kidney, lung, heart and liver.

The collagen superfamily of insoluble extracellular proteins is the major constituent of connective tissue in all organs, most notably cornea, arteries, dermis, cartilage, tendons, ligaments and bone. There are at least 28 distinct collagen molecules (designated with Roman numerals I–XXVIII), each formed by type-specific α-chains that form triple helices of homo- or heterotrimers. Some collagen types have multiple α-chains and therefore different isoforms. Other proteins, not classified as collagens, also contain collagen domains of varying length and continuity. All collagen α-chains have at least one domain with a repeating α-helical segment, largely composed of glycine, proline and hydroxyproline, in which every third amino acid is glycine (Gly-X-Y). Formation of the triple helical structure depends on this primordial collagen domain with its glycine repeat and on ascorbate-dependent posttranslational formation of hydroxyproline. Residues of lysine, hydroxylysine and histidine form tissue-specific intramolecular and intermolecular, covalent cross-links. A continuous, uninterrupted, triple helical organization of α-chains is the predominant structure of the rigid, stiff, fibrillar collagens. Nonfibrillar collagens contain interrupting, flexible, noncollagenous domains that may even be the major portion of the protein. Collagen family members have important structural functions, but they also affect cell differentiation, growth, migration and matrix morphogenesis through interaction with integrin and discoidin domain transmembrane receptors.

Collagen synthesis exemplifies the complexity of posttranslational protein modification. Each molecule is made by self-association of three homotypic or heterotypic α-chains that wind around each other to form a triple helix. The triple helix forms from an α-chain homotrimer (collagens XII–XXVIII), or type-specific homo- or heterotrimers from an α-chain family that is unique for each collagen type. Collagen IV, the predominant basement membrane collagen, assembles as isoforms of at least 3 different heterotrimers containing different combinations of its 6 α-chains. Collagen molecules lose thermal stability when mutations alter the Gly-X-Y sequence, in which case the unstable (denatured) triple helix region is more vulnerable to proteinase activity.

Successful fibrillar collagen synthesis usually results from a series of posttranslational modifications: (1) selection of the three α-chains, aided by chain recognition sequences and prolyl hydroxylation, which drive specific chain alignment and association; (2) ascorbate-dependent hydroxylation of proline and lysine; (3) triple helix formation; (4) packaging into COPII vesicles for transport from endoplasmic reticulum to the Golgi for glycosylation; (5) cleavage of noncollagenous terminal peptides; (6) molecular alignment and microfibril assembly; and (7) covalent cross-linking, mediated by the copper-dependent enzyme lysyl oxidase. Byproducts or breakdown products from synthesis and remodeling, including specific cross-links and peptides, are utilized clinically to assess tissue modifications associated with fibrosis or osteoporosis. Mutations of fibrillar collagens cause diseases of bone (osteogenesis imperfecta), cartilage (achondrogenesis or hypochondrogenesis, chondroplasias or epiphyseal dysplasias), skin, joints and blood vessels (Ehlers-Danlos syndrome) (Chapters 6 and 30).

Fibrillar collagens include types I, II, III, V and XI. Types I, II and III are the most abundant collagens and form continuous fibrils. They are fashioned from a quarter-staggered packing of cross-linked collagen molecules, whose triple helix is uninterrupted (Table 3-2). These fibrillar collagens turn over slowly in most tissues and are largely resistant to proteinase digestion, except by specific matrix metalloproteinases (MMPs). Type I fibril size and structure are modified by incorporation of type V molecules, which nucleate formation of type I fibrils, and association with type III molecules. By analogy, type XI collagen nucleates type II collagen fibrils in cartilage. Mutant interruptions in the triple helix of fibrillar collagens cause lethal to minor pathology in skin, blood vessels, bone or cartilage. Type I is the most abundant collagen, and mutations in the genes for this molecule cause assembly defects in the triple helix that can lead to increased bone fractures, hyperextensible ligaments and dermis or easy bruising (Chapter 6).

Nonfibrillar collagens (Table 3-2) contain a mixture of globular and triple helical domains. The interruption of the triple helical domains confers structural diversity and molecular flexibility not possessed by fibrillar collagens. Nonhelical domains enable small collagens (IX, XII) to associate with fibrillar collagens, thereby modulating fiber packing of a linear collagen. Collagen VI, which forms beaded filament structures (VI) that encircle fibrillar collagens I and II, is found close to cells and associates with elastin in elastic fibers; mutations are associated with certain myopathies and muscular dystrophy, as collagen VI helps connect muscle cells to basement membrane. Other nonfibrillar collagens act as **transmembrane** proteins (XVII) in hemidesmosomes

TABLE 3-2

COLLAGEN MOLECULAR COMPOSITION AND STRUCTURE

Type	Macromolecular Association	Aggregate Form
A. Fibril forming **I** **II** (cartilage) **III** **V, XI**		B. Non–fibril forming (Interrupting noncollagen domains) **VI** **IX** (cartilage, also a proteoglycan) **XII** **XV and XVIII** (also proteoglycans)		Network forming **IV** (basal lamina) **VIII** **X** (hypertrophic cartilage)		Anchoring (epithelium) **VII** **Transmembrane** **XVII** (BP180, BPAG2)		**Hemidesmosome and basement membrane** 
that attach epidermal cells to basement membrane. Collagen VII forms **fibrillar anchors** linking hemidesmosome and basement membrane to underlying stroma. Mutations in these collagens cause mild to severe blistering in junctional and dystrophic epidermolysis bullosa (see Chapter 28). **Network-forming collagens** facilitate formation of flexible, "chicken-wire" networks of basement membrane collagen (IV) or more ordered hexagonal networks (VIII, X) in other tissues. Mutations in some isoforms of collagen IV cause the abnormal glomerular basement membranes seen in Alport syndrome (see Chapter 22). Proteolytic fragments of matrix proteins with biological activity are termed matrikines or matricryptins. Many derive from basement membrane collagens and exhibit a different set of biological properties that act during development and tissue remodeling associated with cancer or repair. For example, fragments of basement membrane collagens IV, XV and XVIII inhibit angiogenesis and tumor growth. Collagens XV and XVIII are found at the interface of the basement membrane with the stroma.

The collagens were once called **scleroproteins,** meaning both white and hard; yet in the cornea, layers of collagen can be transparent. The cornea consists of 10–20 orthogonally stacked layers of composites of type I and type V collagens (Fig. 3-3), the fibrils being uniform and smaller sized than the predominantly type I + type III composite collagen fibers in skin. Each layer has parallel, uniform-sized collagen fibers oriented at right angles to the underlying layer, producing a transparent extracellular matrix. After severe infection or injury, corneas form disorganized white collagenous scars that are opaque and interfere with vision. The structure of the cornea is a striking contrast to the typical loose, random, basket-weave network of dermal collagen or the parallel arrays of collagen in tendons and ligaments. Yet structured orientation of collagen in human skin has long been known. Plastic surgeons use wrinkle lines, which indicate the primary orientation of the underlying dermal collagen, to promote inconspicuous healing. The tensile strength of skin that is broken parallel to creases and wrinkle lines exceeds that which is broken perpendicular to these lines, further suggesting a structured orientation of dermal collagen. Scars have an inappropriate arrangement of thicker, poorly woven collagen fibers.

Elastin and Elastic Fibers

Elastin is a secreted matrix protein that, unlike other stromal proteins, is not glycosylated (Table 3-3). Elastin allows deformable tissues such as skin, uterus, ligaments, lung, elastic cartilage and aorta to stretch and bend with recoil. Its lack of carbohydrate, its extensive covalent cross-linking and its hydrophobic amino acid sequence make it the most insoluble of all vertebrate proteins. The elastic fiber is crucial for the function of several vital tissues, yet it is not efficiently replaced during repair of skin and lung. Emphysema is characterized by loss of lung recoil due to degradation of alveolar elastin without functional replacement. The absence, impaired assembly or slow accumulation of functional elastin following damage to skin or lung is offset by the fact that, once polymerized into fibers, elastin is resistant to proteolysis and turns over slowly. Nevertheless, elastic fibers degenerate and, in skin, decrease owing to a diminished capacity for replacement with aging. This effect brings on dermal atrophy, wrinkling and loss of dermal suppleness. Excess sun exposure causes an increase in abnormal elastotic material that, with age-related collagen loss, predominates in the dermal connective tissue and leads to skin thickening and coarse, furrowed wrinkles.

Elastin stability results from its (1) hydrophobicity, (2) extensive covalent cross-linking (mediated by lysyl oxidase, the same enzyme that cross-links collagen) and (3) resistance to most proteolytic enzymes. Unlike injured skin and lung, the arterial wall can rapidly form new concentric rings of elastic lamellae in response to hypertension and other injuries. Veins that are transplanted in coronary artery bypass surgery rapidly generate new elastic lamellae in the process of arterialization. This observation illustrates the difference in the elastin synthetic capabilities of the vascular smooth muscle cell and those of dermal or lung fibroblasts. Yet elastin formed during repair may be less functional, and with age elastin function decreases owing to degradation and chemical modifications.

Elastic fibers form from the condensation of a soluble elastin precursor on a complex of several microfibrillar glycoproteins. The best-characterized microfibrillar protein is **fibrillin** (Table 3-3). When mutated, abnormal fibrillin

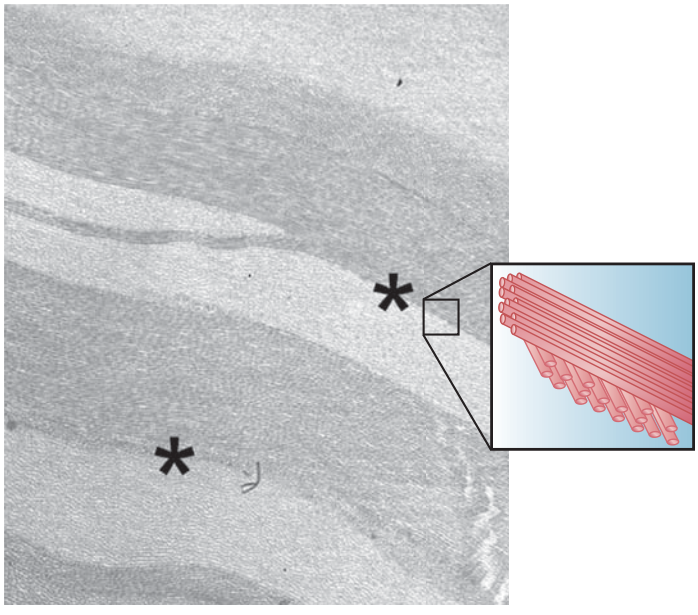

FIGURE 3-3. Human cornea, near center. Collagen fibers are highly organized in the cornea. Multiple plywood-like arrays of collagen fibers are of similar width and layers with distinct orientation are sharply demarcated between asterisks (*). This precise, unique matrix organization, layers of highly ordered collagen bundles at oblique, nearly perpendicular angles, is critical to the transparency and refractive index of the cornea.

TABLE 3-3

NONCOLLAGENOUS MATRIX CONSTITUENTS OF STROMA

Stromal Connective Tissue Components	Chains	Molecular Structure	Molecular Associations	Tissue Structures
Fibronectin	Dimeric protein Chains chosen from ~20 splice variants of one gene		Integrin receptors of many cells (RGD-binding site) Plasma fibronectin is soluble Cellular fibronectin can self-associate into fibrils at cell surface and also binds collagen, heparin, decorin, fibrin, certain bacteria (opsonin), LTBPs	Elastin	Monomer with several splice variants, 1 gene	 Elastin cross-links to form fiber	Self-association to form cross-linked amorphous fibers Formed on scaffold of microfibrillar polymers	Elastin fiber with microfibril polymers Fibrillins	Large glycoproteins—most common microfibrils needed for elastin fiber assembly		Forms beaded polymer Other microfibrillar proteins: LTBPs, fibulins, emilins, MAGP 1 and 2, lysyl oxidase	
Versican (hyaluronan-binding proteoglycans)	Family of 4 related genes Aggrecan found in cartilage Protein core decorated with 10–30 chondroitin sulfate and dermatan sulfate GAG chains		Proteoglycans linked to hyaluronan via link protein to form very large composite structure	Decorin (small leucine-rich proteoglycans)	1 protein core, 1 gene 1 chondroitin sulfate or dermatan sulfate GAG chain Biglycan and fibromodulin structurally related, genetically distinct		Collagen I and II, fibronectin, TGF-β, thrombospondin	
GAG = glycosaminoglycan; LTBPs = latent transforming growth factor-β–binding proteins; MAGP = microfibril-associated growth protein; RGD = Arg-Gly-Asp; TGF-β = transforming growth factor-β.

demonstrates decreased binding and reduced activation of transforming growth factor-β (TGF-β). The result is Marfan syndrome, with pleomorphic manifestations that include dissecting aortic aneurysm (Chapter 6). Mutations in **fibulin** can result in the generalized elastin defect, cutis laxa.

Matrix Glycoproteins

Matrix glycoproteins, sometimes referred to as matricellular proteins, contribute essential biological functions to basement membrane and stromal connective tissue. In general, these are large (150,000–1,000,000 kd) multimeric and multidomain macromolecules, with long arms that bind other matrix molecules and support or modulate cell attachment. Matrix glycoproteins help to (1) organize tissue topography, (2) support cell migration, (3) orient cells and (4) induce cell behavior. The principal matrix glycoprotein of basement membrane is **laminin,** and that of stromal connective tissue is **fibronectin**.

LAMININS: The laminins are a versatile family of basement membrane glycoproteins whose cross-like structure is formed by products of three related gene subfamilies to form α, β and γ heterotrimers (Table 3-1). There are 18 known laminin isoforms, which assemble intracellularly from varying combinations of the five α-, three β- and three γ-chains. Once secreted, some laminin trimers are further processed by proteinases. Laminin molecules self-polymerize into sheets that initiate basement membrane formation by association with type IV collagen sheets and other basement membrane molecules. Expression of laminin isoforms in specific tissues contributes to the heterogeneity of tissue morphology and functions, in part, by supporting cell attachment via binding to membrane sulfated glycolipids and transmembrane receptors. The cell attachments concentrate laminin and construct the lattice on which other basement membrane molecules accumulate. Laminin binds to both heparan sulfate proteoglycans in basement membranes and to heparan sulfate chains on syndecan receptors. Cells also bind to laminin via several integrins, as well as muscle dystroglycan and Lutheran blood grouping receptors, which on red cells may be involved in the release from bone marrow during hematopoiesis. The muscle cell dystroglycan receptor complex binds basement membrane laminin, and mutations in either the receptor or laminin account for different forms of muscular dystrophy (see Chapter 31). The appropriate proteolytic processing of the epidermal laminin isoform is critical for normal epidermal function and reepithelialization of wounds. Epidermal integrity is stabilized at the basal surface by hemidesmosomes, which develop from the binding of basement membrane laminin to epithelial integrin (integrin $\alpha_6\beta_4$) and involve collagen XVII and collagen VII. The latter forms the anchoring fibril that connects the epidermal cell and basement membrane to the dermal connective tissue. Mutations in epidermal laminin or the appropriate integrin, or the previously mentioned collagen VII or collagen XVII, produce different forms of a potentially fatal skin blistering disease, termed **epidermolysis bullosa**.

FIBRONECTINS: Fibronectins are versatile, adhesive glycoproteins that are widely distributed in stromal connective tissue and deposited in wound provisional matrix (Table 3-3). Fibronectin chains form a V-shaped homo- or heterodimer linked at the C terminus by two disulfide bonds. Specific fibronectin domains bind bacteria, collagen, heparin, fibrin, fibrinogen and the cell matrix receptor integrin. Indeed, the integrin receptor family has been partly defined by studies showing its specific binding to fibronectin. The multifunctional dimer links matrix molecules to one another or to cells. Thrombi support cell migration owing to the high concentration of plasma-derived fibronectin that connects fibrin strands. The complex is further stabilized by cross-linking of factor XIII (transglutaminase) to other provisional and dermal matrix components.

Two classes of fibronectin are encoded by a single gene but from different sources: (1) the insoluble, cellular form; and (2) a hepatocyte-derived, soluble form in plasma. As many as 24 fibronectin variants may be formed by alternative splicing. Clot-bound fibronectin supports platelet adhesion. It can also interact with collagen to promote keratinocyte attachment and migration during reepithelialization of corneal and cutaneous wounds by aiding collagen. Fibronectin synthesized by mesenchymal cells such as fibroblasts is assembled into insoluble fibrils with the aid of integrin receptors and collagen fibrils. Polymerized cellular fibronectin is found in granulation tissue and loose connective tissue. Excisional wound clotting and reepithelialization are unaffected by experimentally knocking out plasma fibronectin, suggesting that cellular fibronectin and other factors can compensate for its absence.

Glycosaminoglycans

Glycosaminoglycans (historically known as mucopolysaccharides) are long, linear polymers of specific repeating disaccharides, each containing a uronic acid. GAG chains are distinguished by the disaccharide subunits in the polymer. The chains are negatively charged, owing to the presence of carboxylate groups and, save for hyaluronan, by modification with N- or O-linked sulfate groups. GAGs have the potential for exceptional diversity and biological specificity because of epimerization and variability in modifications (e.g., acetylation and sulfation). When sulfated GAG chains are O-linked to serine residues of protein cores, the structures are called **proteoglycans** (see below). GAG storage disorders result from autosomal recessive (or X-linked) deficiency of one of several lysosomal hydrolases that degrade GAGs, causing intracellular accumulation within lysosomes. The 12 known mucopolysaccharidoses are slowly evolving disorders of connective tissue that significantly decrease life expectancy; affect ossification of cartilage, skeletal structure, stature and facies; and may cause psychomotor problems or even mild retardation.

Hyaluronan

Hyaluronan, the only GAG not covalently linked to a protein, is a linear polymer of 2000–25,000 disaccharides of glucosamine and glucuronic acid. Its charge content makes hyaluronan very hydrophilic. Hyaluronan can associate with protein cores of proteoglycans (defined below) that contain hyaluronan-binding regions and with hyaluronan-binding proteins at the cell surface. Certain proteoglycans bind noncovalently along the hyaluronan backbone via a link protein to form large, space-filling, hydrophilic hyaluronan/proteoglycan composites. These are **aggrecan** and **versican** (Table 3-3), molecules found in cartilage and stromal tissues, respectively. The viscosity of free hyaluronan in solution imparts resilience and lubrication to joints and connective tissue, and pericellular accumulation of these molecules as part of the glycocalyx facilitates cell migration through the extracellular matrix. Hyaluronan is highly prevalent in the stroma

during embryonic development, and it is an early addition to the provisional matrix. The negatively charged carboxylate backbone of hyaluronan binds large amounts of water, creating a viscous gel that produces turgor in the matrix. As a biomaterial, hyaluronan can be chemically modified to act as a temporary dermal filler, joint lubricant or replacement for vitreous humor. Unlike other secreted macromolecules, hyaluronan synthesis occurs at the cell surface, and cells also express several types of hyaluronan receptors. Concentrations of pericellular hyaluronan are higher during dynamic tissue remodeling associated with inflammation, wound repair, morphogenesis or cancer. Resolution of the wound healing process relies on inflammatory monocytes with CD44 receptors to bind to and remove the pericellular hyaluronan matrix and excess hyaluronan in matrix, in concert with the action of hyaluronidases. Reduced hyaluronidase activity in fetal wounds may reduce inflammation and favor less scar formation.

Proteoglycans

Proteoglycans are a diverse family of proteins with varying numbers, types and sizes of attached glycosaminoglycan chains linked by O-glycosidic bonds to serines or threonines. They have a higher carbohydrate content than matrix glycoproteins and, though not branched, show substantial diversity through numerous carbohydrate modifications, such as sulfation, unique linkages and varying sequences. Individual proteoglycans whose names are designated by the core protein can differ widely in number and choice of GAG chains, as well as tissue distribution.

Proteoglycans participate in matrix organization, structural integrity and cell attachment. Though their protein core often has biological activity, the properties of several proteoglycans are largely mediated by the GAG chains themselves. The strongly charged heparan sulfate GAG chains of basement membrane (perlecan, collagen XVIII) and cell receptor proteoglycans (syndecan, glypican) modulate the availability and actions of heparin-binding growth factors, such as vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF) and heparin-binding epidermal growth factor (HB-EGF). PDGF is also more weakly bound to these highly charged molecules. A group of small proteoglycans, which share a core protein domain of leucine-rich repeats, regulates TGF-β activity and fibril formation in collagens I and II (Table 3-3). Sequestered growth factors are released when proteoglycans are degraded by heparanase and other hydrolases.

Tissue expression of extracellular matrix proteins and proteoglycans is shown in Table 3-4.

Remodeling Is the Long-Lasting Phase of Repair

As repair proceeds, inflammatory cells become fewer in number and capillary formation is completed. In remodeling, fibroblast numbers rapidly rise and then fall as an equilibrium between collagen deposition and degradation is restored. MMPs are the main remodeling enzymes, but neutrophil cathepsins and serine proteases are also present at the early phase of wound debridement. Unlike the inflammatory cell proteinases, MMP and ADAM protease activity is highly localized. The superfamily of proteinases with the presence of zinc at the catalytic site (metzincins) includes the MMPs and other subfamilies including ADAM (a disintegrin and metalloproteinase) and ADAM with thrombospondin motifs (ADAMTS). Members of the metzincin superfamily are key regulators in tissue during times of change such as development or remodeling. The activity of these proteases is controlled, in part, by a family of tissue-based molecules known as tissue inhibitors of metalloproteinases (TIMPs).

MMPs are a large family of 25 proteinases with overlapping specificities. They enable cells to migrate through stroma by degrading matrix proteins and so are central to wound healing (Table 3-3). They participate in cell–cell communication and activation or inactivation of bioactive molecules (e.g., immune system components, matrix fragments, growth factors) and influence cell growth and apoptosis. MMPs are synthesized as inactive proenzymes (zymogens), and many secreted MMPs require extracellular activation by already activated MMPs, such as MMP-3, MMP-14 or serine proteinases. The six membrane-anchored MMPs are activated prior to locating at the cell surface. They are attached via a small cytoplasmic tail or, for two of them, via a glycosylphosphatidylinositol (GPI) anchor. Secreted MMPs are named sequentially (e.g., MMP-1, MMP-2), and membrane-type MMPs also have a secondary designation (e.g., MT1-MMP, MT2-MMP). The cell surface activities of MT1- and MT2-MMPs are important for cell migration and invasion. Originally, MMPs were named by their matrix substrates (e.g., collagenase, stromelysin and gelatinase). However, MMPs cleave diverse extracellular substrates, many of which are degraded by more than one MMP. As with integrins, such redundancy emphasizes the importance of these molecules in regulatory control through activating, deactivating and shedding of substrates. ***The list of molecules needed for wound healing is indistinguishable from the list of MMP substrates.*** These include:

- Clotting factors
- Extracellular matrix proteins
- Latent growth factors and growth factor–binding proteins
- Receptors for matrix molecules and cell–cell adhesion molecules
- Immune system components
- Other MMPs, other proteinases and proteinase inhibitors
- Chemotactic molecules

Most MMPs are closely regulated at the transcriptional level, except for MMP-2 (gelatinase A), which is often constitutively expressed and activated at the cell surface by MT1-MMP (MMP-14). Transcription is regulated by (1) integrin signaling, (2) cytokine and growth factor signaling, (3) binding to certain matrix proteins or (4) tensional force on a cell. MMPs have a number of activities that support the remodeling and resolution phases of wound healing. MT1-MMP and MT2-MMP may associate with integrins to aid cell migration and invasion or activate TGF-β. MMP-1 associates with $\alpha_2\beta_1$ integrin, facilitating cell migration of dermal keratinocytes on collagen during the reepithelialization of the wound surface. The integrin binds the cell to the collagen substrate and the MMP-1 cleaves collagen to enable cell release and migration. Membrane-associated proteoglycans (syndecans, CD44) also store and regulate the availability and activity of MMPs. In addition to affecting cell–cell adhesion and release, MMPs activate or inactivate bioactive molecules stored in the matrix. These include growth factors, chemokines, growth factor–binding proteins, angiogenic/antiangiogenic factors and bioactive

TABLE 3-4
TISSUE EXPRESSION OF EXTRACELLULAR MATRIX MOLECULES

Tissue or Body Fluid	Primary Mesodermal Cell	Prominent Collagen Types	Noncollagenous Matrix Proteins	Glycosaminoglycans Proteoglycans (PGs)
Plasma			Fibronectin, fibrinogen, vitronectin	Hyaluronan
Dermis Reticular/papillary Epidermal junction	Fibroblast	I, III, V, VI, XII, XXIV, XXIX, VII, XVII (BP 180), anchoring fibrils, hemidesmosome	Fibronectin, elastin, fibrillin	Hyaluronan, decorin, biglycan, versican
Muscle	Muscle cell	I, III, V, VI, VIII, XII, XV, XXII	Fibronectin, elastin, fibrillin	Aggrecan, biglycan, decorin, fibromodulin
Peri-, epimysium Aortic media/ adventitia	Fibroblast			
Tendon	Fibroblast	I, III, V, VI, XII, XXII	Fibronectin, tenascin (myotendon junction), elastin, fibrillin	Decorin, biglycan, fibromodulin, lumican, versican
Ligament	Fibroblast	I, III, V, VI	Fibronectin, elastin, fibrillin	Decorin, biglycan, versican
Cornea	Fibroblast	I, II, III, V, VI, XII, XXIV		Lumican, keratocan, mimecan, biglycan, decorin
Cartilage	Chondrocyte hypertrophic cartilage	II, IX, VI, VIII, X, XI, XXVII	Anchorin CII, fibronectin, tenascin	Hyaluronan, aggrecan, biglycan, decorin, fibromodulin, lumican, perlecan (minor)
Bone	Osteocyte	I, V, XXIV, XIII	Osteocalcin, osteopontin, bone sialoprotein, SPARC (osteonectin)	Decorin, fibromodulin, biglycan
Nervous system: CNS, PNS (including Schwann cell basement membrane)	Neurons, neurologic cells	I–IX; XI–XIX; XXI–XXIII; XXV, XXVII, XXVIII, XXIX	Laminins, nidogen/entactin, tenascin, thrombospondin	Chondroitin sulfate containing proteoglycans, heparan sulfate containing proteoglycans (agrin, perlecan)
Basement membrane zones	Epithelial (most organs, e.g., kidney), endothelial (capillaries) adipocytes, Schwann cell, muscle cells (endomysium), pericytes, neuromuscular junction	IV, XV, XVIII	Laminins, nidogen/entactin	Heparan sulfate proteoglycans, perlecan Collagen XVIII (vascular), agrin (neuromuscular junctions)

CNS = central nervous system; PNS = peripheral nervous system; SPARC = secreted protein acidic and rich in cysteine.

cryptic fragments of collagens and proteoglycans. The fragments are released when their parent matrix molecules are degraded **(matrikines)**.

Once secreted, MMPs act largely near the cell surface, its activity confined by diffusion/sequestration, reduced activation, substrate specificity and peptide inhibitors. The last group includes the family of TIMPs and the general, plasma-derived proteinase inhibitor, α_2-macroglobulin. The ADAMs function to shed ectodomains of growth factors, chemokines and receptors on cell or neighboring cell surfaces. The ADAMTS family members are released and activated through cleavage of the thrombospondin (TS) domain, thereby generating the cleavage of substrates such as aggrecan, a large proteoglycan of cartilage, and von Willebrand factor.

Cell Proliferation Is Evoked by Cytokines and Matrix

Early in tissue injury, there is a dramatic, transient increase in cellularity that elevates immune surveillance and replaces (some) damaged cells. Cell proliferation and migration initiate and perpetuate **granulation tissue,** a specialized,

highly vascularized tissue that forms transiently during repair (see below). Cells of granulation tissue derive from ephemeral cell populations, including circulating leukocytes, and from adjacent, resident capillary endothelial and mesenchymal cells (fibroblasts, myofibroblasts, pericytes and smooth muscle cells). Local and marrow-derived progenitor cells, which share some properties of leukocytes, can also populate wounds, potentially differentiating into (transient) endothelial and fibroblast populations. Terminally differentiated cells (e.g., cardiac myocytes, neurons) do not for the most part contribute to repair or regeneration (discussed below).

Growth factors and small chemotactic peptides (chemokines) provide soluble autocrine and paracrine signals for cell proliferation, differentiation and migration. Signals from soluble factors and extracellular matrix also work collectively to influence cell behavior.

Behaviors of cells in healing wounds—proliferation, migration and altered gene expression—are largely initiated by three receptor systems that share integrated signaling pathways:

- **Protein tyrosine kinase receptors** for peptide growth factors
- **G-protein–coupled receptors** for chemokines and other factors
- **Integrin receptors** for extracellular matrix

Tyrosine kinase receptors, growth factor matrix integrin receptors and G-protein–coupled receptors act in concert to direct cell behavior. Primarily through integrin-mediated binding to the extracellular matrix, these distinct receptor families are influenced by the mechanical environment. Although they bind distinct ligands, they transmit signals within a network of cascading and intersecting intracellular signaling pathways. These routes amplify the messages, often activating similar processes that affect cytoskeletal organization and gene expression. Even different processes, such as proliferation, differentiation and migration, may share signals, such as those that initiate cytoskeletal changes. The myriad intracellular signaling mechanisms that regulate cell growth, survival and proliferation are beyond the scope of the current discussion. It is important to recognize that tissue responses are governed by integration of signals from all these systems.

REPAIR

Outcomes of Injury Include Repair with Restoration or Regeneration

Repair and restoration follow inflammatory responses, inflammation itself being the primary response to tissue injury (see Chapter 2). To understand how inflammation influences repair, it is useful to review the various possible outcomes of acute inflammation. *Transient* acute inflammation may resolve completely, with locally injured parenchymal elements regenerating without significant scarring. Thus, after a moderate sunburn, occasional acute inflammatory cells accompany transient vasodilation under solar-injured epidermis. By contrast, *progressive* acute inflammation, with eventual macrophage-predominant infiltrates, is central to the sequence of collagen elaboration and repair. Complete regeneration—as opposed to the more usual restoration during adult repair—may occur with injury to liver or bone: that is, normal hepatic structure is replaced after many self-limited hepatic insults.

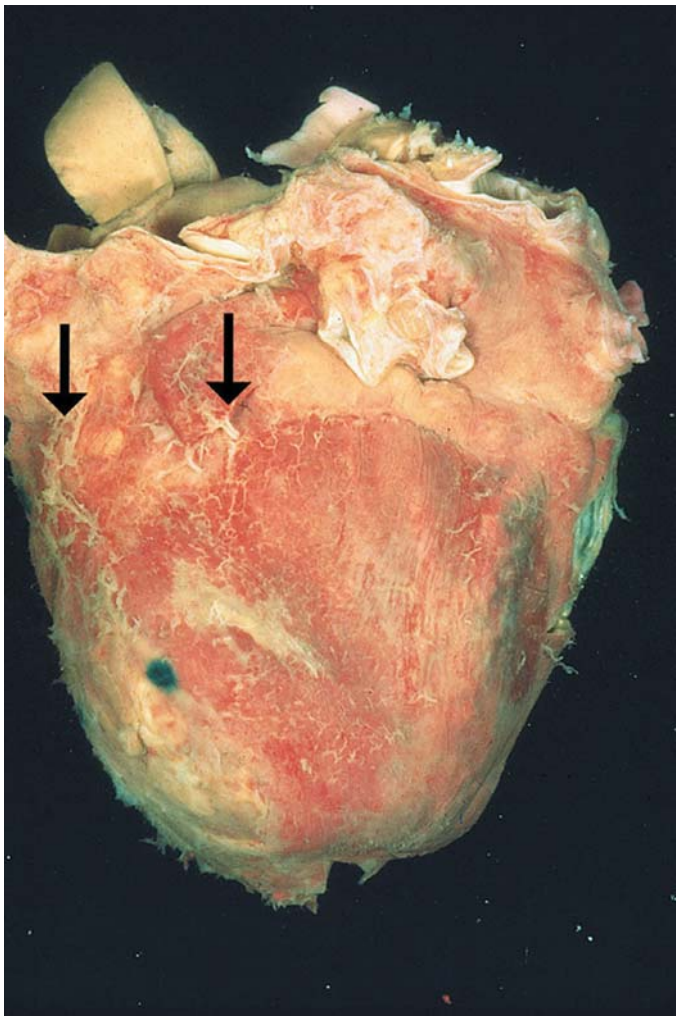

FIGURE 3-4. Organized strands of collagen in constrictive pericarditis (*arrows*). Excess collagen distorts the biomechanical properties of the heart.

Organization is a pathologic outcome of fibrinogen leakage from blood vessels during an inflammatory response. It occurs in serous cavities, like the peritoneum, when fibrin strands are not degraded and form a provisional matrix. Conversion of the provisional matrix to fibrous (granulation) tissue occurs following invasion of connective tissue cells, inflammatory cells and capillaries. In pericarditis, fibroblasts invade the provisional fibrin matrix and secrete and organize a collagenous extracellular matrix among fibrin strands, thus binding visceral and parietal pericardium together (Fig. 3-4). This constricts ventricular filling of the heart and may require surgical intervention. Fibrin strands may become organized in the peritoneal cavity after intra-abdominal surgery. Such adhesions (threads of collagen) can trap loops of bowel and cause intestinal obstruction.

Wound Healing Exhibits a Defined Sequence

Wound healing that results in scar formation remains the predominant mode of adult repair. Given that wounds in the skin and extremities are easily accessible, they have been extensively

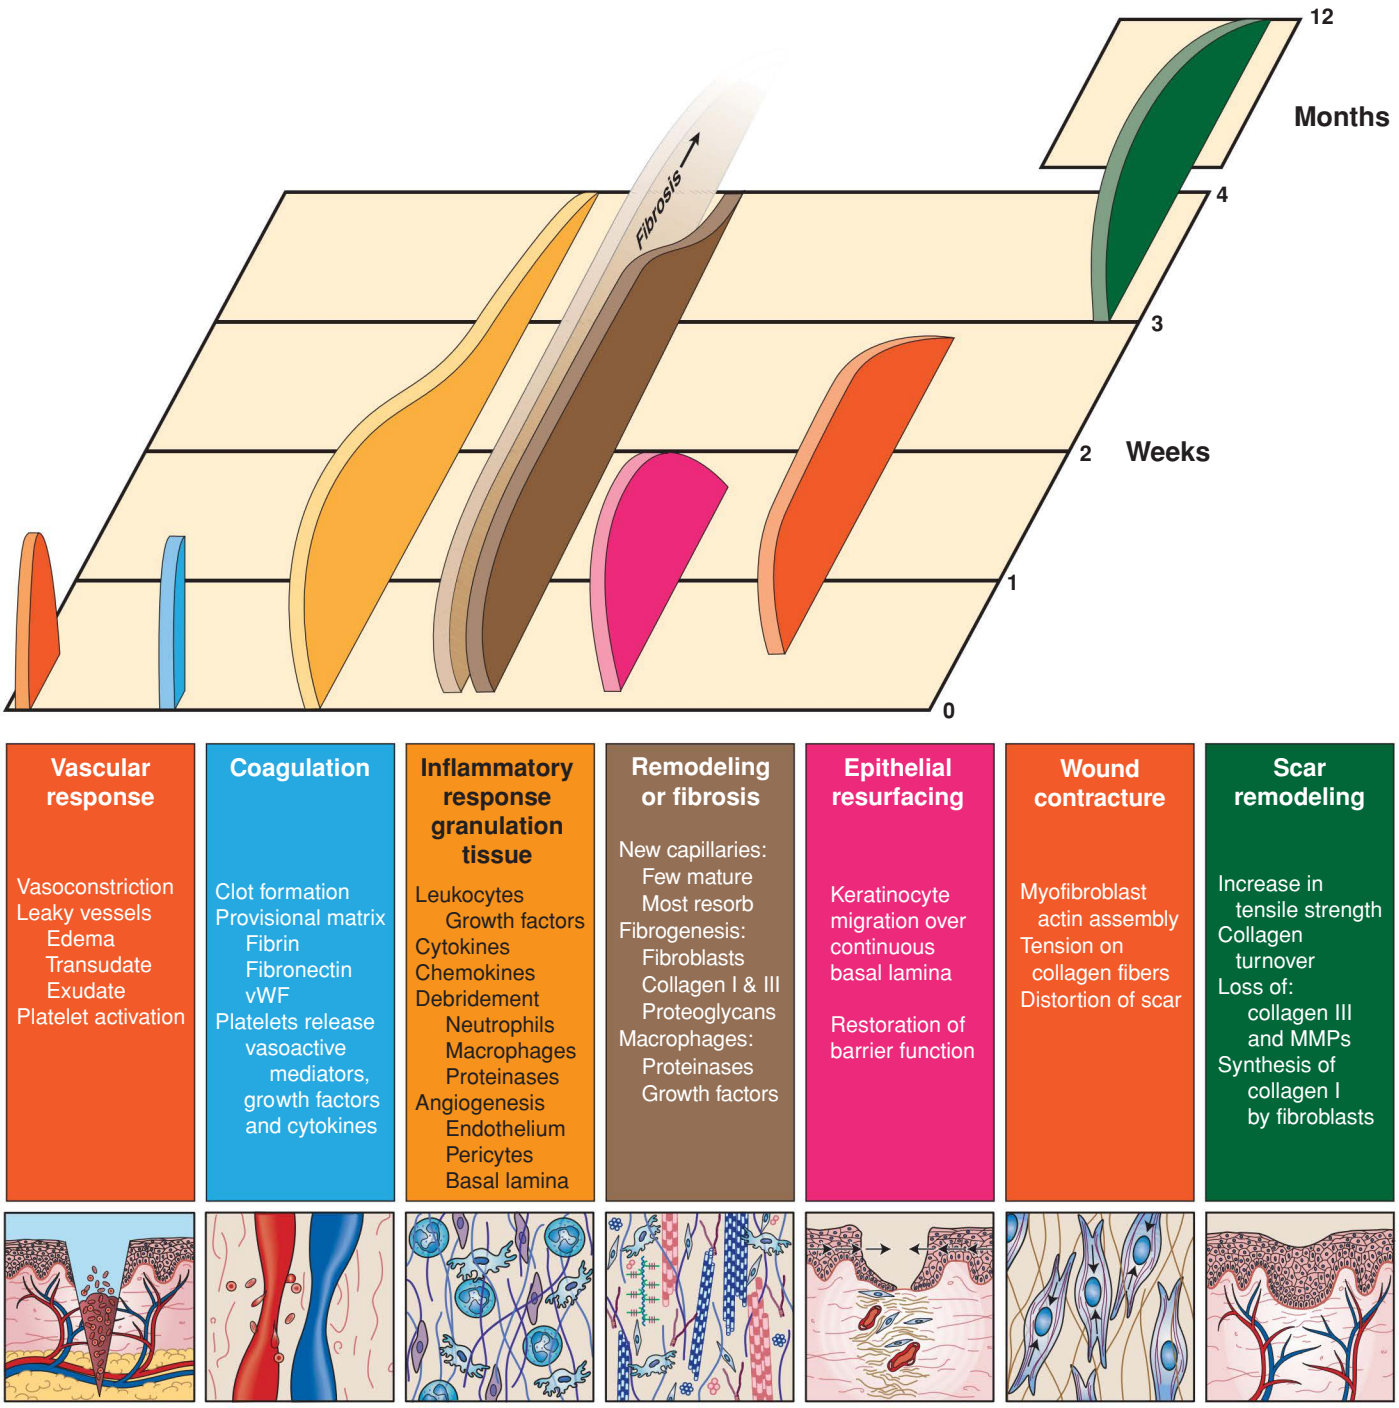

FIGURE 3-5. The sequential phases of the healing process.

studied as models. Healing within hollow viscera and body cavities, though less accessible for study, generally parallels the repair sequence in skin, as illustrated in Figs. 3-5 and 3-6.

Thrombosis

A thrombus (clot)—a **scab** or **eschar** after it dries atop a surface wound—forms a barrier on wounded skin to invading microorganisms. The formation of the fibrin clot is essential to prevent loss of plasma and tissue fluid. Although the clot/thrombus is predominantly plasma fibrin, the thrombus is also rich in the adhesive protein fibronectin. The thrombus also contains contracting platelets, whose aggregation produces an initial burst of stored growth factors. At the site of injury, fibrin is bound to fibronectin and is progressively cross-linked by factor XIII (FXIII), a transglutaminase that forms glutamyl-lysine cross-links between proteins that form the clot and extracellular matrix proteins. Cross-linking aids clot retraction. Transglutaminase 2 (tissue transglutaminase) fosters cell adhesion, cell migration and organization of wound extracellular matrix by (1) interlinking matrix proteins such as fibrinogen, fibronectin, collagen and vitronectin; (2) providing local tensile strength; and (3) maintaining closure during the evolution of new extracellular

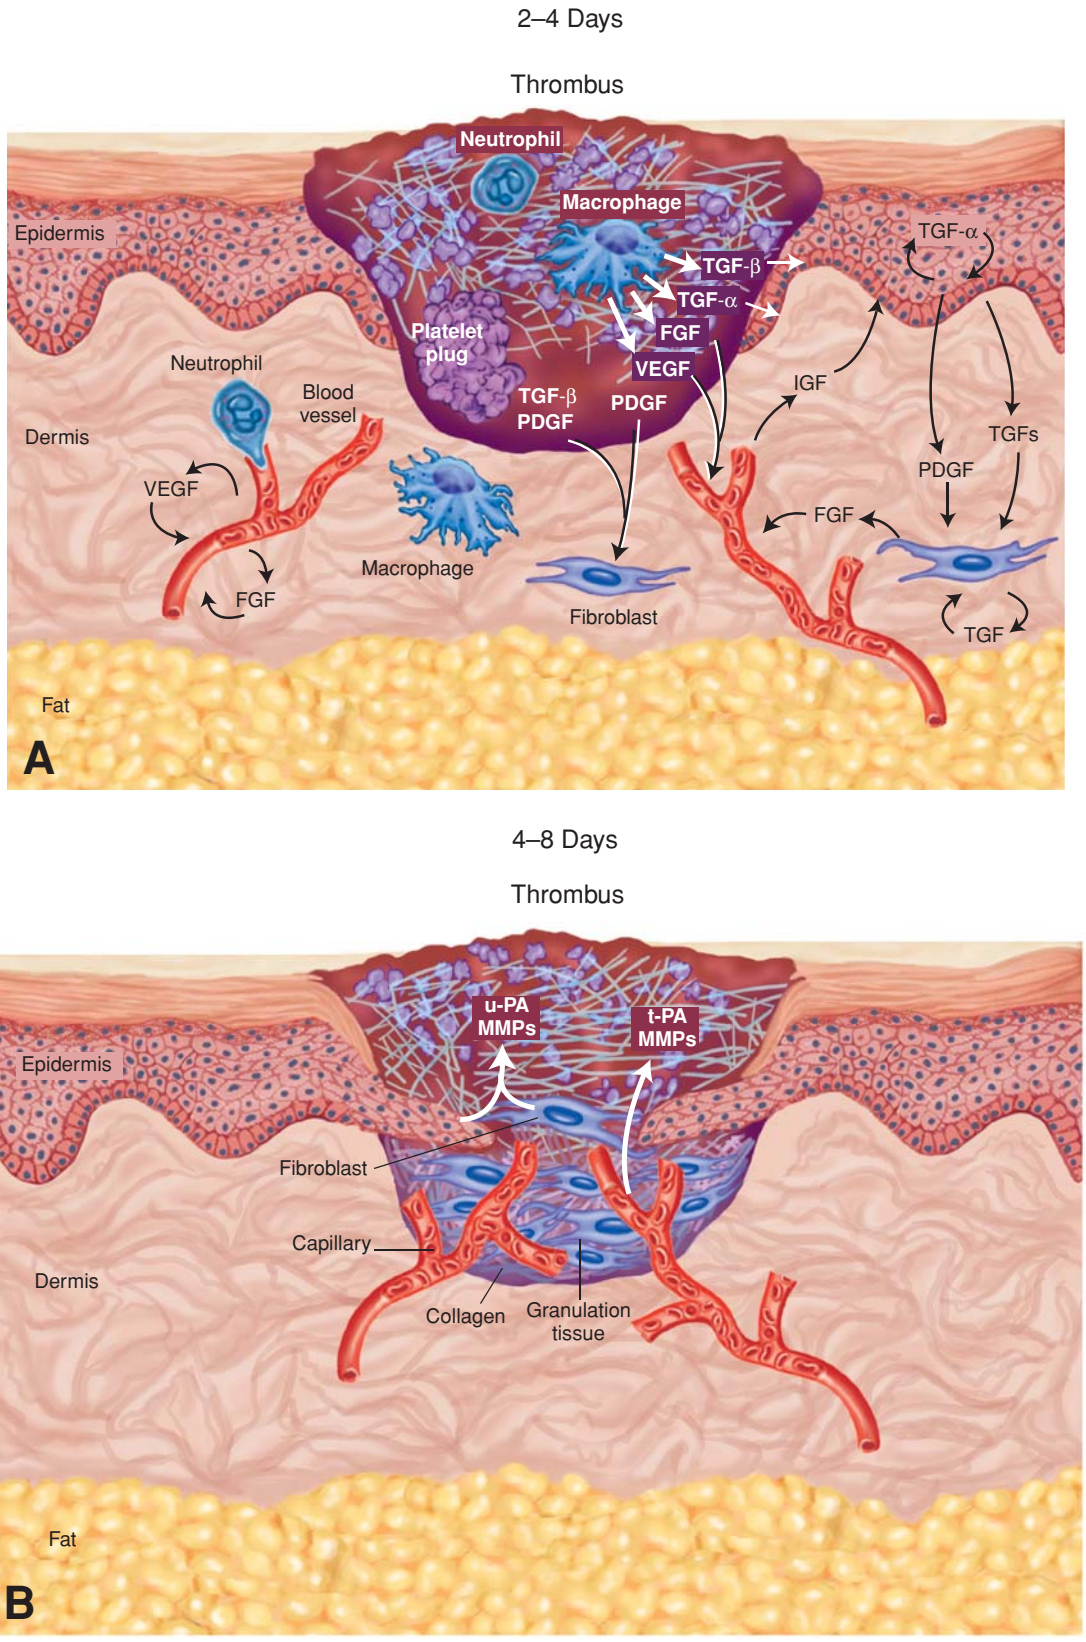

FIGURE 3-6. Cutaneous wound healing. A. 2–4 days. Growth factors controlling migration of cells are illustrated. Extensive redundancy is present, and no single growth factor is rate limiting. Most factors have multiple effects, as listed in Table 3-6. Growth factor signals first arise from degranulating platelets, but activated macrophages, resident tissue cells, injured epidermis and the matrix itself release a complex interplay of interacting signals. **B. 4–8 days.** Capillary blood vessels invade and proliferate within the provisional matrix, and the epidermal keratinocytes advance along the granulation tissue below the thrombus. The upper, acellular portion of the wound site will become an eschar or scab. Fibroblasts deposit a collagen-rich matrix. *FGF* = fibroblast growth factor; *IGF* = insulin-like growth factor; *MMPs* = matrix metalloproteinases; *PDGF* = platelet-derived growth factor; *TGF-β* = transforming growth factor-β; *t-PA* = tissue plasminogen activator; *u-PA* = urokinase-type plasminogen activator; *VEGF* = vascular endothelial growth factor.

matrix. Excess transglutaminase may cause undue scarring. By contrast, factor XIII deficiencies are associated with poor wound healing and bleeding. The internal (nondesiccated) portion of the provisional matrix is transformed into granulation tissue by invasion of mononuclear cells, connective tissue and vascular cells, while the outer portion (eschar) is a temporary repository for spent neutrophils and killed bacteria. As the granulation tissue is partitioned from the eschar by migrating epidermis during normal healing, the portion of the thrombus that is not repopulated by new tissue is digested. The scab then detaches.

Inflammation

Repair sites vary in the amount of local tissue destruction. For example, surgical excision of a skin lesion leaves little or no devitalized tissue. Demarcated, localized necrosis accompanies medium-sized myocardial infarcts. By contrast, widespread, irregularly defined necrosis is a feature of a large third-degree burn. Initially, an acute, neutrophil-dominated, inflammatory response liquefies the necrotic tissue. Acute inflammation persists as long as necrotic material or bacterial infection persists, since these elements must be removed for repair to progress. Before granulation tissue appears, exudative, spent neutrophils may form pus or become trapped in the eschar. Fibronectin, matricryptins, chemokines and cell debris are early chemotactic elements for macrophages and fibroblasts (Figs. 3-5 and 3-7). In epithelial tissues such as skin, a resident population of γδT cells, called dendritic epidermal T cells (DETCs), recognizes adjacent injury and helps initiate the cellular response. It also supports keratinocyte proliferation and survival by secreting growth factors, chemokines and cytokines. ***The repair process begins when macrophages predominate at the site of injury (Fig. 3-8).*** Local tissue macrophages are reported to be capable of proliferation in some tissue settings. However, inflammation triggers significant recruitment of inflammatory cells, including monocyte macrophages. Chemokines facilitate the mobilization of monocytes from bone marrow and a splenic reserve. Chemokines and neutrophil granule contents then attract circulating monocytes to the site of injury. Recruited monocytes (1) initially move into tissue, (2) transform into macrophages, (3) ingest remnants of neutrophils and (4) secrete matrix metalloproteinases, with further degradative activity facilitating liquefaction. Classification of macrophage and dendritic cell subtypes, or even the distribution between these two cells types, is problematic, as the cell markers currently utilized for classification schemes overlap. Nevertheless, it is important to recognize the plasticity and functional variation within these cell types and their importance in inflammation, immunity, repair and regeneration. Macrophages can assume proinflammatory (M1) or anti-inflammatory (M2) phenotypes, though, practically speaking, there exists a continuum of macrophage phenotypes, with the balance changing through the wounding process. M1, or classically activated macrophages, secrete inflammatory growth factors, cytokines, chemokines and MMPs. M2, or alternatively activated anti-inflammatory macrophages, secrete factors that stimulate fibroblast proliferation, collagen secretion, neovascularization and wound resolution. Macrophage phagocytosis of apoptotic neutrophils favors their inflammatory to anti-inflammatory transition. Regulatory dendritic cells or regulatory macrophages, which may derive from M2 macrophages, suppress the inflammatory response further, supporting wound resolution. Classic dendritic cells are also recruited from bone marrow and migrate to lymph nodes, where they present antigen and activate T helper cells. TIP-DCs (tumor necrosis factor [TNF]- and inducible nitric oxide [NO] synthase–producing inflammatory dendritic cells [DCs]) differentiate from recruited inflammatory macrophages.

Granulation Tissue

Granulation tissue is the transient, specialized organ of repair, which replaces the provisional matrix. Like a placenta, it is only present where and when needed. It is deceptively simple, with a glistening and pebbled appearance (Fig. 3-9). Microscopically, a mixture of fibroblasts, mononuclear cells and red blood cells first invades the provisional matrix. This is followed by the development of extracellular matrix and patent, single cell-lined capillaries, which are surrounded by pericytes and provide a blood supply to fibroblasts and inflammatory cells.

A key step in the process is recruitment of monocytes to the site of injury by chemokines and fragments of damaged matrix. Later, plasma cells are conspicuous, even predominating. Activated macrophages progressively shift from a proinflammatory phenotype to the more constructive M2 phenotype(s), in which they release growth factors and cytokines (Table 3-5, and see below) that direct angiogenesis, activate fibroblasts to form new stroma and continue the degradation and removal of the provisional matrix.

Granulation tissue is fluid-rich, and its cellular constituents supply immunoglobulins, antibacterial peptides **(defensins)** and growth factors. It is highly resistant to bacterial infection, allowing the surgeon to create anastomoses at such nonsterile sites as the colon, in which fully one third of the fecal contents consist of bacteria.

Fibroblasts are also early responders to injury. These collagen-secreting cells (Fig. 3-10) are activated by cytokines, particularly PDGF, FGF, TGF-β and the biochemical environment. Fibroblasts are involved in inflammatory, proliferative and remodeling phases of wound repair. These cells are capable of further differentiation to contractile myofibroblasts (Fig. 3-11), which are characterized by abundant actin stress fibers containing smooth muscle actin. The bone marrow also produces mononuclear cells that can take on a fibroblast phenotype. Such cells include mesenchymal stem cells and fibrocytes; the latter has been suggested as a contributor to fibrosis and scar formation. Although marrow-derived fibroblast-like cells are recruited to wounds, they do not appear to become a permanent part of the connective tissue.

Fibroblast Proliferation and Matrix Accumulation

Early granulation tissue matrix contains hyaluronan, proteoglycans, glycoproteins and fine collagen fibers that predominantly consists of type III collagen (Figs. 3-5 and 3-6). Cytokines released by cells in the damaged area cause vascular leakage and attract both inflammatory cells and vascular endothelial cells. About 2–3 days after injury, activated fibroblasts and capillary sprouts are seen. Fibroblasts in the wound change from oval to bipolar, as they begin to produce collagen (Figs. 3-7 and 3-10) and other matrix proteins, such as fibronectin, and develop contractile properties. Secretion of type III collagen is

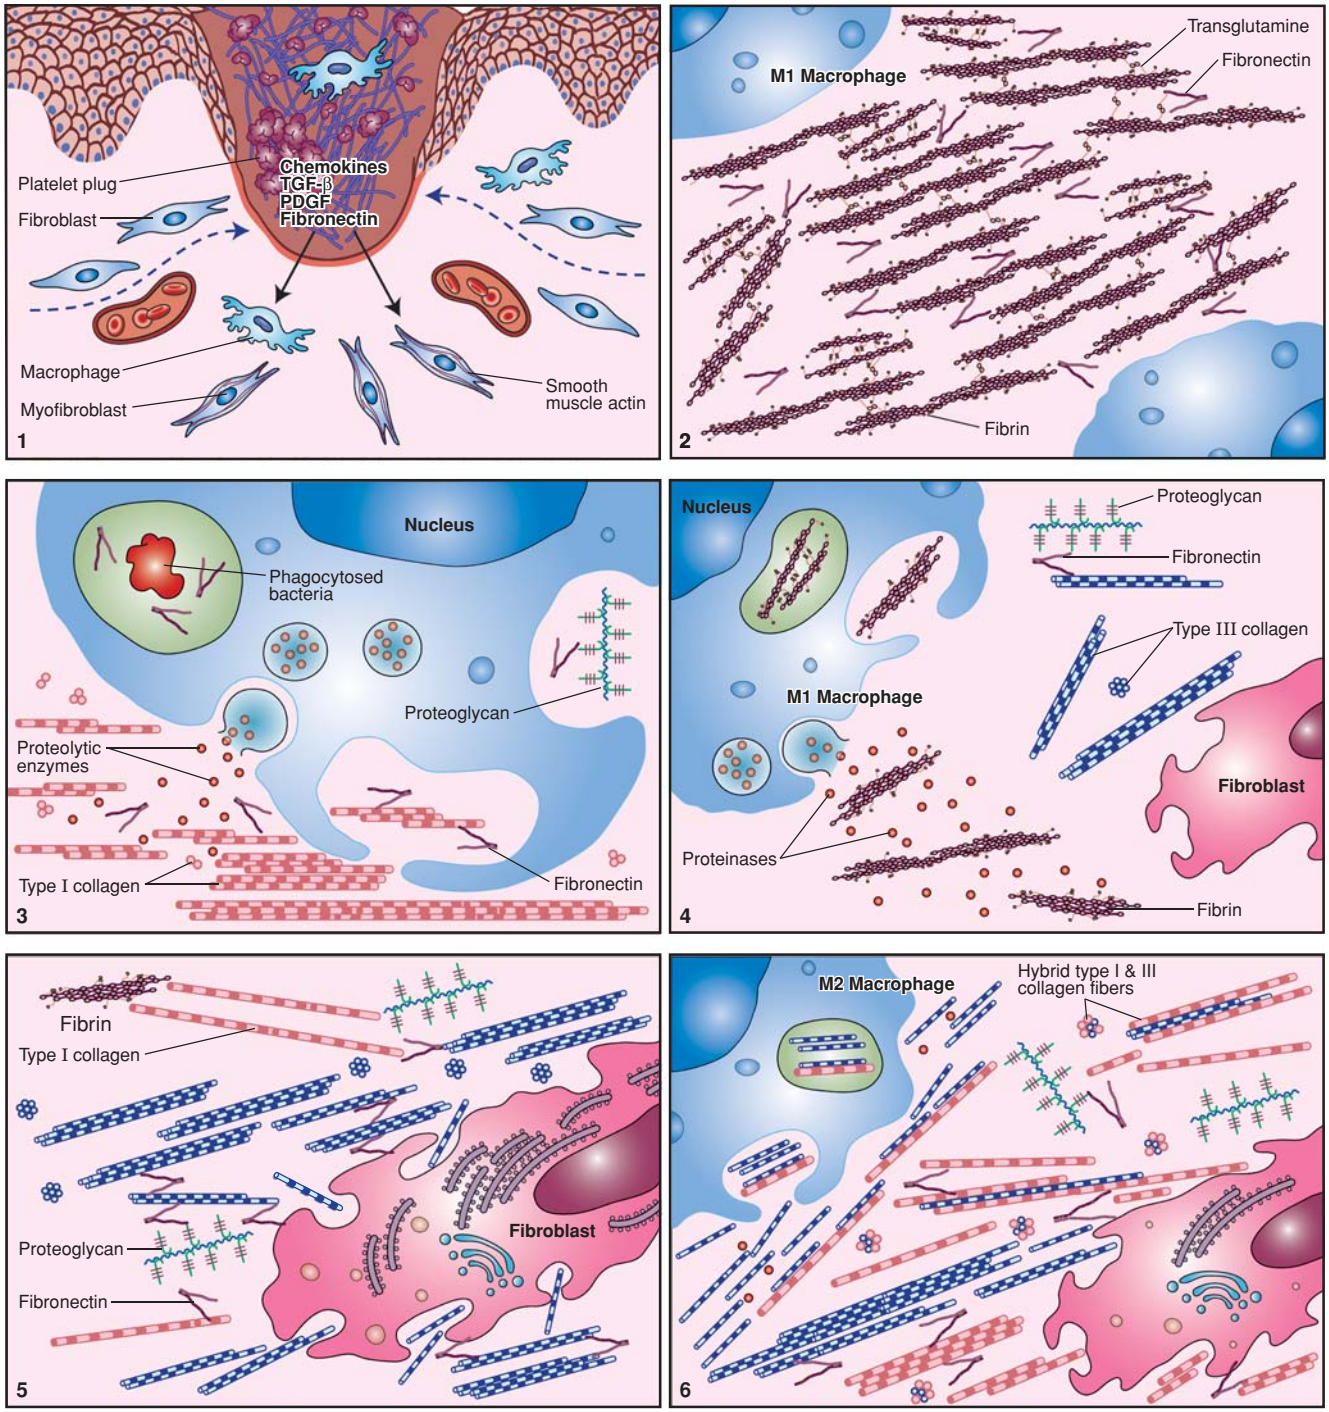

FIGURE 3-7. Summary of the healing process. 1. Inflammatory cell migration. A low-power view of the wound site depicts the mobilization of macrophages, fibroblasts and smooth muscle actin-containing myofibroblasts as they migrate to the wound from the surrounding tissue into the provisional matrix. Fibronectin, growth factors, chemokines, cell debris and bacterial products are chemoattractants for a variety of cells that are recruited to the wound site (2–4 days). The initial phase of the repair reaction typically begins with hemorrhage into the tissues. **2.** A **fibrin clot** forms from plasma and platelets, and it fills the gap created by the wound. Fibronectin from the extravasated plasma binds fibrin, collagen and other extracellular matrix components within fibrin strands that are cross-linked by the action of transglutaminase (factor XIII). This cross-linking provides a provisional mechanical stabilization of the wound (0–4 hours) and a substrate for integrin-dependent cell migration. Neutrophils rapidly infiltrate in the presence of chemotactic signals from bacteria or damaged tissue. **3. Macrophages** recruited to the wound area further process cell remnants and damaged extracellular matrix. The binding of fibronectin to cell membranes, collagens, proteoglycans, DNA and bacteria (opsonization) facilitates phagocytosis by these macrophages and contributes to the removal of debris (1–3 days). **4.** During the intermediate phase of the repair reaction, recruited **fibroblasts** deposit a new extracellular matrix at the wound site that is initially enriched in type III collagen and hence finer collagen fibers. Concurrently, the fibrin clot is cleared by a combination of extracellular proteolysis and phagocytosis (2–4 days). **5.** Together with fibrin removal by macrophages, there is continued fibroblast production of a **temporary matrix** including proteoglycans, glycoproteins such as polymerized cellular fibronectin and fibers enriched in type III collagen (2–5 days). Integrin receptors aid in the assembly of fibronectin complexes, and both integrins and fibronectin help assemble collagen fibrils. **6. Final phase of the repair reaction.** Fibroblasts progressively convert to production of thicker, stiffer collagen fibers that are enriched in type I collagen and the temporary, thinner collagen III–enriched fibers are turned over, leading to the stronger definitive matrix (5 days to weeks). Many other matrix molecules are involved in the assembly of the collagen network.

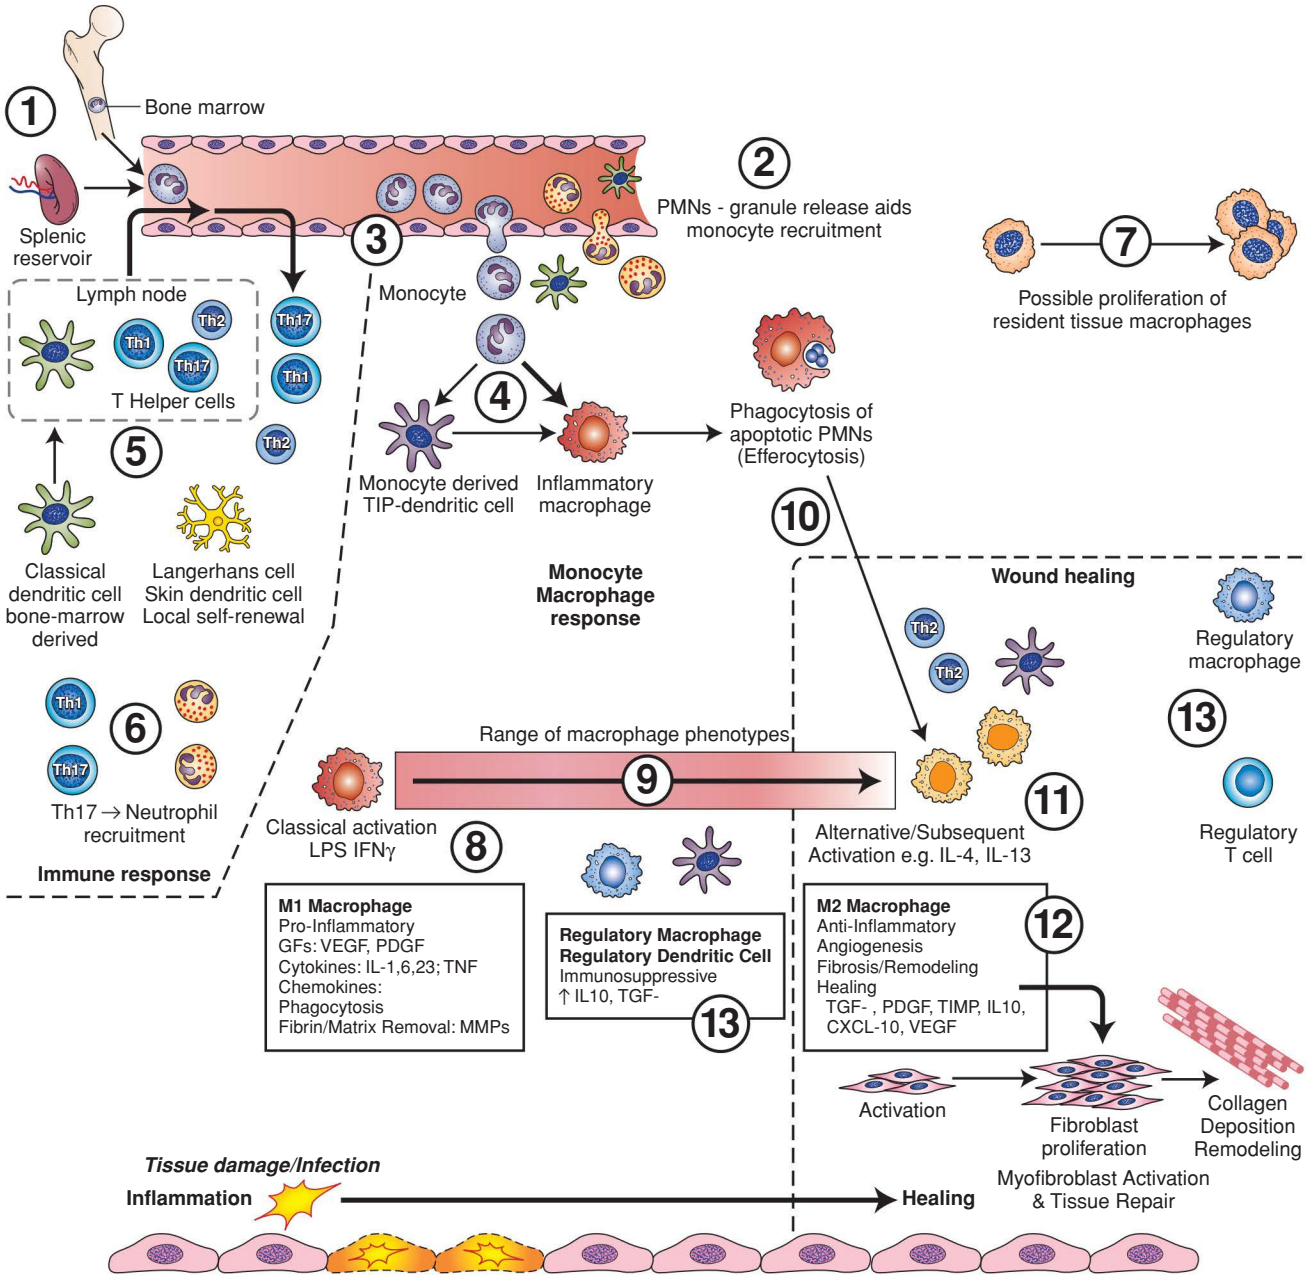

FIGURE 3-8. Macrophage recruitment and function at the site of the wound. Under normal conditions, approximately 5% of the circulating leukocytes are monocytic, some of which crawl along vascular endothelium, apparently patrolling tissue vasculature for injury. Chemokine release, caused by inflammation, stimulates release of neutrophils and monocytes from bone marrow (1). Monocytes may also be recruited from a reservoir in the subcapsular red pulp of the spleen (1). Neutrophil granule release aids in attracting monocytes to the site of injury (2). Monocytes and dendritic cells (DCs) have separate and shared paths of differentiation and often have shared markers but different functions; plasticity is a feature of both cell types. Classic dendritic cells populate tissue from bone marrow. In skin resides a resident population of dendritic cells called Langerhans cells, which resemble resident tissue macrophages and arise prenatally from a macrophage population. Dendritic cells renew locally and are not as likely to migrate to lymph nodes as classic DCs unless activated by antigen. Monocytes entering tissue (3) develop the phenotype of an inflammatory/M1 macrophage or TIP-DCs (tumor necrosis factor– and inducible nitric oxide synthase–producing inflammatory DCs) (4). As part of the innate immune response, dendritic cells phagocytose antigen and migrate (5) to a local lymph node where they encounter hundreds of T lymphocytes, activating those able to recognize the antigen. The T helper/effector cells (Th1 or Th17) then return to the tissue to aid in the immune response. During the early response, Th17 cells secrete interleukin-17, attracting more neutrophils (6). Resident tissue macrophages have been shown to proliferate in some tissues (7); however, the bulk of macrophages migrate from the circulation to the site of injury. Recruited macrophages are M1 macrophages, activated by interferon and infectious particles. They are proinflammatory and secrete cytokines, growth factors, chemokines and matrix metalloproteinases (8) to attract more inflammatory cells and stimulate breakdown and removal of infectious agents and debris. The macrophages at the wound site are a mixture of transitional (9) phenotypes, with M1 cells predominating during early phases (8). As macrophages phagocytose apoptotic neutrophils (10) and the cytokine environment transitions from inflammatory cytokines to immunosuppressive cytokines while growth factors increase, an anti-inflammatory, M2, macrophage (11) begins to predominate. Under this influence, angiogenesis and fibrogenesis prevail as the restorative process initiates. Fibroblasts accumulate, and under the influence of macrophage-derived transforming growth factor-β (TGF-β), a portion of these cells transform into myofibroblasts, leading to increased collagen and matrix synthesis, mechanical tension and contraction of the wound (12). Regulatory T cells and macrophages (13) aid in development and maintenance of an immunosuppressive phenotype in the presence of interleukin-10 (IL-10) and TGF-β, and the wound transitions to remodeling of the early matrix.

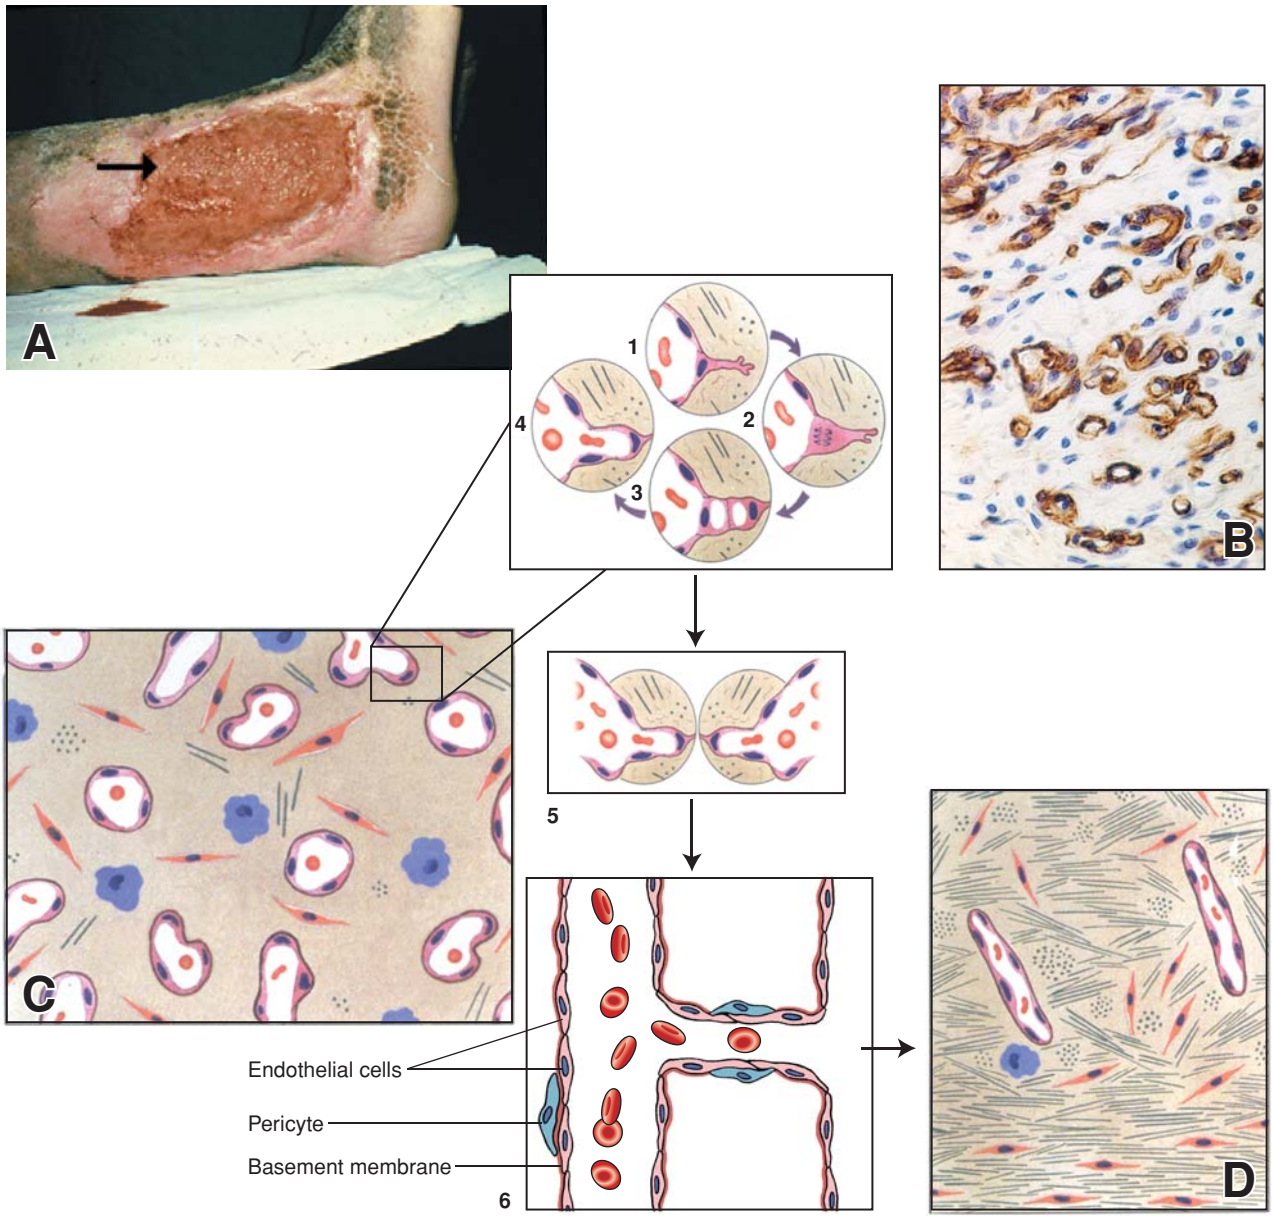

FIGURE 3-9. Granulation tissue. A. A venous stasis leg ulcer illustrates the cobbled appearance of exposed granulation tissue. **B.** A photomicrograph of granulation tissue shows thin-walled capillary sprouts immunostained to highlight the basement membrane collagens. The infiltrating capillaries penetrate a loose connective tissue matrix containing mesenchymal cells and occasional inflammatory cells. **C.** Granulation tissue has two major components: stromal cells and proliferating capillaries. Initially, capillary sprouts of granulation tissue are a key feature, growing in a loose matrix in the presence of fibroblasts, myofibroblasts and macrophages. The macrophages are derived from monocyte migration to the wound site. The fibroblasts derive from adjacent connective tissue or possibly from circulating fibrocytes and mesenchymal stem cells; myofibroblasts derive from fibroblasts, fibrocytes or pericytes; and the capillaries arise primarily from adjacent vessels by division of the lining endothelial cells (steps 1–6), in a process termed ***angiogenesis***. Endothelial cells put out cell extensions, called ***pseudopodia,*** that grow toward the wound site. Cytoplasmic flow enlarges the pseudopodia, and eventually the cells divide. Vacuoles formed in the daughter cells eventually fuse to create a new lumen. The entire process continues until the sprout encounters another capillary sprout, with which it will connect. At its peak, granulation tissue is the most richly vascularized tissue in the body. **D.** Once repair has been achieved, most of the newly formed capillaries undergo apoptosis, leaving a pale, avascular scar rich in collagen.

rapidly overwhelmed by type I collagen, which promotes the assembly of larger-diameter fibrils with greater tensile strength. Eventually, the matrix resumes its original composition of predominantly type I collagen and 15%–20% type III collagen.

The rate of matrix accumulation peaks at 5–7 days, depending on the tissue. This process is strongly influenced by the production of TGF-β, which increases synthesis of collagen, fibronectin, TIMPs and other matrix proteins, while decreasing MMP transcription and matrix degradation. Extracellular cross-linking of newly synthesized collagen progressively increases wound strength.

Growth Factors and Fibroplasia

The discovery of epidermal growth factor (EGF) and later identification of at least 20 other growth factors have helped

TABLE 3-5
EXTRACELLULAR SIGNALS IN WOUND REPAIR

Phase	Factor(s)	Source	Effects
Coagulation	XIIIa	Plasma	Cross-linking of fibrin thrombus
	TGF-α, TGF-β, PDGF, ECGF, FGF	Platelets	Chemoattraction and activation of subsequent cells
Inflammation	TGF-β, chemokines	Neutrophil, M1 macrophages, endothelial cells	Attract monocytes and fibroblasts; differentiate fibroblasts and stem cells
	TNF-α, IL-1, IL-6, CXCL12, CX3CL1, PDGF		
Granulation tissue formation	FGF-2, TGF-β, HGF	Keratinocytes, monocytes then fibroblasts	Various factors are bound to proteoglycan matrix
Angiogenesis	VEGFs, FGFs, HGF, angioprotein-1/-2	Monocytes, macrophages, fibroblasts, endothelial cells	Development of blood vessels
	PDGF		Pericyte growth
Contraction	TGF-β1, β2	Macrophages, fibroblasts, keratinocytes	Myofibroblasts differentiate, bind to each other and to collagen and contract
Reepithelialization	KGF (FGF-7), HGF, EGF, HB-EGF, TGF-α, activin, TGF-β3, CXCL10, CXCL11	Macrophages, platelets, fibroblasts, keratinocytes, endothelial cells	Epithelial proliferation, migration and differentiation
Maturation, fibroplasia, arrest of proliferation	TGF-β1, PDGF, CTGF, IL-27, IL-4, CX3CL1, thrombospondin	M2 macrophages, fibroblasts, keratinocytes	Accumulation of extracellular matrix, fibrosis, tensile strength
	Heparan sulfate proteoglycan (HSPG)	Endothelium	HSPG: Capture of TGF-β, VEGF and basic FGF in basement membrane
		Secretory fibroblasts	
	Decorin proteoglycan		Decorin: Capture of TGF-β, stabilization of collagen structure, downregulation of migration, proliferation
	Interferon, CXCL10, CXCL11	Plasma monocytes	Suppresses proliferation of fibroblasts and endothelial cells and accumulation of collagen
	Increased local oxygen, decreased mechanotransduction	Repair process	Suppression of release of cytokines
Resolution and remodeling	PDGF-FGF, TGF-β, interleukins	Platelets, fibroblasts, keratinocytes, macrophages	Regulation of MMPs and TIMPs
			Remodeling by restructuring of ECM (e.g., collagen III replaced by collagen I)
	MMPs, t-PAs, u-PAs	Sprouted capillaries, epithelial cells, fibroblasts	
	Tissue inhibitors of MMPs	Local, not further defined	Balance the effects of MMPs in the evolving repair site
	Signals for arrest:	Basal keratinocytes	
	CXCL11 or IP-9,	Neovascular endothelium	Reduce cellularity CXCR3 signals
	CXCL10 or IP-10		Reduced migration and proliferation of fibroblasts, endothelial cells, increased migration of keratinocytes

CTGF = connective tissue growth factor; CXCL10 and 11 = chemokine CXC-type ligand 10 and 11; IP = interferon-γ–induced protein; ECGF = endothelial cell growth factor; ECM = extracellular matrix; EGF = epidermal growth factor; FGF = fibroblast growth factor; HB-EGF = heparin-binding EGF; HGF = hepatocyte growth factor; IL = interleukin; KGF = keratinocyte growth factor (FGF-7); MMPs = matrix metalloproteinases; PDGF = platelet-derived growth factor; SDF-1 = stromal cell–derived factor-1; TIMP = tissue inhibitor of metalloproteinase; TGF = transforming growth factor; TNF = tumor necrosis factor; t-PA = tissue plasminogen activator; u-PA = urokinase-type plasminogen activator; VEGF = vascular endothelial growth factor.

define the signaling mechanisms that rapidly change the course of repair and restoration. The interactions among growth factors, other cytokines and MMPs are illustrated in Tables 3-6 and 3-7. Each signal has a predominant function in repair, but gene deletion studies in mice have revealed the redundancy of many pathways. Frequently, conditional gene deletion is needed because of the essential role of a factor during fetal development. Specificity derives from (1) selective expression from members of large families (e.g., FGF and TGF-β), (2) temporal expression of different

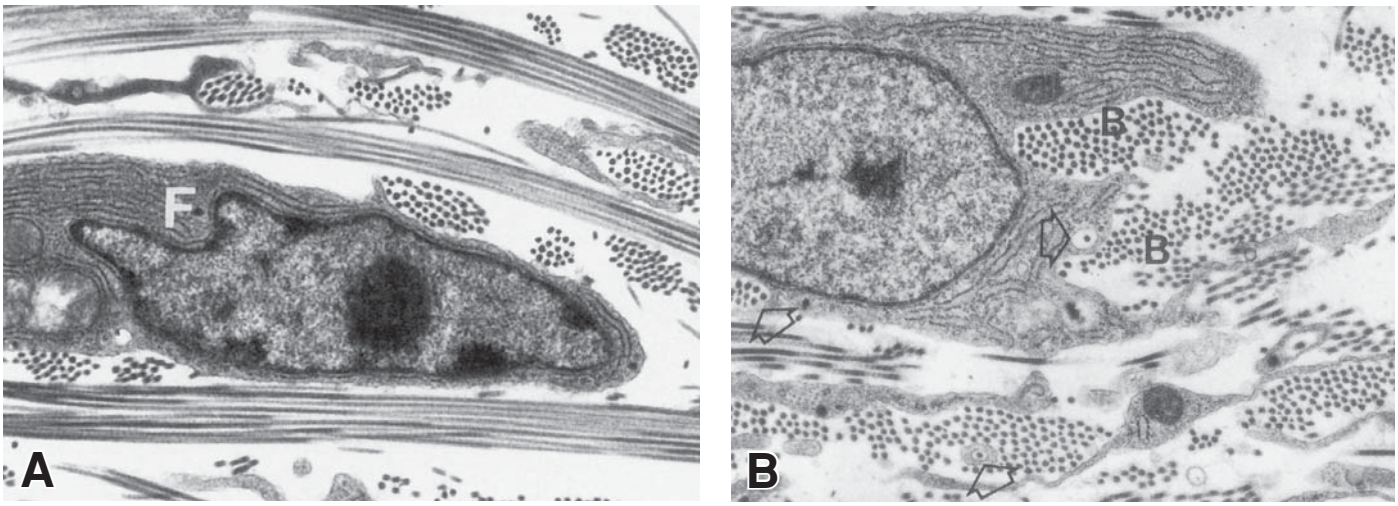

FIGURE 3-10. Fibroblasts and collagen fibers. Electron micrographs. A. Chick embryo fibroblast (F) lying between collagen fibers. The collagen fibers are seen as crosswise strands traversing the field and along the long axis, at a right angle, as dots. **B.** A chick embryo dermal fibroblast with abundant endoplasmic reticulum consistent with secretory activity and cell surface–associated collagen fibril bundles (B); some bundles are enveloped by fibroblast membrane and cytoplasm, indicating that collagen fibers can be assembled and extruded from long cellular processes (fibropositors; *arrows*). The fibrils are visualized in cross-section as dots.

tyrosine kinase receptors and isotypes in unrelated cell populations, (3) variation in response pathways or intensity by distinct receptors and (4) latency or activation of growth factors (Table 3-5). Tables 3-6 and 3-7 show how growth factors control specific events in repair.

Several growth factor ligands are presented to their (tyrosine kinase) receptors by local release from extracellular matrix components, such as heparan sulfate proteoglycan and matricellular and microfibrillar proteins. There are some domains in matrix molecules in the laminin, collagen, tenascin and decorin families that bind weakly to growth factor

TABLE 3-6
GROWTH FACTORS CONTROL VARIOUS STAGES IN REPAIR

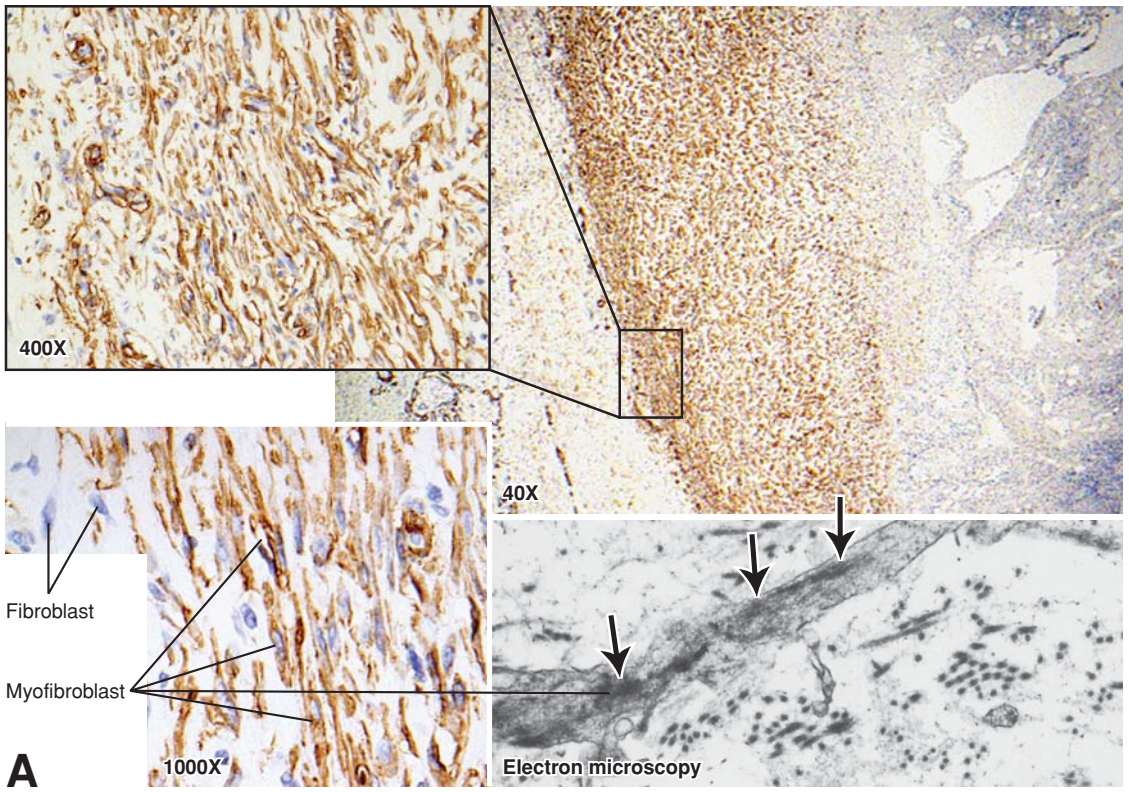
Attraction of Monocytes/ Macrophages	PDGFs, FGFs, TGF-β, MCP-1 (CCL2)
Attraction of fibroblasts	PDGFs, FGFs, TGF-β, CTGF, EGFs, SDF-1
Proliferation of fibroblasts	PDGFs, FGFs, EGFs, IGF, CTGF
Angiogenesis	VEGFs, FGFs, HGF
Collagen synthesis	TGF-β, PDGFs, IGF, CTGF
Collagen secretion	PDGFs, FGFs, CTGF
Epithelial migration and proliferation	KGF, TGF-α, HGF, IGF of epithelium–epidermis
Resolution of repair	IP-9 (CXCL11), IP-10 (CXCL10)

CCL2 = C-type chemokine ligand 2; CXCL 10 and 11 = CXC-type chemokine ligand 10 and 11; CTGF = connective tissue growth factor; EGF = epidermal growth factor; FGF = fibroblast growth factor; HGF = hepatocyte growth factor; IGF = insulin-like growth factor; IP-9/10 = interferon-γ–inducible protein 9/10; KGF = keratinocyte growth factor; MCP-1 = macrophage chemotactic protein-1; PDGF = platelet-derived growth factor; SDF-1 = stromal cell–derived factor-1; TGF = transforming growth factor; VEGF = vascular endothelial growth factor.

TABLE 3-7
GROWTH FACTORS, ENZYMES AND OTHER FACTORS REGULATE PROGRESSION OF REPAIR AND FIBROSIS

Secretion of Collagenase	PDGF, EGF, IL-1, TNF, Proteases
Movement of surface and stromal cells	t-PA (tissue plasminogen activator) u-PA (urokinase-type plasminogen activator) Elastase MMPs (matrix metalloproteinases) MMP-1 (collagenase 1) MMP-2 (gelatinase A) MMP-3 (stromelysin 1) MMP-8 (collagenase 2) MMP-9 (gelatinase B) MMP-13 (collagenase 3) MT1-MMP (MMP-14; membrane bound) MMP-19
Maturation or stabilization of blood vessels	Angiopoietins (Ang1, Ang2); PDGF; HIF-1
Inhibition of collagenase production	TGF-β
Increase of TIMP production	
Reduction in collagen production and turnover	Reduction in mechanotransduction feedback and release/activation of latent TGF-β
Collagen cross-linking and maturation	Lysyl oxidase, integrin receptors, fibronectin polymers, small proteoglycans

EGF = epidermal growth factor; HIF-1 = hypoxia-inducible factor 1; IL = interleukin; PDGF = platelet-derived growth factor; TGF = transforming growth factor; TIMP = tissue inhibitor of metalloproteinases; TNF = tumor necrosis factor.



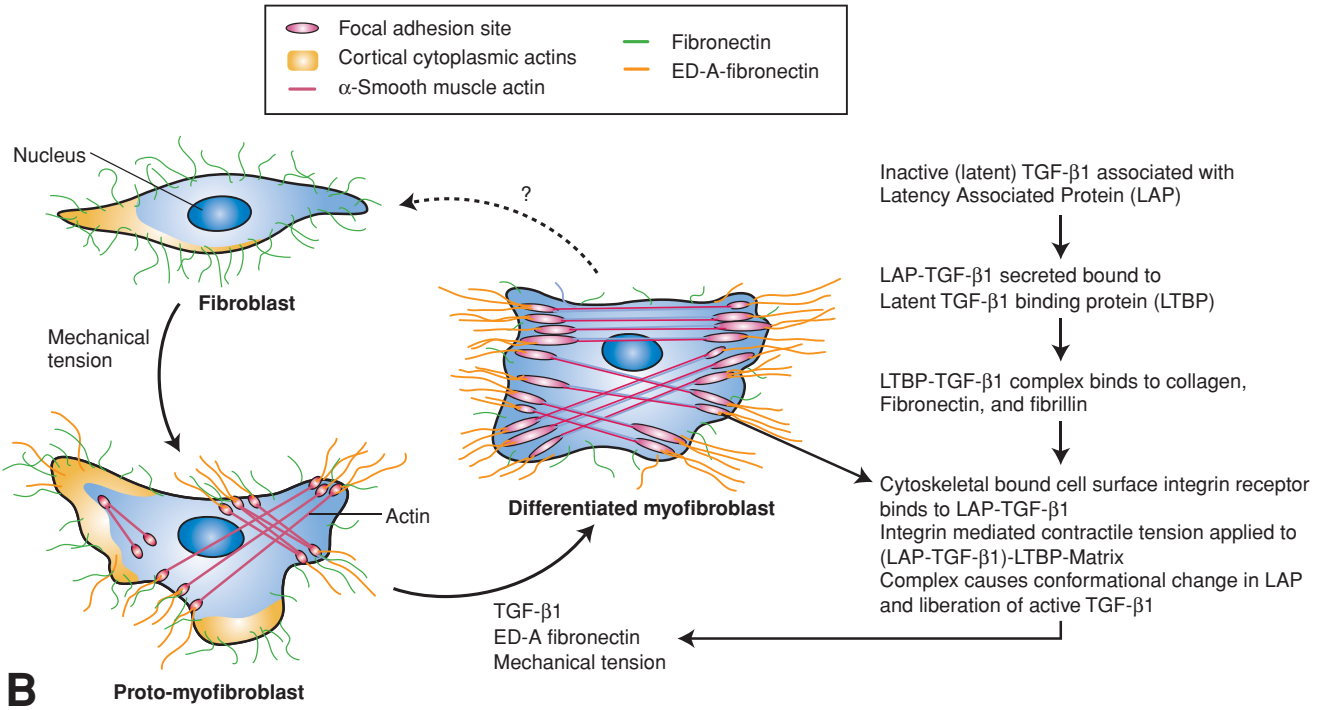


FIGURE 3-11. Myofibroblasts. Myofibroblasts have an important role in the repair reaction. These cells derive from pericytes or fibroblasts, with features intermediate between those of smooth muscle cells and fibroblasts, and they are characterized by the presence of discrete bundles of α-smooth muscle actin in the cytoplasm (*arrows*). Their clustered integrin receptors adhere tightly to and aid in formation of insoluble fibrils of cellular fibronectin, which align the cytoskeleton and bind collagen fibers, generating contractile forces important in wound contraction. **A. Myofibroblasts stained with anti–smooth muscle actin** can be viewed by light microscope at different magnifications. A band of cells (nuclei stain blue, α-smooth muscle actin stains brown) are stained in the papillary dermis of an ulcerated skin wound. Pericytes that surround capillaries also contain α-smooth muscle actin. α-Smooth muscle actin is seen in dense bundles by electron microscopy (*arrows*). **B. Development of myofibroblasts** from fibroblast and a model involving increased matrix production and matrix stiffness, leading to increased cytoskeletal contractility that activates matrix-bound latent transforming growth factor-β (TGF-β), hence creating a positive feedback system that magnifies matrix deposition and contractility. It is thought that this loop is normally interrupted by the phenomenon of tensional homeostasis, a biochemical set point.

receptors. Equally important in growth factor signaling is the presence of cell surface proteoglycans, which weakly tether the signal molecule, and integrins that place receptor binding into a biochemical context by linking the extracellular matrix (ECM) with the cell interior. Unlike hormones, the signals generated by these interactions are confined, persistent and concentrated.

Growth factors expressed or mobilized early in wound responses (VEGF, FGF, PDGF, EGF, keratinocyte growth factor [KGF, FGF7] and others) support migration, recruitment and proliferation of cells involved in fibroplasia, reepithelialization and angiogenesis. Growth factors that peak later (TGF-β, insulin-like growth factor-I [IGF-I]) sustain the maturation phase, growth and remodeling of granulation tissue. Tissue restoration is driven by complex, interactive signaling networks, which, in cooperation with matrix, support self-renewal, maintenance and differentiation of progenitor cells.

Wound outcomes can be improved after various exogenous growth factors are added to experimental wounds. PDGF is clinically effective in accelerating healing in neuropathic diabetic foot ulcers. However, topical application of a single growth factor in a bolus form generally does not prevent scars and does not consistently speed up or improve healing in all problem wounds when compared to accepted methods of chronic wound management. Limited success results, in part, from the lack of responsiveness of the target tissue and wound diagnosis. Progress in cell culture, matrix and growth factor biology has sped the engineering of cultured skin substitutes that express or can be genetically engineered to express many growth factors, which—in combination—can improve clinical outcomes in chronic wounds.

Growth factor participation in the early phases of repair is reasonably well understood, but the mechanisms for limiting and terminating repair are not well defined. Diminishing anoxia as repair progresses and reduced matrix turnover may trigger the denouement of the repair process. Recent evidence suggests that cytokines that bind to the CXCR3 receptor may be important for regression of granulation tissue and limiting scarring. Finally, increased storage and decreased release of growth factors may stabilize the matrix, which may then transmit mechanical signals that reduce the effects of growth factors. Granulation tissue eventually becomes scar tissue, as the equilibrium between collagen synthesis and breakdown comes into balance within weeks of injury. Fibroblasts continue to alter scar appearance for several years.

Angiogenesis

The Growth of Capillaries

At its peak, granulation tissue has more capillaries per unit volume than any other tissue. New capillary growth is essential for delivery of oxygen and nutrients. New capillaries form by angiogenesis (i.e., sprouting of endothelial cells from preexisting capillary venules) (Fig. 3-9) and create the granular appearance for which the tissue is named. Less often, new blood vessels form de novo from angioblasts (endothelial progenitor cells [EPCs]). The latter process, known as **vasculogenesis,** is primarily associated with ontogeny.

Angiogenesis in wound repair is tightly regulated. Quiescent capillary endothelial cells are activated by loss of basement membrane and local release of cytokines and growth factors. Disruption or paucity of basement membranes surrounding endothelial cells and surrounding pericytes precedes or predicts sites of endothelial cells sprouting into the provisional matrix. Endothelial passage through the matrix is an invasive process that requires the cooperation of plasminogen activators, matrix MMPs and integrin receptors. The growth of new capillaries is supported by proliferation and assembly of endothelial cells (Fig. 3-9). There is also a possible contribution of limited numbers of mononuclear, bone marrow–derived endothelial progenitor cells, recruited, at least transiently, to support growing vessels.

Migration of cells into a wound site is directed by soluble ligands. It proceeds as cells follow cytokine signals (by **chemotaxis**) on and inherent signals from matrix substrates (by **haptotaxis**), together with adhesive and mechanical signals from matrix (**durotaxis** or **mechanotaxis**). Once capillary endothelial cells are immobilized, cell–cell contacts form, and an organized basement membrane develops on the exterior of the nascent capillary. Interplay between endothelial cells and pericytes occurs during angiogenesis. Endothelial association with pericytes and signals from angiopoietin I, TGF-β and PDGF are essential to establish a mature vessel phenotype of nonleaky capillaries. New capillaries that have not matured are leaky, create hemorrhage or edema and may undergo apoptosis.

Experimentally, stimulation of angiogenesis in cell culture requires extracellular matrix and growth factors, mainly VEGF. Loss of even one VEGF allele causes lethal defects in embryonic vasculature. In vivo, angiogenesis is initiated by hypoxia and a redundancy of cytokines, growth factors and various lipids, which stimulate or regulate VEGF. The transcription factor HIF-1α (see Chapter 1), whose stability is exquisitely regulated by tissue oxygen tension, is the main trigger for VEGF expression. MicroRNA (miRNA) expression is directly and indirectly influenced by wounding and levels of tissue oxygenation, varying with healing phases in ways that may be specific to cell and tissue. Activated granulation tissue macrophages and endothelial cells produce basic FGF (FGF-2) and VEGF, and wound epidermal cells release VEGF in response to KGF (FGF-7) that is expressed by dermal cells. Because the chief target of VEGF is endothelial cells, this molecule is critical for embryonic vascular development and angiogenesis, endothelial survival, differentiation and migration. Splice variants of VEGF concentrate along soluble and matrix-bound gradients to ensure appropriate vessel branching.

The binding of angiogenic growth factors to heparan sulfate containing GAG chains on proteoglycans of basement membrane and syndecan receptors is crucial to angiogenesis. Association with heparan sulfate chains affects the availability and action of growth factors and vessel pattern formation by (1) creating a storage reservoir of VEGF and basic FGF in capillary basement membranes and (2) using cell surface proteoglycan receptors to regulate VEGF and FGF receptor congregation, as well as signal delivery and intensity.

Angiogenesis and Receptor Crosstalk

Surface integrin receptors sense changes in extracellular matrix and can react by modulating cellular responses to growth factors. This crosstalk is possible because integrin and growth factor signal cascades converge to trigger many of the processes that support cell survival, proliferation, differentiation and migration. Unlike growth factors, integrin receptors drive cell locomotion by organizing

cytoskeletal changes at the membrane. When exposed to growth factors or the loss of an organized basement membrane, quiescent endothelial cells express new integrins that modulate their migration on provisional matrix proteins. Capillary sprouting relies principally on β_1-type integrins. Survival and spatial organization of the capillary network are regulated by other integrins, such as $\alpha_v\beta_3$, which respond to the composition and structure of their extracellular matrix ligands. Without appropriate matrix or sufficient growth factor signaling, endothelial cells are vulnerable to apoptotic cues.

Reepithelialization

The epidermis constantly renews itself by the mitosis of keratinocyte stem cells in the basal layer. The squamous cells then cornify or keratinize as they mature, move toward the surface and are shed a few days later. Maturation requires an intact layer of basal cells that are in direct contact with one another and the basement membrane (Fig. 3-1.5). If cell–cell contact is disrupted, basal epidermal cells migrate laterally and divide to reestablish contact with other basal cells. In partial-thickness skin wounds where the epidermis is destroyed, specialized progenitor cells in the hair follicle become a primary source of regenerating epithelium (Fig. 3-1.5). Once reestablished, the epidermal barrier demarcates the scab from the newly formed granulation tissue. When epithelial continuity is reestablished, the epidermis resumes its normal cycle of maturation and shedding.

Epidermal integrity protects against infection and fluid loss. Epithelial cells in the skin and many hollow organs cover or close wounds either by migrating to cover the damaged surface or, less often in minor abrasions, by a cinching process called **purse-string closure,** augmenting fibroblast/myofibroblast-mediated wound contraction. Skin provides an intensively studied example of epithelial repair, since there are complex differentiation patterns in the epidermal surface itself, the hair follicle and the sweat glands. The basal layer **epidermal keratinocytes** contribute important cytokines (interleukin-1 [IL-1], VEGF, TGF-α, PDGF, TGF-β) that initiate healing and local immune responses as part of the innate immune system. To begin migration, keratinocytes, like capillary endothelium, must transiently differentiate into a migratory cell phenotype before forming a new covering over the wound. These cells normally bind laminin in the underlying basement membrane by hemidesmosome protein complexes containing $\alpha_6\beta_4$ integrin. Several members of the collagen family, namely, type XVII collagen (BP-180) and collagen type VII, also termed **anchoring fibril** (Table 3-2), are associated with the hemidesmosome complex. The anchoring fibril connects the hemidesmosome–basement membrane complex to the dermal connective tissue collagen fibers. Mutations in collagen XVII, epidermal basement membrane laminin, integrin $\alpha_6\beta_4$ or collagen VII produce a potentially fatal skin blistering disease, termed **epidermolysis bullosa**. Autoantibodies against the transmembrane collagen XVII (BP180, BPAG2) cause acquired blistering disorders like **bullous pemphigoid** (see Chapter 28).

Epithelial cells are connected at their lateral edges by **tight junctions** and **adherens junctions** composed of cadherin receptors. Cadherins are calcium-dependent, integral membrane proteins that form extracellular cell–cell connections and anchor intracellular cytoskeletal connections. In adherens junctions, they bind stable actin bundles to a cytoplasmic complex of α-, β- and γ-catenins. The layer of actin that encircles the epithelial cytoplasm creates lateral tension and strength and is called the **adhesion belt**. ***The shape and strength of epithelial sheets result from the tension of cytoskeletal connections to basement membrane and cell-to-cell connections.***

Cellular migration is the predominant means by which wound surfaces are reepithelialized. Groups of basal and suprabasal keratinocytes originate at the margin of a wound and migrate along the provisional matrix. At the same time, adjacent progenitor cells in the basal layer, hair follicles or sweat glands undergo mitosis, resulting in a thickened (hypertrophic) and less differentiated epidermis. If the basement membrane is lost, cells come in contact with unfamiliar stromal or provisional matrix components, which stimulates cell locomotion and proteinase expression. As a result, β_1 integrins that recognize stromal collagens shift from the lateral to the basal epithelial surface. Keratinocytes at the leading edge of the wound margin become migratory and secrete MMPs. These enzymes facilitate their detachment from the basement membrane and remodeling of the granulation tissue surface. Cells migrate along a soluble chemical gradient **(chemotaxis),** owing to matrix concentration or adhesion **(haptotaxis)** and matrix pliability or stiffness **(durotaxis)**.

Epithelial motility is activated by assembly of actin fibers at focal adhesions organized by integrin receptors. Distinct sets of integrins bind to components of the wound, namely, stromal or basement membrane matrices, and direct the migrating cells along the margin of viable dermis. Movement through cross-linked fibrin apposed to the granulation tissue also requires activation of plasmin from plasminogen to degrade fibrin. In addition to degrading fibrinogen and fibrin, plasmin activates specific MMPs. Proteolytic cleavage of stromal collagens I and III and laminin at focal adhesion contacts can release cell adhesion or enable keratinocyte migration. Migrating keratinocytes that have undergone this **epithelial-mesenchymal transition** (EMT) (see Chapter 5) eventually resume their normal phenotype. They become less hypertrophic after re-forming a confluent layer and attaching to their newly formed basement membrane.

Wound Contraction

Open wounds contract and deform as they heal, depending on the degree of attachment to underlying connective tissue structures. A central role in wound contraction and fibrosis in particular is played by a specialized cell of granulation tissue, the **myofibroblast** (Fig. 3-11). Without special immunostaining, this modified fibroblast-like cell is indistinguishable from collagen-secreting fibroblasts. Myofibroblasts contain abundant actin stress fibers (often α-smooth muscle actin), desmin, vimentin and a particular fibronectin splice variant (ED-A) that forms polymerized cellular fibronectin. Myofibroblasts respond to physical or mechanical forces and agents that cause smooth muscle cells to contract or relax. In short, they look like fibroblasts but behave like smooth muscle cells. In addition to differentiating from fibroblasts, the wound myofibroblast has been postulated to derive from circulating, marrow-derived fibrocytes and by EMT in the lung and kidney. Myofibroblasts may also arise from closely related cells in the wound environment, such as perivascular- or perisinusoidal-like pericytes, mesangial

cells in the glomerulus and stellate cells in the liver. ***Together with fibroblasts, myofibroblasts contribute to normal wound contraction and become more prevalent in deforming, pathologic wound contracture.*** Myofibroblasts usually appear about the third day of wound healing, in parallel with the sudden appearance of contractile forces, which then gradually diminish over the next several weeks. These cells are associated with an increase in type I collagen and are prevalent in fibrosis and hypertrophic scars, particularly burn scars. Myofibroblasts and fibroblasts (and other mesenchymal cells) sense the stress exerted by the stiffness of the extracellular matrix on the integrin receptors. This effect triggers contraction in myofibroblasts via intracellular actin stress fibers. The action of cell contraction on the ECM through integrins facilitates the activation of TGF-β, which then reinforces the fibrotic response. Myofibroblasts extend their contractile effects through specific cell–cell interconnections, while fibroblasts are widely distributed in the extracellular matrix. The latter cells lack α-smooth muscle actin and are surrounded by collagen fibers, but with less of the ED-A fibronectin variant.

Wound Strength

Skin incisions and surgical anastomoses in hollow viscera ultimately develop 75% of the strength of the unwounded site. Despite a rapid increase in tensile strength at 7–14 days, by the end of 2 weeks the wound still has a high proportion of type III collagen and has only about 20% of its ultimate strength. Most of the strength of the healed wound results from synthesis and intermolecular cross-linking of type I collagen during the remodeling phase. A 2-month-old incision, although healed, is still obvious. Incision lines and suture marks are distinct, vascular and red. By 1 year, the incision is white and avascular, but usually still identifiable. As the scar fades further, it is often slowly deformed into an irregular line by stresses in the skin.

REGENERATION

Regeneration returns an injured tissue or lost appendage to its original state. Both regeneration and tissue maintenance require a population of stem or progenitor cells that can replicate and differentiate.

The adult human body is composed of several hundred types of well-differentiated cells, yet it maintains the remarkable potential to sustain its form and function by replenishing dying cells. It also heals itself by recruiting or activating cells that repair or regenerate injured tissue. Epithelial cells in the skin and gastrointestinal tract turn over rapidly, but for the most part tissue remodeling is much slower in other adult tissues. Some forms of regeneration may be viewed as partially recapitulating embryonic morphogenesis from pluripotent stem cells. In most cases, regeneration appears to be overwhelmed in the adult by inflammation and fibrosis. The power to replenish or regenerate tissue is derived from a small number of long-lived, unspecialized **stem cells,** unique in their slow replication rate, capacity for self-renewal and production of clonal progeny that rapidly divide and differentiate into more specialized cell types. Stem cells in most tissues, including bone marrow, epidermis, intestine and liver, maintain sufficient developmental plasticity to orchestrate tissue-specific regeneration.

Embryonic and Adult Stem Cells Are Key to Regeneration

Embryonic stem (ES) cells, up to the stage of the preimplantation blastocyst, can differentiate into all cells of the adult organism *and* preserve small populations of more restricted stem cells. Hence, these cells are pluripotent. Postnatal progenitor/stem cells, which are able to divide indefinitely without terminally differentiating, inhabit many adult tissues, and they have been identified even in tissues not known to regenerate. These **adult stem cells** may inhabit a specific tissue or be recruited to sites of injury from circulating cells of bone marrow origin. Either way, the recently appreciated presence of stem cells in many tissues underscores the importance of a permissive and supportive environment for stem cell–driven regeneration (Table 3-8). Multipotential stem cells of adult tissues have a more restricted range of cell differentiation than ES cells and can be isolated from autologous tissue, reducing concerns of immunologic rejection after implantation. More recently, regulators of transcription patterns active in embryonic stem cells have been used to restore pluripotency in differentiated cells of adult tissues (induced pluripotential stem [iPS] cell).

Adult stems cells are challenging to identify and categorize because (1) any organ or tissue may contain more than one type of stem cell, (2) similar stem cells may be found in different organs and (3) a stem cell found in tissue may have originated in the bone marrow. Stem cells may be generally defined by common properties that reflect their exquisite regulation, including:

- Ability to divide without limit, avoid senescence and maintain genomic integrity
- Capacity to intermittently undergo division or to remain quiescent
- Ability to propagate by self-renewal and differentiation of daughter cells
- Absence of lineage markers
- In some cases, specific anatomic localization
- Shared presence of growth and transcription markers common to uncommitted cells

Self-Renewal

Self-renewal is the defining property of adult stem cells and of early ES cells in vivo. The definition of a stem cell depends on the ability of the cell to differentiate into multiple cell types, in vitro or in vivo. Stem cells achieve self-renewal by asymmetric cell division, which produces a new stem cell and a daughter cell that is able to proliferate transiently and to differentiate. In contrast to stem cells, these **progenitor** cells (transit amplifying cells) have little or no capability for self-renewal.

Stem Cell Differentiation Potential

The ability of ES cells to differentiate into all lineages diminishes as the embryo develops. Cells from the zygote and the first few divisions of the fertilized egg are **totipotent;** they can form any of approximately 200 different cell types in the adult body and the cells of the placenta. Nuclei of adult somatic cells can be totipotent, as dramatically proven by nuclear transplantation cloning experiments in amphibians and now several species of domesticated mammals.

TABLE 3-8
ADULT STEM CELLS DESCRIBED IN MAMMALS

Cell Type	Cell Source and Stability	Tissue Stem Cell and Role
Bone marrow–derived stem cells	Hematopoietic stem cells (HSCs) Mesenchymal stem cells (MSCs)	HSC—Hematopoiesis, formation of all blood system cells MSC—Replenish non-blood cells of bone and bone marrow, provide HSC niche and potential source of progenitor cells for certain other tissues
Adult tissue stem cells except connective tissue (some may be bone marrow derived)	*Constantly renewing (labile) cells* –Epithelial and epithelial-like cells of epidermis and gut (ectoderm or endoderm derived)	*Epidermis:* unipotent basal keratinocyte basal stem cell and multipotent stem cells of hair follicle bulge and sebaceous gland *Gut:* multipotent columnar cells of small and large intestine crypt base *Cornea:* corneal epithelial stem cells are located in the basal layer of the limbus between the cornea and the conjunctiva (corneal stromal stem cells are similarly located but beneath the epithelial basement membrane)
	Persistent (stable) cells in tissues with less turnover –Epithelial, parenchyma, neural (endoderm or ectoderm derived)	*Liver:* compensatory hepatocyte hyperplasia for maintenance, for regeneration and in response to surgical resection (other liver cells also divide); hepatic stem cells, DNA markers in label retention studies are seen in cells in the canals of Hering, intralobular bile duct cells, peribiliary null cells and peribiliary hepatocytes *Lung:* putative lung bronchioalveolar progenitor or stem cells that form bronchiolar Clara cells and possibly alveolar cells. Some evidence for alveolar epithelial type II progenitor cells *Ear:* mammalian cochlea are not known to regenerate sensory hair cells, though some nonmammalian vertebrates do. Human mesenchymal stem cells have been differentiated to hair cells and auditory neurons in vitro *Neural stem cells:* multipotent, thought to be ependymal cells or astrocytes; subventricular zone of the lateral ventricle (possibly inactive in adult humans); subgranular zone of dentate gyrus of the hippocampus. Other potential sites are the olfactory bulb and subcallosal zone under the corpus callosum.
Connective tissue or mesenchymal stem cells outside bone marrow	*Mesoderm derived* Progenitors of connective tissue cells; isolated from several tissues, although bone marrow origin cannot be excluded *Muscle cells*	*Skeletal:* satellite cells—between sarcolemma and overlying basement membrane of myofiber—also derived from pericytes or bone marrow mesenchymal stem cells *Adipose:* fat is a rich source of multipotential mesenchymal cells *Kidney:* there are findings supportive of kidney renal tubular and parietal epithelial podocyte (Bowman capsule) stem/progenitor cells. Cells of the kidney are of mesodermal origin, with the possible exception of the endothelial cell *Cardiac:* cardiac progenitor or stem cells—multipotent cardiomyocytes capable of maintaining homeostasis, limited differentiation and proliferation after ischemic injury; bone marrow mesenchymal stem cells

[a]These may be the same as multipotent adult progenitor cells (MAPCs), which represent bone marrow stromal cells whose differentiation is influenced by in vitro growth conditions. These cells are capable of seeding tissues outside the bone marrow by one or more several possible processes: (1) specific progenitors or multipotent progenitors, (b) transdifferentiation, (c) cell fusion and (d) dedifferentiation.

However, this should not be confused with stem cell potency. Somatic cells can now be converted into the totipotent iPS cell with the potential to supply new tissues from the same individual. Postembryonically, implanted ES cells can also form teratomas owing to unregulated differentiation. ES cells that are derived from the inner cell mass of the blastocyst are **pluripotent,** meaning they may differentiate into nearly all cell lineages within any of the three germ layers. Pluripotent stem cells of the postfertilization zygote, such as neural crest cells, may differentiate into many cell types, but they are not totipotent. Those adult cells that must self-renew throughout the lifetime of the organism are generally **multipotent,** or able to differentiate into several cell types within one lineage or one of the germ layers. Hematopoietic stem cells, for example, are lineage restricted; they can form all the cells found in blood (Table 3-8). Marrow stromal cells (also known as mesenchymal stem cells [MSCs]) are multipotent stem cells within bone marrow that can mobilize into the bloodstream and be recruited to (injured) organs. MSCs can be induced to differentiate into multiple cell types

in vitro (adipocytes, chondrocytes, osteoblasts, myoblasts, fibroblasts) derived from a single cell lineage, the mesoderm germ layer. Mesenchymal stem cells have also been isolated from cord blood and many other connective tissues.

Tissue-specific cells support renewal as multipotent stem cells or as progenitor cells. Progenitor cells are **stable cells** that are distinguished from stem cells by their incapacity for self-renewal; however, they maintain the potential for differentiation and rapid proliferation. They are sometimes referred to as **unipotent** stem cells, as exemplified by the interfollicular basal keratinocyte of skin, although other skin cells may be multipotent or oligopotent. An example is the more versatile bulge stem cells of the hair follicle, which are able to reconstitute the hair follicle and sebaceous gland and contribute to repair of epidermis.

In addition to normal differentiation pathways within a single tissue, cells of one tissue can **transdifferentiate** into cells of another tissue. In the adult, injured epithelium (renal tubules, pulmonary) may have the ability to transform into fibroblasts under the influence of cytokines such as TGF-β, adding to scarring and fibrosis; cardiac endothelial cells may have the same capacity.

Bone marrow contains hematopoietic, mesenchymal and endothelial stem cells, providing a multifaceted regenerative capacity. Bone marrow stem cells, which are set aside during embryonic development, replenish the bone marrow mesenchyme and hematopoietic population. Endothelial progenitor cells from bone marrow have been implicated in tissue angiogenesis and may supplement endothelial hyperplasia during regeneration of blood vessels. Likewise, bone marrow–derived mesenchymal stem cells can populate repairing tissues in many distant sites (Table 3-8).

Cornified skin epithelium and hair follicles regenerate from stem cells in basal epidermis and the bulge region of the hair follicle. Intestinal epithelium turns over rapidly and is replenished by intestinal stem cells that reside in the crypts of Lieberkühn. Liver reconstitution after partial hepatectomy is a hyperplastic response by mature differentiated hepatocytes of the remaining lobes and is not thought to involve stem cells. However, there is evidence for stem, or progenitor, cell–driven liver regeneration when hepatocytes are damaged by viral hepatitis or toxins. This regeneration is thought to arise from "oval cells" in the small bile ducts. These putative stem cells have characteristics of both hepatocytes (α-fetoprotein and albumin) and bile duct cells (γ-glutamyl transferase and duct cytokeratins) and may reside in terminal ductal cells in the canal of Hering.

Influence of Environment on Stem Cells

Stem cells exist in **microenvironments** or **niches** that provide sustaining signals from extracellular matrix and neighboring cells to limit their differentiation and to ensure their perpetuation, while providing feedback mechanisms that control cell number, fate and motility. Important features of several stem cell niches are basement membrane matrix molecules and proximity of mesenchymal cells, chemokines and specific growth and differentiation factors. The mere presence of adult stem cells or progenitor cells is not sufficient for tissue regeneration when tissue is damaged. Many tissues contain resident progenitor cells, yet do not heal by regeneration. The method of repair is also influenced by the environment of the injury, that is, the growth factors, cytokines, proteinases and composition of the extracellular matrix. Whether a wound is repaired by regeneration or scarring and fibrosis is at least partly determined by the concentration, duration and composition of environmental signals present during inflammation. Maintenance regeneration of adult epidermis or intestinal epithelium generally occurs without inflammation and within an innate extracellular matrix. In such instances, normal structures and architecture are assembled in the absence of fibrosis or scarring. Wounds eventually shift to an inflammatory response and a matrix expression profile that places emphasis on protection (scarring) rather than perfection (regeneration). Spinal cord injury, as an example, provides a particularly difficult challenge. Injury-induced cellular reactions lead to death of neurons, glial cells and oligodendrocytes. Further inflammatory damage results in glial scar development by astrocytes, which release chondroitin sulfate proteoglycans and proteins that block axonal growth. The current strategies for regeneration rest upon the possibility that transplantation of an appropriate stem cell population might reestablish normal tissue function and prevent scarring. Fibrosis, an urgent response to preserve mechanical integrity after tissue damage, is a key impediment to regeneration.

Differentiated Cells Can Revert to Pluripotency

Cell differentiation involves controlled regulation of gene expression within an existing DNA sequence. This occurs via (1) **epigenetic modification** to DNA without changing or rearranging the sequence; (2) reduced expression of pluripotency-limiting genes, including the Polycomb group proteins; and (3) increased expression of lineage development genes. Epigenetic modifications include nucleic acid modifications within the DNA sequence, such as methylation, expression of microRNAs and remodeling of chromatin organization by chromatin-associated proteins and modification of histone proteins (see Chapter 5).

Epigenetic modifiers stabilize and restrict transcriptional states as necessary for cell differentiation and are heritable by progeny (monoallelic alteration inherited from egg or sperm is called **imprinting**). Interplay between epigenetic modifiers and lineage-determining transcription factors is necessary for the progressive differentiation states in a cell lineage. Differentiation is controlled at many levels. It may involve cell–cell contact and extracellular signals, but coactivation and coregulation of transcription factors associated with potency or lineage and epigenetic modifications are also key to the final state of a cell.

Cells Can Be Classified by Their Proliferative Potential

Cell populations divide at different rates. Some mature cells do not divide at all, while others cycle repeatedly.

LABILE CELLS: Labile cells are found in tissues that are in a constant state of renewal. Tissues in which more than 1.5% of the cells are in mitosis at any one time are composed of labile cells. However, stable cells are also constituents of labile tissues with high rates of cell turnover. Labile epithelial tissues that typically form physical barriers between the body and the external environment self-renew constantly. Examples include epithelia of the gut, skin, cornea, respiratory tract, reproductive tract and urinary tract. Hematopoietic cells of the bone marrow and lymphoid organs

involved in immune defense are also labile. Polymorphonuclear nucleocytes and reticulocytes are terminally differentiated cells that are rapidly renewed. ***Under appropriate conditions, tissues composed of labile cells regenerate after injury, provided enough stem cells remain.***

STABLE CELLS: Stable cells populate tissues that normally are renewed very slowly but are populated with progenitor cells capable of more rapid renewal after tissue loss. Liver, bone and proximal renal tubules are examples of stable cell populations. Stable cells populate tissues in which less than 1.5% of cells are in mitosis. Stable tissues (e.g., endocrine glands, endothelium and liver) do not have conspicuous stem cells. Rather, their cells require an appropriate stimulus to divide. ***The potential to replicate, not the actual number of steady state mitoses, determines the ability of an organ to regenerate.*** For example, the liver, a stable tissue with less than one mitosis for every 15,000 cells, rapidly recovers through hepatocyte hyperplasia after loss of up to 75% of its mass.

PERMANENT CELLS: Permanent cells are terminally differentiated, have lost all capacity for regeneration and do not enter the cell cycle. Traditionally, neurons, chondrocytes, cardiac myocytes and cells of the lens were considered permanent cells. If lost, cardiac myocytes and neurons may be replaced from progenitors, but not from division of existing cardiac myocytes or mature neurons. Permanent cells do not divide, but do renew their organelles. The extreme example of permanent cells is the lens of the eye. Every lens cell generated during embryonic development and postnatal life is preserved in the adult without turnover of its constituents.

CONDITIONS THAT MODIFY REPAIR

Local Factors May Influence Healing

Location of the Wound

In addition to its size and shape, the location of a wound also affects healing. In sites where scant tissue separates skin and bone (e.g., over the anterior tibia), a wound in the skin cannot contract. Skin lesions in such areas, particularly burns, often require skin grafts because their edges cannot be apposed. Complications or other treatments, like infection, obesity, diabetes, chemotherapy, glucocorticoids or ionizing radiation, also slow repair processes.

Blood Supply

Lower extremity wounds of diabetics often heal poorly or may even require amputation because advanced atherosclerosis in the legs (peripheral vascular disease) and defective angiogenesis compromise blood supply and impede repair. Varicose veins of the legs, due to failure of the venous valves to ensure venous return, can cause edema, formation of thick (fibrin) cuffs around microvessels, ulceration and nonhealing (venous stasis ulcers). Bed/pressure sores (decubitus ulcers) result from prolonged, localized, dependent pressure, which diminishes both arterial and venous blood flow and results in intermittent ischemia. Joint (articular) cartilage is largely avascular and has limited diffusion capacity. Often it cannot mount a vigorous inflammatory response, so that articular cartilage repairs poorly in the face of progressive, age-related wear and tear.

Systemic Factors

No specific effect of age alone on repair has been found, although there is evidence that stem cell reserves are reduced with aging (see Chapter 10). Scarring peaks during adolescence and diminishes with age. Healing also declines in postmenopausal women. Although reduced collagen and elastin may make the skin of a 90-year-old person fragile and thus heal slowly, that person's colon resection or cataract extraction heals normally because the bowel and eye are practically unaffected by age.

Coagulation defects, thrombocytopenia and anemia impede repair. Local thrombosis decreases platelet activation, reducing the supply of growth factors and limiting the healing cascade. The decrease in tissue oxygen that accompanies severe anemia also interferes with repair. Exogenous corticosteroids retard wound repair by inhibiting collagen and protein synthesis and by suppressing both destructive and constructive aspects of inflammation.

Fibrosis and Scarring Contrasted

Successful wound repair that leads to localized, transient scarring promotes rapid resolution of local injury. Scars reflect altered deposition of matrix compared to normal, surrounding tissue. Scars may vary in size and may be larger than the wound site, depending on the nature of the wound or its treatment. This occurs particularly where there exists greater mechanical movement and tension, such as over limb joints. Scarring is a typical response to tissue ischemia or infarction, where resident cells cannot be replaced. By contrast, in many chronic diseases of skin and parenchymal organs, including many autoimmune diseases (e.g., scleroderma), inflammation persists. It then progresses to diffuse and progressive **fibrosis,** or **continued and excessive deposition of matrix** proteins, particularly collagen. Inhaled smoke or inhaled silica particles induce chronic inflammation in the lung, while other disturbances of alveolar epithelial type II cell homeostasis foreshadow development of life-threatening idiopathic pulmonary fibrosis. Innate and adaptive immune-mediated inflammation, such as that of joints in rheumatoid arthritis, leads to differentiation and activation of fibroblasts. Both inflammatory and noninflammatory factors cause cardiac, hepatic, lung and kidney fibrosis. By example, glomerulosclerosis in the kidney results from infection, hypertension or diabetes.

Ongoing insult or inflammation, mediated via the interplay of M1 macrophages and T helper (Th2, Th17) lymphocytes, results in persistently high levels of cytokines (IL-1β, IL-6, TNF-α), fibrogenic growth factors (TGF-β) and locally destructive enzymes, such as matrix metalloproteinases. Resolution of a fibrogenic response is associated with M2 macrophages and, in some studies, Th1 and T regulatory cells. The fibrotic reaction, once initiated, may resolve with early removal of the inflammatory or noninflammatory triggers. Fibrosis itself further alters matrix composition, stiffness and mechanical stress, propagating fibroblast conversion to myofibroblasts and further matrix production. The composition of matrix changes from provisional matrix during fibrogenesis and remodeling, providing opportunities for a matrix that supports continued fibrosis. Uncontrolled fibrosis self-perpetuates, despite absence of continued inflammation; it features myofibroblast production of extracellular matrix.

The protein osteonectin/BM-40/SPARC (secreted protein acidic and rich in cysteine) is a nonstructural extracellular matrix protein secreted into the extracellular space (matricellular protein) during development and during fibrosis. SPARC dissociates collagen from the cell surface by competing with binding of fibrillar collagens to the cellular discoidin domain receptor, and it may encourage further collagen secretion and deposition. Similarly, osteopontin is associated with persistent fibrosis in several organs. Regardless of the underlying mechanism, fibrosis of parenchymal organs such as the heart, lungs, kidney or liver disrupts normal architecture and impedes function. The functional unit (smooth muscle, alveolus, hepatic lobule or renal glomerulus or tubule) is replaced by disordered collagen. Such fibrosis and resulting dysfunction are largely irreversible. Correction requires removing the inciting stimulus by treatment, as in rheumatoid arthritis, to suppress inflammation and so minimize tissue damage. Otherwise, tissue architecture and mechanics are so impaired that regenerative processes cannot reverse the injury.

Fibrosis is the pathologic consequence of persistent injury and causes loss of function. Fibrosis is an abnormal process that develops from persistent or impaired normal processes. Often it is the final common result of diverse diseases or injuries, the causes of which cannot be ascertained from the end result. As an example, in scars of former glomeruli damaged following bacterial or immunologic injury to the kidney, the specific cause is no longer identifiable. Scarring, however, is often beneficial; it restores structural (if not necessarily functional) integrity to the injured area.

Prevention of fibrosis requires either blocking the stimulus of matrix production or increasing the level of matrix degradation. TGF-β and connective tissue growth factor (CTGF, CCN-2) are regulators of matrix production and have been associated with fibrotic connective tissue diseases. The process is also regulated by cytokines, growth factors, Wnt/β-catenin signaling and microRNAs. Approaches to controlling fibrotic progression to end-stage kidney disease have targeted profibrotic factors such as TGF-β and plasminogen activator inhibitor-1 (PAI-1). Inhibition of PAI-1 elicits activation of plasminogen. As a result, plasmin degradation of extracellular matrix is increased, directly or through activating MMPs. Matrix deposition in the glomerulus is reduced, protecting the glomerulus from scarring and obliteration. Interestingly, inhibition of PAI could also reduce the incidence of **intra-abdominal adhesions,** a persistent problem of abdominal surgery and an important cause of intestinal obstruction. These adhesions are initiated by fibrin deposition when mesothelial lining is disrupted or heals ineffectively. If the fibrin matrix is not dissolved by plasmin within a few days, the provisional matrix is invaded by fibroblasts and eventually transformed into a permanent fibrotic adhesion, with collagen, capillaries and nerves.

There is accumulating evidence that resolution of the fibrotic process may not derive merely from reducing activating signals or developing an appropriate level of tensile strength and elasticity. Members of the CXCL3 family of cytokines, which includes interferon-γ–inducible protein 9 (IP-9 or CXCL11) and IP-10 (or CXCL10), are produced by fibroblasts and epithelial cells, among other cell types. Increases in these proteins are associated with reduced fibrosis, while their absence can lead to exaggerated scarring.

Specific Sites Exhibit Different Repair Patterns

Skin

Healing in the skin involves repair, primarily dermal scarring, and regeneration, principally of the epidermis and its appendages, innervation and vasculature. The salient features of primary and secondary healing are provided in Fig. 3-12.

Primary healing occurs when the surgeon closely approximates the edges of a wound. The actions of myofibroblasts are minimized owing to the lack of mechanical strain, and regeneration of the epidermis is optimal, since epidermal cells need migrate only a minimal distance.

Secondary healing proceeds when a large area of hemorrhage and necrosis cannot be totally corrected surgically. In this situation, myofibroblasts contract the wound and reinforce healing with extensive ECM. Resultant scarring repairs the defect.

The success and method of healing following a burn wound depends on the depth of the injury. If it is superficial or does not extend beyond the upper dermis, stem cells from sweat glands and hair follicles regenerate the epidermis. If deep dermis is involved, the regenerative elements are destroyed and surgery with epidermal or keratinocyte grafts is necessary to cover or heal the wound site and reduce scarring and severe contractures. In this case, epidermal appendages (follicles, sweat glands) are not regenerated, but cytokines produced by the grafted epidermis may contribute to the improved outcome.

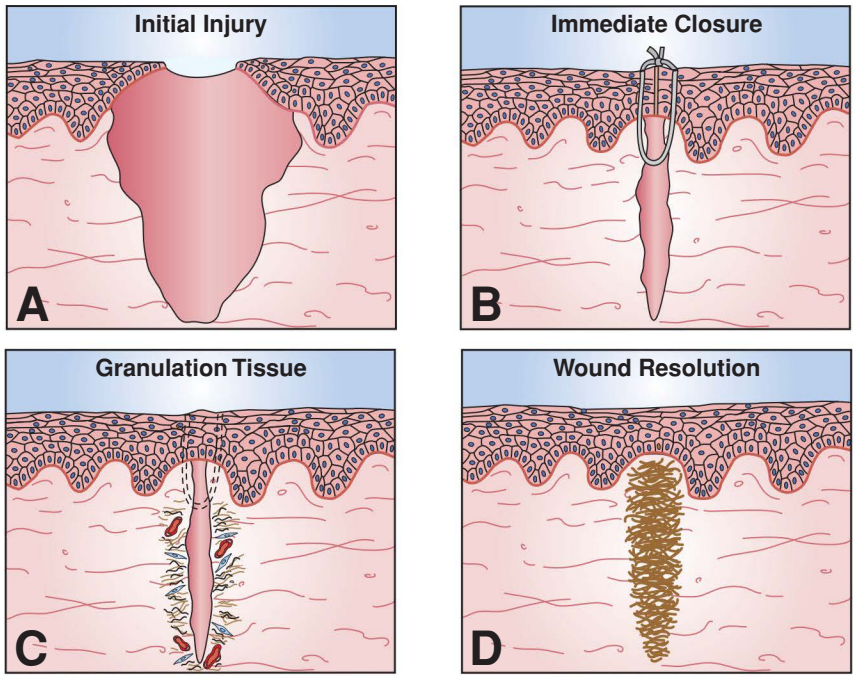
Cornea

The cornea differs from skin in its stromal organization, vascularity and cellularity. Like skin, corneal stratified squamous epithelium is continually renewed by a stem cell population, at the periphery of the corneal limbus. Epithelial damage that does not involve stroma heals by keratinocyte migration and replication without scarring. Chemical, infectious, surgical or traumatic injury to the cornea results in scarring, owing to the distortion of the precisely arranged collagen fibers, effectively blinding the eye. Parenthetically, the cornea, because of its relative avascularity, was the first organ or anatomic structure to be successfully transplanted. Trachoma, an infectious human disease caused by an inflammatory response to *Chlamydia trachomatis,* is the world's most common cause of blindness, resulting from scarring and opacity of the cornea (see Fig. 33-1).

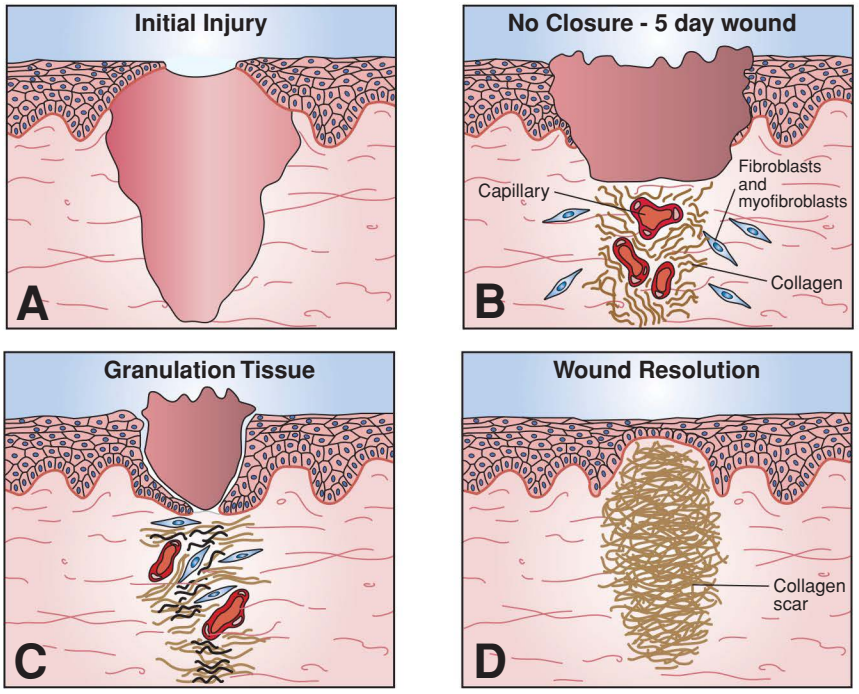
Liver

The liver has tremendous regenerative capacity, even though the normal liver almost totally lacks mitoses and virtually all hepatocytes are in cell cycle phase G_0. After resection, liver regenerates by compensatory hyperplasia of hepatocytes. The necessary conditions for hepatic regeneration are complex (see Chapter 20). Suffice it to say here that regeneration ceases when the normal ratio of liver to total body weight is reestablished; the molecular switch that regulates this ratio is unknown but may involve the *Hippo* pathway, a kinase cascade that controls organ size.

Acute chemical injury or fulminant viral hepatitis causes widespread necrosis of hepatocytes. However, if the connective tissue stroma, vasculature and bile ducts survive, liver parenchyma regenerates, and normal form and function



HEALING BY PRIMARY INTENTION (WOUNDS WITH APPOSED EDGES)



HEALING BY SECONDARY INTENTION (WOUNDS WITH SEPARATED EDGES)

FIGURE 3-12. Top. Healing by primary intention. A. An initial open, incised wound **(B)** with closely apposed wound edges is held together with a suture, leading to minimal tissue gaping or loss. **C.** There is decreased granulation tissue. Such a wound requires only minimal cell proliferation and neovascularization to heal. **D.** The result is a narrow, linear scar. **Bottom. Healing by secondary intention. A.** A gouged wound that remains or is left to remain open. The edges remain far apart and there is substantial tissue loss. **B.** The healing process requires wound contraction (mechanical strain), extensive cell proliferation, matrix accumulation and neovascularization (granulation tissue) to heal. **C.** The wound is reepithelialized from the margins, and collagen fibers are deposited throughout the granulation tissue. **D.** Granulation tissue is eventually resorbed, leaving a large collagenous scar that is functionally and esthetically imperfect.

are restored. There is evidence for liver stem cells capable of supporting regeneration at the canal of Hering, within or peripheral to intralobular bile ducts, and among peribiliary hepatocytes (Table 3-8). By contrast, in chronic injury, viral hepatitis or alcoholism, broad collagenous scars develop within the hepatic parenchyma, termed **cirrhosis** of the liver (Fig. 3-13). Hepatocytes form regenerative nodules that lack central veins and expand to obstruct blood vessels and bile flow. Despite adequate numbers of regenerated hepatocytes, architectural disarray impairs liver function and patients eventually suffer hepatic insufficiency.

Kidney

Although the kidney has limited regenerative capacity, removal of one kidney (nephrectomy) is followed by compensatory hypertrophy of the remaining kidney. If renal injury, such as acute kidney injury due to nephrotoxins or ischemia, is not extensive and the extracellular matrix framework, in particular the basement membrane, is not destroyed, tubular epithelium will regenerate. In most renal diseases, however, the matrix is disrupted, leading to incomplete regeneration with scar formation. The regenerative capacity of renal tissue

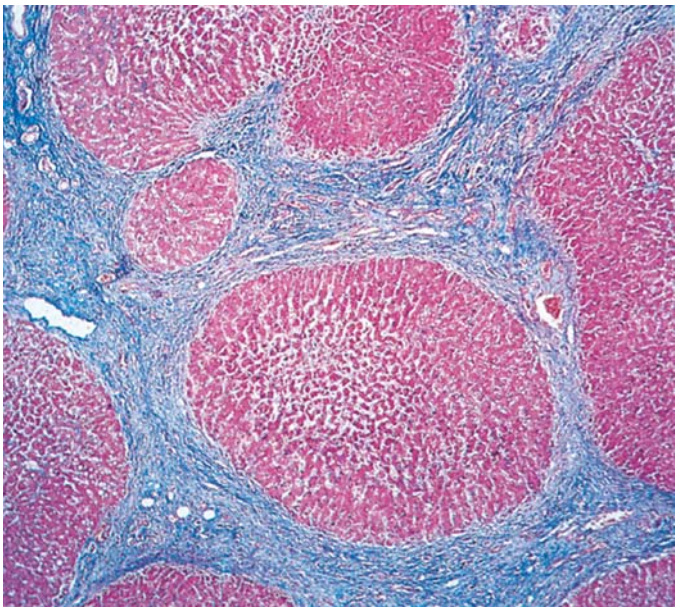


FIGURE 3-13. Cirrhosis of the liver. The consequence of chronic hepatic injury is the formation of regenerating nodules separated by fibrous bands. A microscopic section shows regenerating nodules (*red*) surrounded by bands of connective tissue (*blue*).

is maximal in cortical tubules and less in medullary tubules. Podocyte hypertrophy or regeneration appears to be a possibility in some diseases like diabetes or chronic nephropathy, in which scarring and disease are reversed with pancreatic transplants or inhibition of angiotensin-converting enzyme. Recent data suggest that tubule repair occurs not from bone marrow–derived cells but as a result of proliferation of endogenous, multipotent tubular stem cells.

Cortical Renal Tubules

Tubular epithelium normally turns over and cells are shed into the urine. No reserve cell has been identified, and simple division accomplishes replacement. The outcome of injury hinges on the integrity of the tubular basement membrane. As long as the basement membrane is continuous, surviving tubular cells in the vicinity of a wound flatten, acquire a squamous-like appearance and migrate into the injured area along the basement membrane. Mitoses are frequent, and occasional clusters of epithelial cells project into the lumen. The flattened cells soon become more cuboidal, and differentiated cytoplasmic elements appear. Tubular morphology and function return to normal in 3–4 weeks.

Tubulorrhexis

Following tubulorrhexis, or rupture of the tubular basement membrane, events resemble those in tubular damage with an intact basement membrane, except that interstitial changes are more prominent. Fibroblasts proliferate, increased extracellular matrix is deposited and tubular lumina collapse. Some tubules will regenerate and others will become fibrotic, with consequent focal losses of functional nephrons.

Medullary Renal Tubules

Medullary diseases of the kidney are often associated with extensive necrosis, which involves tubules, interstitium and blood vessels. The necrotic tissue sloughs into the urine. Healing by fibrosis produces urinary obstruction within the kidney. Although there is some epithelial proliferation, there is no significant regeneration.

Glomeruli

Unlike tubules, glomeruli do not regenerate. Necrosis of glomerular endothelial or epithelial cells, whether focal, segmental or diffuse, heals by scarring (Fig. 3-14). Mesangial cells are related to smooth muscle cells and seem to have some capacity for regeneration. Following unilateral nephrectomy, glomeruli in the remaining kidney enlarge by both hypertrophy and hyperplasia. Podocyte progenitor cells in the Bowman capsule may replace lost podocytes.

Lung

The epithelium lining the respiratory tract can regenerate to some degree, if the underlying extracellular matrix framework is not destroyed. Superficial injuries to tracheal and bronchial epithelia heal by regeneration from adjacent epithelium. The progenitor cell has not been clearly identified, although bronchioalveolar stem cells have been proposed, and there is evidence for an alveolar epithelial type II progenitor. Bone marrow–derived stem cells may

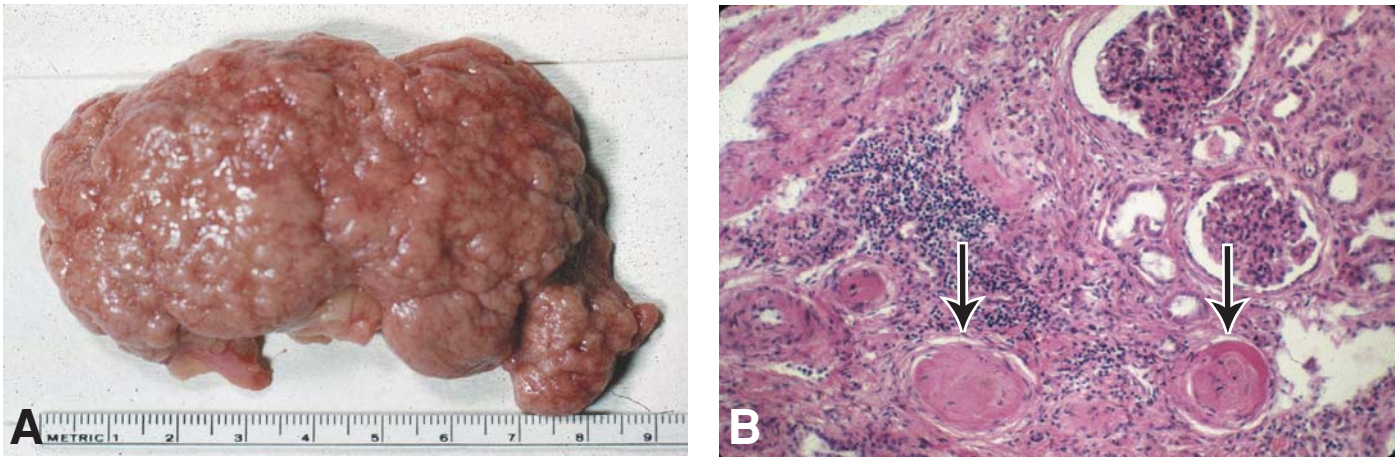

FIGURE 3-14. Scarred kidney. A. Repeated bacterial urinary tract infections have scarred the kidney. **B.** Many glomeruli have been destroyed and appear as circular scars (*arrows*).

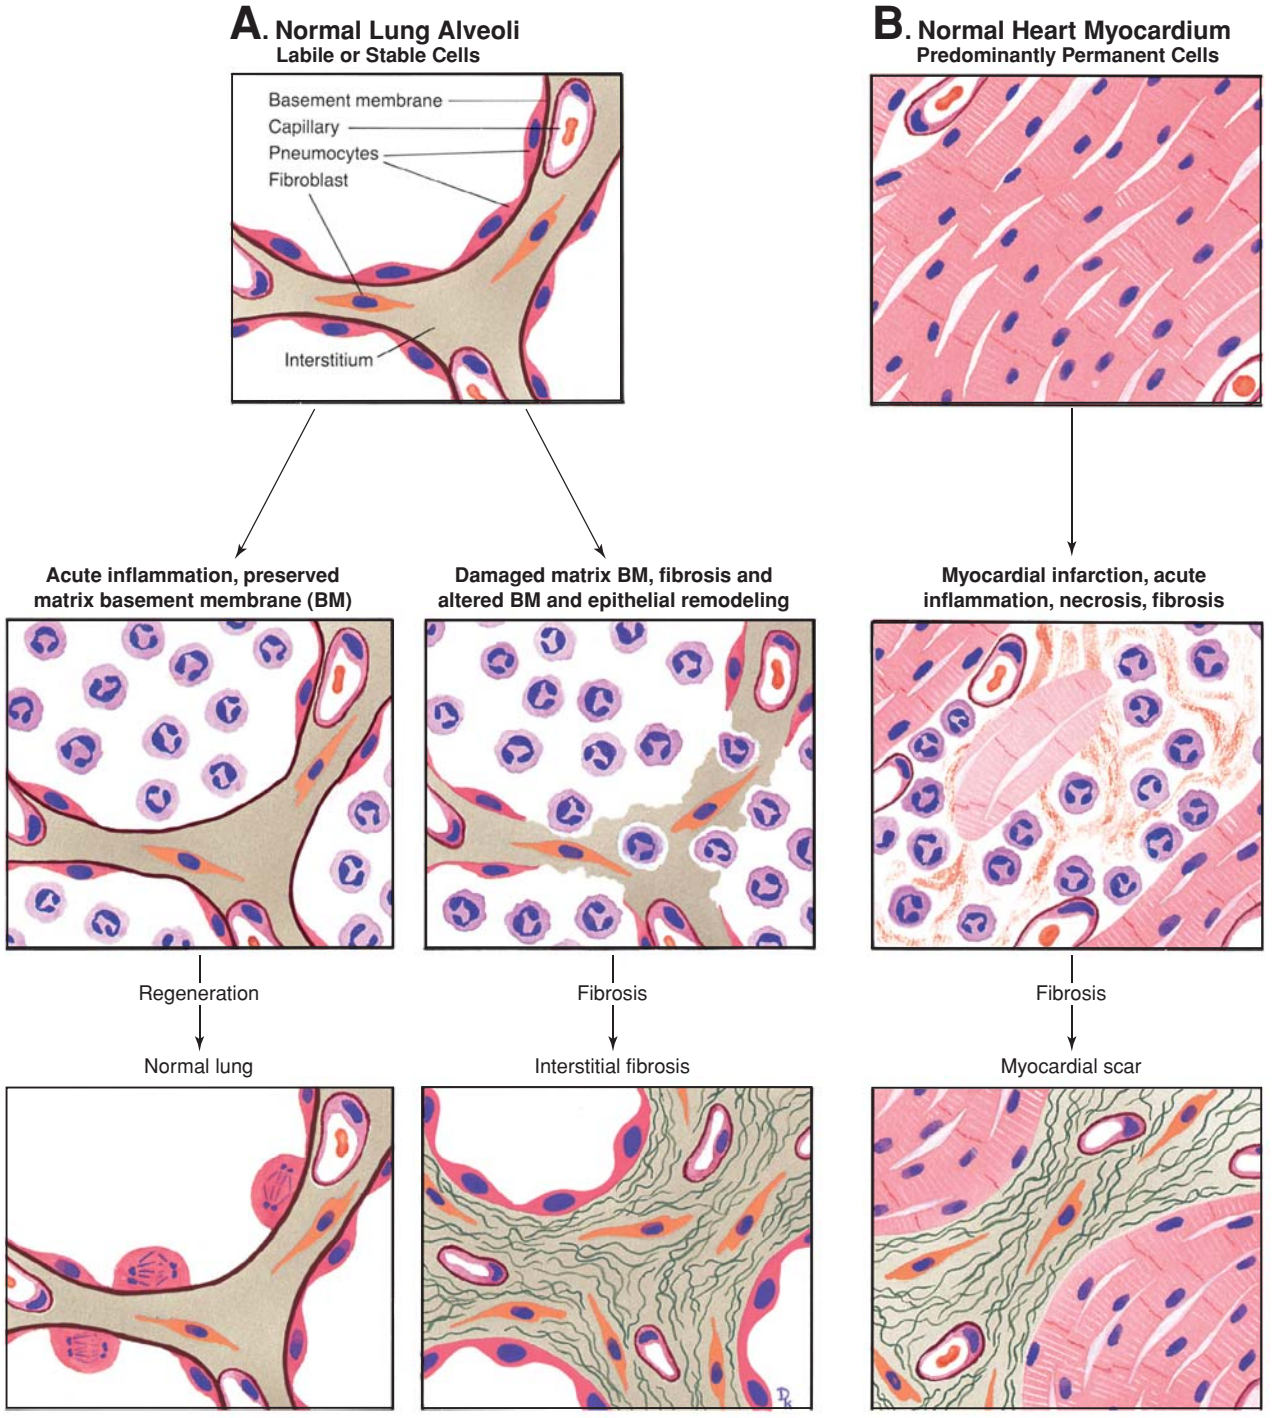

FIGURE 3-15. Examples of fibrotic and regenerative repair. A. The lung alveoli are lined with type I and type II epithelial cells (pneumocytes) that lie on a basement membrane. If the basement membrane remains intact following lung damage, there is rapid reepithelialization and return to normal lung architecture. If the basement membrane is damaged, type II epithelial cells proliferate on the underlying extracellular matrix, and fibroblasts and myofibroblasts are recruited to deposit a collagen-rich matrix, leading to fibrosis. **B.** Though small numbers of cardiac stem cells have been described, regeneration of myocardium is rarely observed. By and large cardiomyocytes are terminally differentiated and not capable of renewal. Myocardial damage due to infarction and acute inflammation is repaired by fibrosis and scar formation, increasing chances of arrhythmia or heart failure.

also take residence in the lung. The outcome of alveolar injury ranges from complete regeneration of structure and function to incapacitating fibrosis. As with the liver, the degree of cell necrosis and the extent of the damage to the extracellular matrix framework determine the outcome (Fig. 3-15).

Alveolar Injury with Intact Basement Membranes

Alveolar injury from causes such as infections, shock and oxygen toxicity produces variable alveolar cell necrosis. Alveoli are flooded with an inflammatory exudate rich in plasma proteins. As long as the alveolar basement membrane is intact, healing can occur by regeneration. Neutrophils and

macrophages clear the alveolar exudate, but if they fail to do so, it is organized by granulation tissue, and intra-alveolar fibrosis results. Alveolar type II epithelial cells or pneumocytes (the alveolar reserve cells) migrate to denuded areas and divide to form cells with features intermediate between type I and type II pneumocytes. These cells cover the alveolar surface and establish contact with other epithelial cells. Mitosis then stops and the cells differentiate into type I pneumocytes. Bone marrow–derived cells or putative lung bronchioalveolar progenitor or stem cells may participate by differentiating into bronchiolar Clara cells and alveolar cells (Table 3-8).

Alveolar Injury with Disrupted Basement Membranes

Extensive damage to alveolar basement membranes evokes scarring and fibrosis. Mesenchymal cells from alveolar septa proliferate and differentiate into fibroblasts and myofibroblasts. The role of macrophage products in inducing fibroblast proliferation in the lung is well documented. The myofibroblasts and fibroblasts migrate into the alveolar spaces, where they secrete extracellular matrix components, mainly type I collagen and proteoglycans, to produce pulmonary fibrosis. The most common chronic pulmonary disease is emphysema, which involves airspace enlargement and the destruction of alveolar walls. Ineffective replacement of elastin in this condition is associated with irreversible loss of tissue resiliency and function.

Heart

Cardiac myocytes had long been considered permanent, nondividing, terminally differentiated cells. There is recent evidence that cardiomyocytes, while not able to sufficiently repair damaged myocardium, are able to regenerate at a very low rate and maintain myocyte homeostasis during the low rates of myocyte turnover. The origin of these cells, whether they reside in the myocardium as cardiomyocyte progenitors or migrate there from bone marrow or sites unknown, is not resolved. For practical purposes, myocardial necrosis, from whatever cause, heals by the formation of granulation tissue and eventual scarring (Figs. 3-15 and 3-16). Not only does myocardial scarring result in the loss of contractile elements, but also the fibrotic tissue decreases the effectiveness of contraction in the surviving myocardium. With ischemia or infarction in the heart, as is often the case in other organs, healing results in scarring despite the presence in the tissue of stem or progenitor cells.

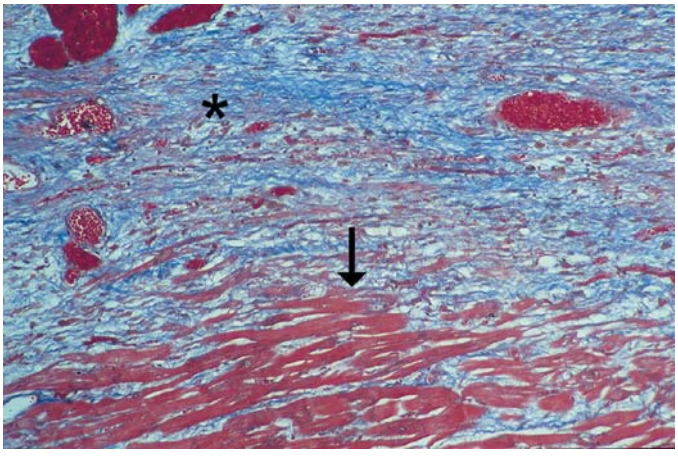

FIGURE 3-16. Myocardial infarction. A section through a healed myocardial infarct shows mature fibrosis (*) and disrupted myocardial fibers (*arrow*).

Nervous System

Mature neurons have been historically considered as permanent and postmitotic cells. There is limited regenerative capacity in the brain from stem cells, derived from bone marrow and perhaps other sources. Nonetheless, the poor reparative capabilities of the nervous system are well documented. Following trauma, only regrowth and reorganization of the surviving neuronal cell processes can reestablish neural connections. Although the peripheral nervous system can regenerate axonals, the central nervous system cannot. The olfactory bulb and hippocampal dentate gyrus regions of adult mammalian brain are now known to regenerate via neural precursor or stem cells. Multipotent precursor cells have also been seen elsewhere in the brain, raising hope that repair of neural circuitry may eventually be possible (Table 3-8).

Central Nervous System

Damage to the brain or spinal cord is followed by growth of capillaries and gliosis (i.e., inflammatory immune cell response, proliferation of astrocytes and microglia). Gliosis in the central nervous system is the equivalent of scar formation elsewhere; once established, it is permanent. In spinal cord injuries, axonal outgrowth can be seen up to 2 weeks after injury. After 2 weeks, gliosis has taken place and attempts at axonal regeneration end, having been inhibited by release of molecules such as myelin-associated glycoprotein and chondroitin sulfate proteoglycans. In the central nervous system, axonal regeneration occurs only in the hypothalamo-hypophysial region, where glial and capillary barriers do not interfere.

Peripheral Nervous System

Neurons in the peripheral nervous system can regenerate axons, and under ideal circumstances, interruption in the continuity of a peripheral nerve may result in complete functional recovery. However, if cut ends are not in perfect alignment or are prevented from establishing continuity by inflammation or a scar, a traumatic neuroma results (Fig. 3-17). This bulbous lesion consists of disorganized

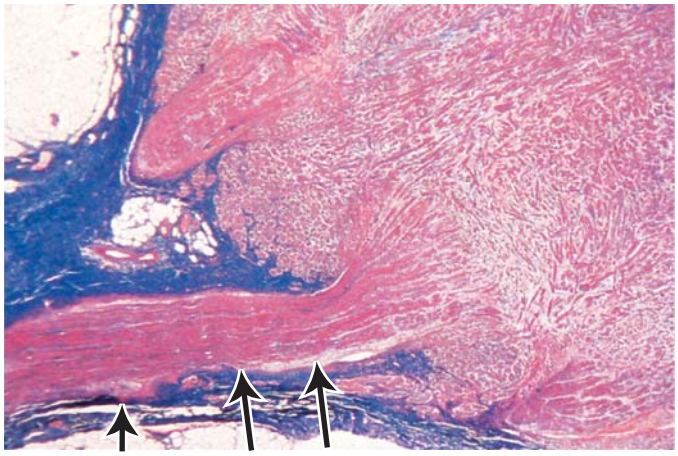

FIGURE 3-17. Traumatic neuroma. In this photomicrograph, the original nerve (*arrows*) enters the neuroma. The nerve is surrounded by dense collagenous tissue, which appears dark blue with this trichrome stain. Excessive repair obstructs axonal reconnection.

axons and proliferating Schwann cells and fibroblasts. The regenerative capacity of the peripheral nervous system can be ascribed to (1) the fact that the blood-nerve barrier, which insulates peripheral axons from extracellular fluids, is not restored for 2–3 months, and (2) the presence of Schwann cells with basement membranes. Laminin, a basement membrane component, and nerve growth factor (NGF) guide and stimulate neurite growth.

Effects of Scarring

In the absence of the ability to form scars, mammalian survival would hardly be possible. Yet scarring in parenchymal organs modifies their complex structure and never improves their function. For example, in the heart, the scar of a myocardial infarction serves to prevent rupture of the heart, but it reduces the amount of contractile tissue. If extensive enough, it may cause congestive heart failure or lead to a ventricular aneurysm (see Chapter 17). Similarly, an aorta that is weakened and scarred by atherosclerosis is prone to dilate as an aneurysm (see Chapter 16). Scarred mitral and aortic valves injured by rheumatic fever are often stenotic, regurgitant or both, leading to congestive heart failure. Persistent inflammation within the pericardium produces fibrous adhesions, which result in constrictive pericarditis and heart failure.

Pulmonary alveolar fibrosis causes respiratory failure. Infection in the peritoneum or even surgical exploration may create adhesions and intestinal obstruction. Immunologic injury generates replacement of renal glomeruli by collagenous scars and, if it is extensive, renal failure. Scarring in the skin after burns or surgery produces unsatisfactory cosmetic results and may severely limit mobility. An important goal of therapeutic intervention is to create optimum conditions for "constructive" scarring and prevent pathologic "overshoot" of this process.

Wound Repair Is Often Suboptimal

Abnormalities in any of the three healing processes—repair, contraction and regeneration—result in unsuccessful or prolonged wound healing. The skill of the surgeon is often of critical importance.

Deficient Scar Formation

Inadequate formation of granulation tissue or an inability to form a suitable extracellular matrix gives rise to deficient scar formation and its complications.

Wound Dehiscence and Incisional Hernias

Dehiscence (a wound splitting open) is most frequent after abdominal surgery and can be life-threatening. Increased mechanical stress on an abdominal wound from vomiting, coughing, pathologic obesity or bowel obstruction may cause dehiscence of that wound. Systemic factors predisposing to dehiscence include metabolic deficiency, hypoproteinemia and the general inanition that often accompanies metastatic cancer. **Incisional hernias** of the abdominal wall are defects caused by weak surgical scars owing to insufficient deposition of extracellular matrix or inadequate cross-linking in the collagen matrix. Loops of intestine may be trapped within incisional hernias.

Ulceration

Wounds can ulcerate if an intrinsic blood supply is inadequate or if vascularization is insufficient during healing. Failure of the venous valves in the lower leg leads to tissue edema, the formation of pericapillary fibrin cuffs and the generation of venous stasis ulcers, often on the inner aspect of the lower leg. This is the most prevalent chronic wound in Western society. Severe atherosclerosis or peripheral arterial disease can evoke the formation of arterial ulcers on the outer part of the lower leg or the foot. Diabetic foot ulcers are brought about by a combination of poor arterial and capillary blood supply that may be accompanied by a **diabetic peripheral neuropathy** that renders the patient insensitive to the progressing ulcer. Diabetes also reduces expression of and cellular responsiveness to growth factors, making it difficult to stimulate the healing process. This form of ulceration, if left unchecked, proceeds to infection of the underlying bone **(osteomyelitis)** and progressive loss of the extremity. Nonhealing wounds also develop in areas devoid of sensation because of trauma or pressure. Such **decubitus ulcers** are commonly seen in patients who are immobilized in either beds or wheelchairs. Constant pressure on the skin over a bony process can produce a local infarct in as little as 2–3 hours. These ulcers can be both broad and deep, with infection penetrating deep into connective tissue.

Excessive Scar Formation in the Skin

Excessive deposition of extracellular matrix, mostly excessive collagen, at the wound site results in hypertrophic scars and keloids. **Keloids** are exuberant scars that tend to progress beyond the site of initial injury and recur after excision (Fig. 3-18), thus having properties akin to a benign tumor. Keloids are unsightly, and attempts at surgical repair are always problematic, the outcome likely being a still larger keloid. Keloids are generally restricted to adolescence and early adulthood and to the upper trunk, neck and head, with the exception of the scalp. This aspect reflects the (epigenetic) heterogeneity of fibroblast populations in different locations. Dark-skinned persons are more frequently affected, suggesting a genetic basis for this condition. Unlike normal scars, these keloids do not reduce collagen synthesis if glucocorticoids are administered.

By contrast, **hypertrophic scars** are not associated with race or heredity, but the severity of scarring can decline with age. The scar is confined within the wound margins, and the development of the scar is often associated with unrelieved mechanical stress. Hypertrophic scars often have a reddened appearance indicative of hypervascularity, and they are pruritic, which suggests activation of mast cells producing histamine. Histologically, both types of scars exhibit broad and irregular collagen bundles, with more capillaries and fibroblasts than is normal for a scar of the same age. The rate of collagen synthesis and number of reducible cross-links remain high. This situation suggests a "maturation arrest," or block, in the healing process, a hypothesis that is supported by the overexpression of fibronectin.

Excessive Contraction

A decrease in the size of a wound depends on the presence of fibroblasts and myofibroblasts, development of cell–cell contacts and sustained cell contraction. An exaggeration of these processes is termed **contracture** and results in severe deformity of a wound and surrounding tissues. Interestingly,

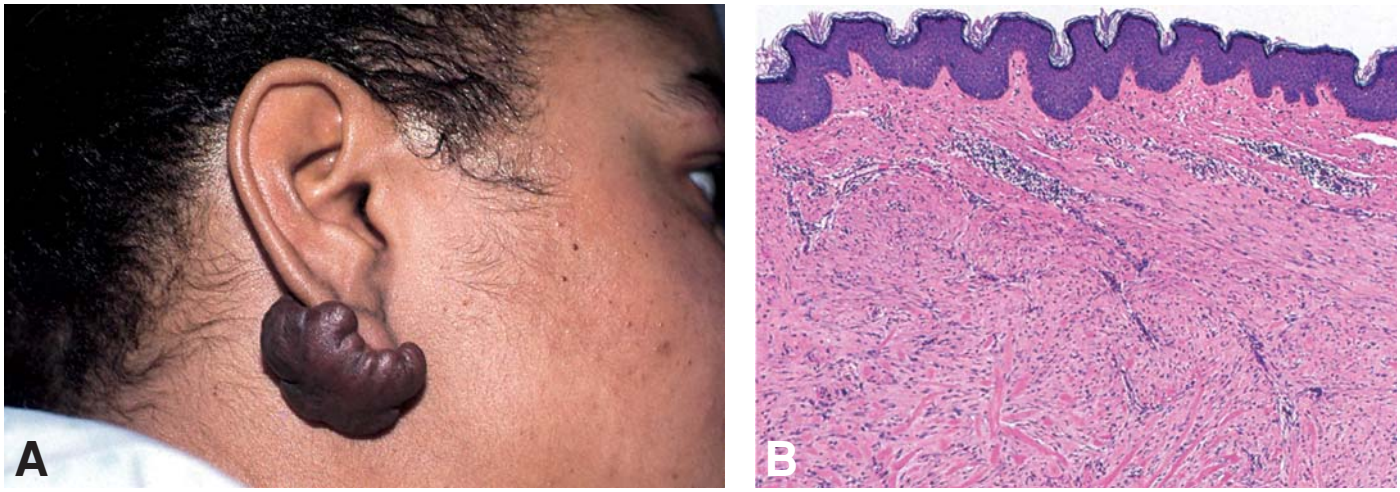

FIGURE 3-18. Keloid. A. A light-skinned black woman developed a keloid as a reaction to having her earlobe pierced. **B.** Microscopically, the dermis is markedly thickened by the presence of collagen bundles with random orientation and abundant cells.

regions that normally show minimal wound contraction (e.g., the palms, soles and anterior aspect of the thorax) are often prone to contractures. Contractures are particularly conspicuous when serious burns heal, and they can be severe enough to compromise the movement of joints. In the alimentary tract, a contracture (stricture) can obstruct the passage of food in the esophagus or block the flow of intestinal contents.

Several diseases are characterized by contracture and irreversible fibrosis of the superficial fascia, including Dupuytren contracture (palmar contracture), Lederhosen disease (plantar contracture) and Peyronie disease (contracture of the cavernous tissues of the penis). In these diseases, there is no known precipitating injury, even though the basic process is similar to contracture in wound healing.

The Biology of the Immune System

The multifaceted, integrated immune system of higher vertebrates has evolved to protect the host from invasion by foreign agents. Toxins, chemicals, drugs, viruses, microorganisms, multicellular parasites and transplanted foreign tissues can all elicit immunity. Responses are characterized by their capacity to distinguish self from nonself, discriminate among invaders (specificity) and generate immune memory and amplification loops (i.e., to recall previous exposures and mount an intensified—**anamnestic**—response on subsequent exposures).

INNATE AND ADAPTIVE IMMUNITY

Humans possess barriers such as regionally adapted epithelia (e.g., thick keratinized skin, ciliated respiratory epithelium), chemical-mechanical surface coatings (e.g., antibacterial peptides, mucus) and indigenous microbial flora that compete with potential pathogens. Patterned responses, cell surface and soluble mediator systems (e.g., complement) and phagocytes (e.g., neutrophils) that bind targets through mechanisms not dependent on specific antigen recognition are integral to **host defense** (see Chapter 2). Host defenses that are not antigen specific constitute the **innate immune system**.

Antigen-specific or **adaptive** immunity encompasses specialized antigen-presenting cells (APCs) (e.g., dendritic cells), clonal lymphocytes (B and T cells) that express and/or secrete molecules (T-cell receptor [TCR]), antibodies that specifically bind foreign structures, and many cell surface and soluble regulatory mediators. The adaptive system also encompasses generative lymphoid organs (bone marrow, thymus) that produce immune cells, secondary lymphoid structures (lymph nodes, spleen, regionally adapted lymphoid tissues) that facilitate the colocalization and concentrated exposure of foreign antigens to immune cells via a system of cell trafficking and recirculation (via the lymphatics and vascular system) orchestrated by soluble chemotactic factors, and location-specific intercellular adhesion molecules. These integrated systems enable the relatively few lymphocytes that express a particular antigen receptor to efficiently interact with individual specific target molecules among the wide variety of incoming antigens. The abilities of APCs to interact with T cells to stimulate immune responses and of antigen-specific cytotoxic T effector cells to kill (e.g., virus-infected) host cells are mediated by cell surface **histocompatibility molecules** (human leukocyte antigens) encoded by genes of the **major histocompatibility complex** (**MHC**).

It is important to consider components of the immune system under the general rubrics of acute and chronic

inflammation, cell injury and cell death (see Chapter 2). Immune responses are involved in tissue- and organ-specific pathology whether in the context of infections, hypersensitivity reactions, autoimmune diseases or transplantation.

Innate Immunity Entails Pattern Recognition Responses

The innate immune system is the "first line" defense against foreign agents. Unlike adaptive responses, which develop over a period of several days, cells and soluble mediators of the innate system are either already completely functional or rapidly activated (minutes to hours) upon exposure to invaders. The innate system appeared early in evolution and evolved in concert with microorganisms as the latter developed novel mechanisms to circumvent host defenses. Innate immunity is multilayered. Epithelial barriers and surface defense molecules retard microbial entry into the host. Both resident and recruited phagocytes respond quickly to agents that have penetrated the outer defense, and a redundant set of soluble mediators and circulating phagocytes attack agents that have entered. The innate system distinguishes self from nonself in a manner that is far less fine-tuned than occurs in adaptive immunity. Germline-encoded receptors recognize and bind to categories of structures **(pathogen-associated molecular patterns [PAMPs])** present on the surfaces of microbes but not on host cells. **Pattern recognition receptors (PRRs)** exhibit far less diversity (hundreds of patterns) than antibodies and TCRs (many thousands of specificities) and are not clonal (i.e., each is identical on all cell types). PRRs of the innate system are diverse, are redundant, and have evolved to counter both extracellular and intracellular invaders. Finally, the innate system is functionally linked to many levels of the adaptive system.

As noted, the first levels of innate immunity encompass mechanical epithelial barriers, chemical defenses and resident host defense cells. Whether cutaneous, respiratory, gastrointestinal or urothelial, barrier epithelial cells are held together by tight junctions and exhibit region-specific adaptations (e.g., keratin layers, cilia and mucus production) that enhance their defense functions. Chemical defenses include low pH (e.g., skin and gastric juice) as well as secreted **defensins** and **cathelicidins**. Defensins are 18- to 45-amino-acid cationic peptides, classified into α, β and θ families based on the locations of six conserved cysteine residues that form internal disulfide bonds. They are produced by a variety of leukocytes and epithelial cells (skin, respiratory, gastrointestinal) and bind microbes in which they form pore-like surface defects. Cathelicidins are 12- to 80-amino-acid peptides made by neutrophils and activated macrophages and barrier cells. The physical and chemical barriers of innate immunity are backed by phagocytes (neutrophils, monocytes, macrophages and antigen-presenting cells [e.g., dendritic cells]) as well as nonphagocytic natural killer (NK) cells, mast cells and specialized lymphocytes with limited antigen receptor diversity. Lymphocytes that exhibit less antigen receptor diversity than do the B and T lymphocytes include γδ T cells, intraepithelial T cells with α/β TCRs, NK T cells, B1 B cells and marginal zone B cells.

PRRs recognize PAMPs. These are biochemical moieties expressed by microbes but not by mammalian cells and thus "seen" as nonself (Table 4-1). A separate set of endogenous moieties, produced by injured or dying host cells, are the **damage-associated molecular patterns (DAMPs)** (Table 4-1). Receptors among the heterogeneous group of PRRs recognize PAMPs and/or DAMPs. PRRs are encoded by nonrecombinatory germline genes that, in contrast to immunoglobulins and TCRs, exhibit limited structural variability and thus exhibit a more limited repertoire of specificities. For example, a particular PRR might recognize most or all lipopolysaccharides. Various lipopolysaccharides exhibit chemical differences, but all have a similar categorical structure and are found on the surfaces of essentially all gram-negative bacteria. DAMPs are revealed by injured or dying cells whether the result of infection, trauma or other injury. In addition to their varied structures, PRRs may be soluble, external cell membrane associated, endosomal membrane associated or cytosolic (Table 4-2). This anatomic distribution of PRRs reflects their varied roles in innate host defense. Soluble and extracellular PRRs provide defense against extracellular microorganisms (e.g., pyogenic bacteria), while endosomal or cytosolic PRRs play important roles in defense against viruses and intracellular bacteria. The relationships between cellular locations of PRRs and various types of infections (e.g., pyogenic bacterial vs. viral) are reflected by the types of infections observed among patients with various immunodeficiency disorders.

TABLE 4-1
PATHOGEN-ASSOCIATED (PAMPs) AND DAMAGE-ASSOCIATED MOLECULAR PATTERNS (DAMPs)

	Molecular Moiety (Examples)	Microbe Type
PAMPs		
Cell wall lipids	Lipopolysaccharide (LPS) Teichoic acid	Gram-negative bacteria Gram-positive bacteria
Cell wall carbohydrates	Mannans Glucans	Fungi
Cell surface proteins	Flagellin Pilin	Bacteria
Microbial nucleic acids	ssRNA dsRNA CpG sequences	Viruses Microorganisms
DAMPs		
Stress-induced proteins	Heat-shock proteins (HSPs)	N/A
Nuclear proteins	High-mobility group box 1	N/A
Crystals (foreign)	Monosodium urate	N/A

CpG = cytidine-guanidine dinucleotide; dsRNA = double-stranded RNA; N/A = not applicable; ssRNA = single-stranded RNA.

Toll-like Receptors

Toll-like receptors (TLRs) are leucine-rich transmembrane receptors found throughout the animal kingdom (Fig. 4-1). There are nine human TLRs. Toll-like receptors form

TABLE 4-2
PATTERN RECOGNITION MOLECULES

	Cellular/Anatomic Location	Examples
Membrane Associated		
Toll-like receptors (TLRs)	Plasma membranes Endosomal membranes	TLR1, -2, -4, -5, -6 TLR3, -7, -8, -9
C-type lectin-like receptors	Plasma membrane	Mannose receptor
Scavenger receptors	Plasma membrane	CD36 (Platelet gpIIIb)
N-formyl peptide receptors	Plasma membrane	N-formyl peptide receptor
Cytosolic		
NOD-like receptors (NLRs)	Cytosol	NOD1/2
RIG-like receptors (RLRs)	Cytosol	RIG-1
Soluble		
Natural antibodies (IgM)	Plasma	IgM antiphosphorylcholine
Complement	Plasma	C3, C1qrs[a]
Pentraxins	Plasma	C-reactive protein
Collectins	Plasma/alveoli	Mannose-binding lectin Surfactant protein, SP-A
Ficolins	Plasma	Ficolin

[a]C1qrs binds to span two Fc domains of fixed immunoglobulin molecules and directly to some pattern-associated molecular patterns.
IgM = immunoglobulin M; NOD = nucleotide oligomerization domain–containing protein; RIG = retinoic acid–inducible gene.

dimers that recognize PAMPs and, as noted in Table 4-2, are expressed specifically on either plasma or endosomal membranes. Plasma membrane TLRs (TLR1, -2, -4, -5, -6) recognize surface moieties of extracellular microbes (e.g., bacterial lipopeptides, lipopolysaccharides, flagellin, bacterial peptidoglycan), while endosomal TLRs (TLR3, -7, -8, -9) recognize microbial nucleic acid moieties (e.g., double-stranded RNA [dsRNA], single-stranded RNA [ssRNA], CpG DNA). In turn, engagement of TLRs by foreign invaders, whether extracellular or intracellular, leads to signal transduction events that culminate in the expression of proinflammatory genes (e.g., cytokines, chemokines, endothelial adhesion molecules, costimulatory molecules) and/or antiviral genes (e.g., type I interferons). In some cases, TLR-mediated cell activation by a PAMP is enhanced by accessory molecules (e.g., lipopolysaccharide-binding protein, CD14 and MD2).

Several additional categories of cell surface PRRs participate in innate host defense. C-type lectin receptors, through a calcium-dependent mechanism, bind to carbohydrate

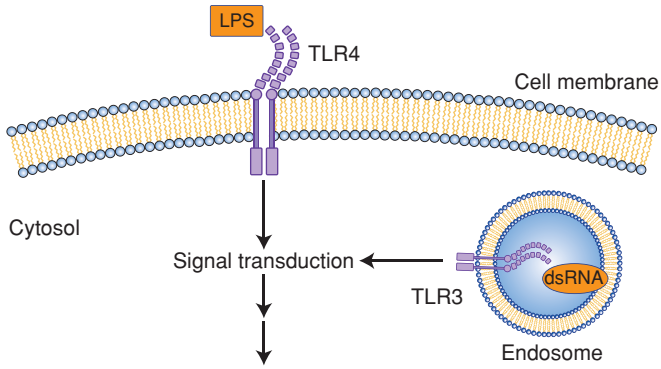

FIGURE 4-1. Toll-like receptors (TLRs) form transmembrane dimers that bind pathogen-associated molecular patterns (PAMPs) on the outer surfaces of cells and on the inner surfaces of phagocyte endosomes. Plasma membrane TLRs (e.g., TLR4) mediate defense against extracellular pathogens (e.g., pyogenic bacteria) and endosomal TLRs (e.g., TLR3) mediate defense against intracellular pathogens (e.g., viruses). In both cases, signal transduction leads to a variety of proinflammatory and/or antiviral cellular responses. The extracellular and intraendosomal TLR domains that recognize and bind PAMPs contain leucine-rich repeat sequences.

moieties (e.g., β-glucans, mannose, glucose, N-acetylglucosamine) characteristic of microorganisms but not mammals, thus conferring distinction of nonself from self. The best-studied C-type lectin receptors are dectin-1, dectin-2 and the mannose receptor (CD206). Dectin-1 and dectin-2 bind β-glucan and mannose-rich oligosaccharides, which are expressed by the yeast and hyphal forms, respectively, of *Candida albicans*. Diverse scavenger receptors bind a range of cell surface moieties, mediate uptake of oxidized lipoproteins and carry out microbe phagocytosis. Finally, N-formyl peptide receptors are guanosine triphosphate (GTP)-binding proteins expressed by phagocytes. N-formyl peptides are produced only by bacteria (and within mitochondria). Engagement of these receptors induces cell activation and chemotaxis.

NOD-like and RIG-like Receptors

NOD-like (nucleotide oligomerization domain–containing protein) and RIG-like (retinoic acid–inducible gene I) receptors for PAMPs and DAMPs are cytosolic receptors that are distinct from cell surface and endosomal receptors. They monitor the cytosolic compartment (Table 4-2) and are linked to activation pathways for inflammation and/or type I interferon generation. Nearly two dozen NOD-like receptors (NLRs), grouped into three subfamilies, have been identified. Most NLR proteins have a leucine-rich microbial recognition domain like TLRs. Other functional domains allow formation of oligomers and the formation of multiunit signaling complexes. NOD1 and NOD2 (expressed in gastrointestinal epithelial cells and phagocytes) play important roles in innate responses to the gastrointestinal pathogens *Helicobacter pylori* and *Listeria monocytogenes*. Mutations that affect the pyrin effector domain of NOD-like receptor P3 (NLRP3) are associated with hereditary periodic fever syndromes. Finally, some crystalline substances like monosodium urate also act via NLRs to trigger an inflammatory response and assembly and activation of the "inflammosome" (see Chapter 1). RIG-like receptors (RLRs) sense cytosolic viral RNA and mediate generation of antiviral type I interferons.

Table 4-2 also lists five groups of soluble pattern recognition molecules. Members of each group are active in plasma and extracellular tissue fluid, possess high molecular weights and contain several extended PAMP ligand-binding domains. **Natural immunoglobulin M (IgM) antibodies** and the complement protein complex C1qrs are most familiar. C1qrs spans adjacent Fc domains of surface-bound immunoglobulin molecules, thus initiating the classical complement pathway and functionally linking the adaptive immune system (antibodies) to the complement system. **C1qrs** and **C3** also directly bind microbial structures and thus serve as components of innate immunity. **Pentraxins,** including C-reactive protein, contain five extended binding domains. **Collectins** include mannose-binding lectin, a key mediator of the third complement pathway (nonclassical, nonalternative) and the pulmonary alveolar surfactant proteins, SP-A and SP-D. **Ficolins** possess structural homology to both C1qrs and collectins and bind to a variety of PAMPs found on the surfaces of gram-positive bacteria.

Activated innate system pathways facilitate the acute inflammatory response, which plays an important role in host defense. Acute inflammation is characterized by a stereotyped set of vascular changes including vasodilatation, slowing of blood flow, leakage of fluid into the extravascular space, concentration of leukocytes and an ordered set of leukocyte-endothelial activation, binding and recruitment/extravasation events (see Chapter 2). The innate immune system also participates in host defense via the antiviral response. A variety of PRRs, including several TLRs, NLRs and RLRs, mediate the production of type I interferons. Interferons-α and -β are classified as type I interferons. Type I interferons upregulate class I MHC molecules on potential target cells for cytotoxic T lymphocytes, increase the cytotoxic activities of NK cells and cytotoxic T lymphocytes, facilitate the conversion of naive T cells to Th1 helper cells, increase intranodal lymphocyte sequestration and, via the type I interferon receptor, induce host cell resistance to viral infection. Finally, the activated innate immune system also facilitates the adaptive immune response through induction of the "second signal" (e.g., CD80 [B7-1], CD86 [B7-2]) needed in antigen-induced responses, through the conversion of naive T helper cells into Th1 and Th17 effector cells and through the stimulation of proliferation and differentiation of lymphocytes via the induction of various cytokines.

CELLS AND TISSUES OF THE IMMUNE SYSTEM

The cells of the immune and hematopoietic systems are derived from multipotent **hematopoietic stem cells** (HSCs). Near the end of the first month of embryogenesis, HSCs appear in the extraembryonic erythropoietic islands adjacent to the yolk sac. At 6 weeks, the primary site of hematopoiesis shifts to fetal liver and then to bone marrow. The latter process begins at 2 months and by 6 months has completely shifted to bone marrow. While sequential changes in the primary site of hematopoiesis are well defined, there are periods of overlap. By 8 weeks' gestation, **lymphoid progenitors** derived from HSCs circulate to the thymus where they differentiate into mature but naive T lymphocytes. ("Naive" indicates that the lymphocytes have not been exposed to foreign antigens.) Lymphoid progenitors destined to become B cells differentiate first within fetal liver (8 weeks) and later within bone marrow (12 weeks). In both thymus-derived T-lymphocyte and bone marrow–derived B-lymphocyte development, microenvironment (e.g., thymic epithelium, bone marrow stromal cells and growth factors) is critical. Thymus and bone marrow are "generative" lymphoid organs, while peripheral lymphoid tissues (lymph nodes, spleen and regionally adapted areas) are "secondary." Mature lymphocytes exit the thymus and bone marrow and "home" to peripheral lymphoid tissues (e.g., lymph nodes, spleen, skin and mucosa). The colonization of peripheral lymphoid tissues by mature B and T lymphocytes and the rapid deployment and recirculation of mature lymphocytes to different, often remote, parts of the immune system is anatomically specific. **Lymphocyte homing and recirculation** are orchestrated by a series of complementary leukocyte and endothelial surface molecules that include site-specific **selectins** and **addressins** (see below). The processes of lymphocyte development and homing/recirculation are important in understanding immune responses, immunodeficiency states, regional host defense and the underpinnings of modern therapeutics (e.g., HSC transplantation).

Cells of the immune system express a vast array of surface molecules important in differentiation and cell-to-cell communication. These surface molecules also serve as markers of cell identity. The International Workshop on Human Leukocyte Differentiation Antigens is responsible for nomenclature and assigns so-called **cluster of differentiation** or **cluster designation (CD)** numbers. Currently, 300 different molecules have been assigned CD numbers.

HSCs Are the Progenitors for the Cells of the Immune System

Multipotent HSCs account for 0.01%–0.1% of nucleated bone marrow cells, exhibit characteristic light-scattering properties as assessed by flow cytometry, can self-renew, usually express CD34 and c-KIT cell surface proteins and lack cell surface molecules that characterize more mature lymphocyte subpopulations (e.g., CD2, CD3 and others). The absence of lineage-specific molecules is referred to as "LIN–." HSCs differentially express more than 2000 genes involved in a variety of cellular functions. It is clear that stem cells cycle, replicate and give rise to progenitor cells. As progenitor cells differentiate into lymphocytes, red blood cells, neutrophils and so forth, they lose proliferative capacity (Fig. 4-2). Prevailing models of hematopoiesis/lymphopoiesis suggest that primitive stem cells give rise to committed progenitors (the **hierarchical model**) or that stem cells can develop either into progenitor cells or back to stem cells (the **cell cycle or continuum model**).

Circulating $CD34^+$ HSCs account for 0.01%–0.1% of peripheral blood mononuclear cells. Bone marrow and blood HSCs are heterogeneous in terms of lymphocyte marker expression, myeloid markers, activation antigens and capacity to engraft bone marrow. Infusion of sufficient numbers of peripheral blood HSCs into transplant recipients leads to faster marrow recovery than occurs in recipients of marrow-derived HSCs. In clinical HSC transplantation, it is current practice for donors to receive recombinant growth factors prior to HSC harvest. This practice leads to higher yields of harvested HSCs, decreased time to engraftment and improved engraftment rates. The overall efficacy of peripheral blood HSCs versus marrow preparations in patients with leukemia is still being debated.

Mature hematopoietic and lymphoid cells are derived from a common population of multipotential HSCs (Fig. 4-2).

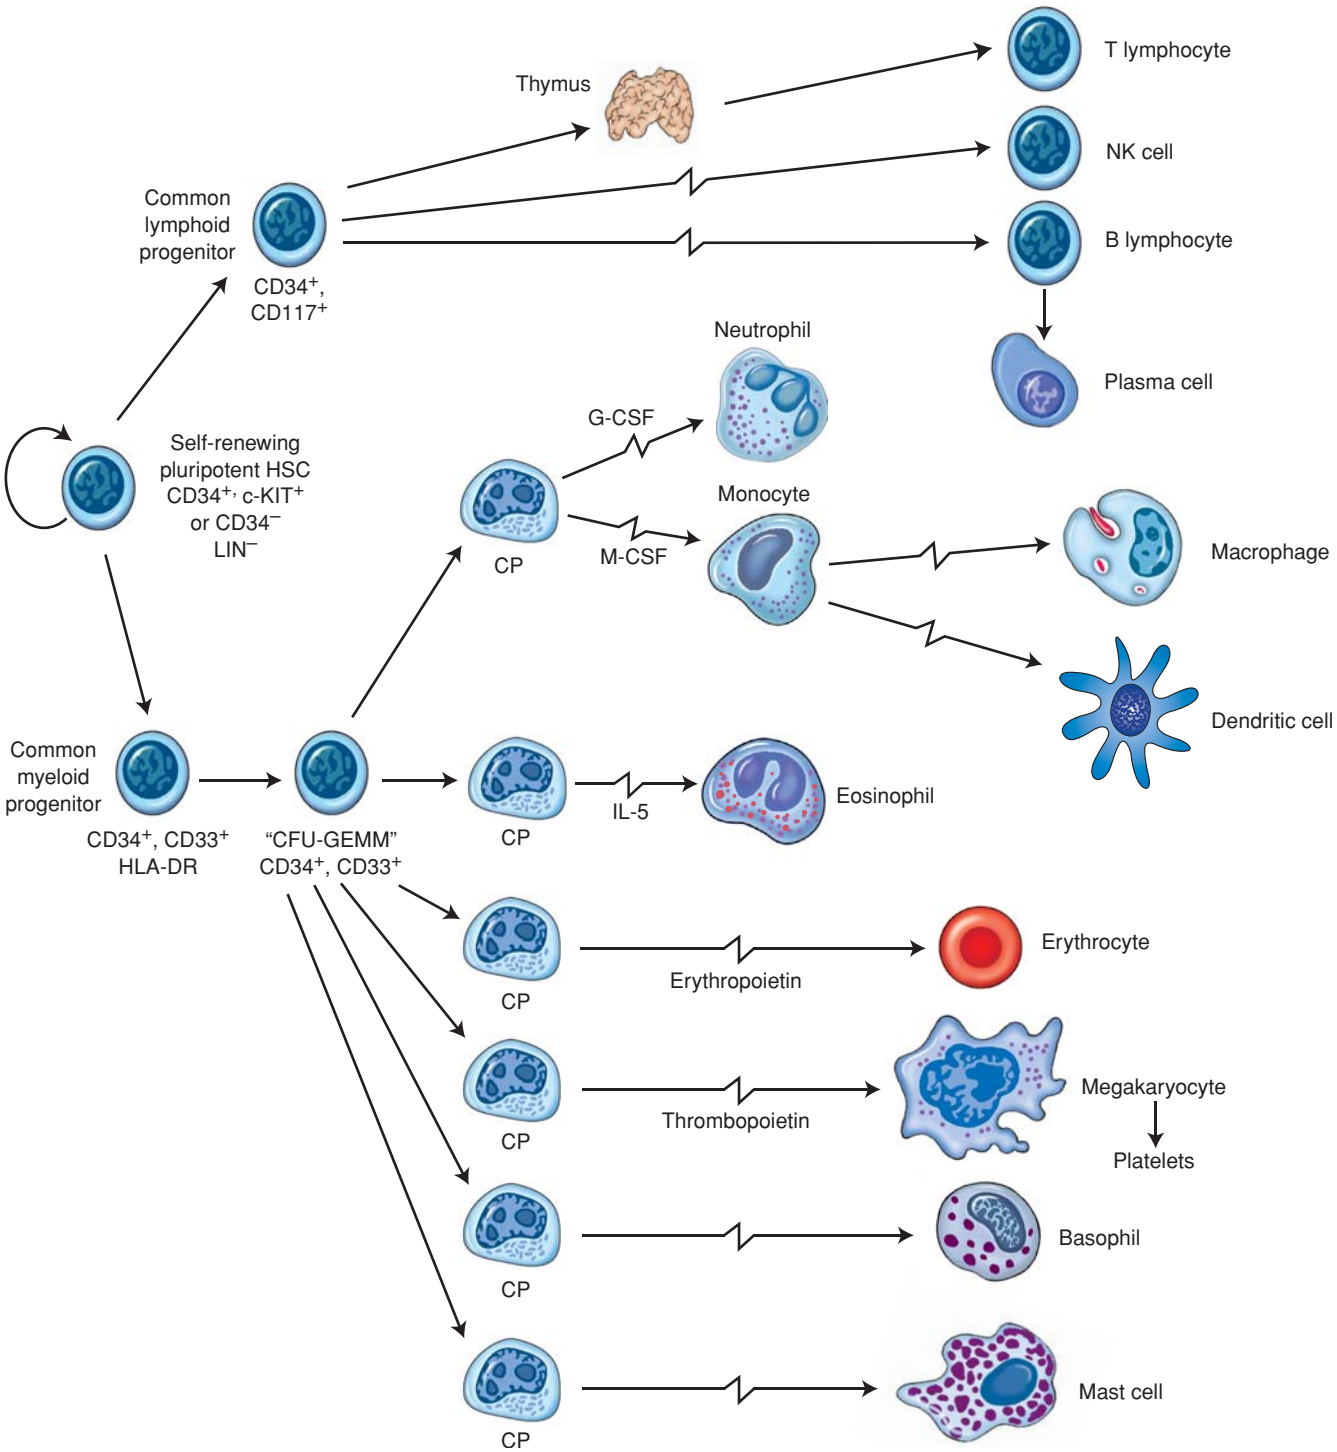

FIGURE 4-2. Pluripotent hematopoietic stem cells (HSCs) differentiate into either common lymphoid or myeloid progenitors and, in the case of myeloid cells, into lineage-specific colony-forming units (CFUs). Under the influence of an appropriate microenvironment and growth factors, committed precursors (CPs) give rise to definitive cell types. Lymphoid progenitors are precursors of natural killer (NK) cells, T lymphocytes and B lymphocytes. B lymphocytes give rise to plasma cells. *Lin−* = lineage-negative; *CD* = cluster designation; *CFU-GEMM* = granulocytic, erythroid, monocytic-dendritic and megakaryocytic colony-forming units; *HLA* = human leukocyte antigen. "Colony-forming unit" refers to an in vitro bioassay.

The primary branch point in differentiation is between lymphoid and myeloid progenitors. The former ultimately give rise to T lymphocytes, B lymphocytes and NK cells, while the latter develop into granulocytic, erythroid, monocytic-dendritic and megakaryocytic colony-forming units (GEMM-CFUs). Colony-forming units (CFUs) are the cells that give rise to specified populations of derivative cells, such as granulocytes, monocytes and so forth. Downstream CFUs become increasingly lineage specific: for example, CFU-GM (granulocyte-monocyte), CFU-Eo (eosinophil) and CFU-E (erythrocyte).

Lymphocytes

Committed lymphoid progenitor (CLP) cells, derived from HSCs, in turn give rise to B lymphocytes, T lymphocytes and NK cells (Fig. 4-3). There are three major types of lymphocytes—T cells, B cells and NK cells—which together make up 25% of peripheral blood leukocytes. Blood lymphocytes are about 80% T cells, 10% B cells and 10% NK cells. The relative proportions of lymphocytes in the peripheral blood and central and peripheral lymphoid tissues vary. In contrast to blood, only 30%–40% of splenic and bone marrow lymphocytes are T cells.

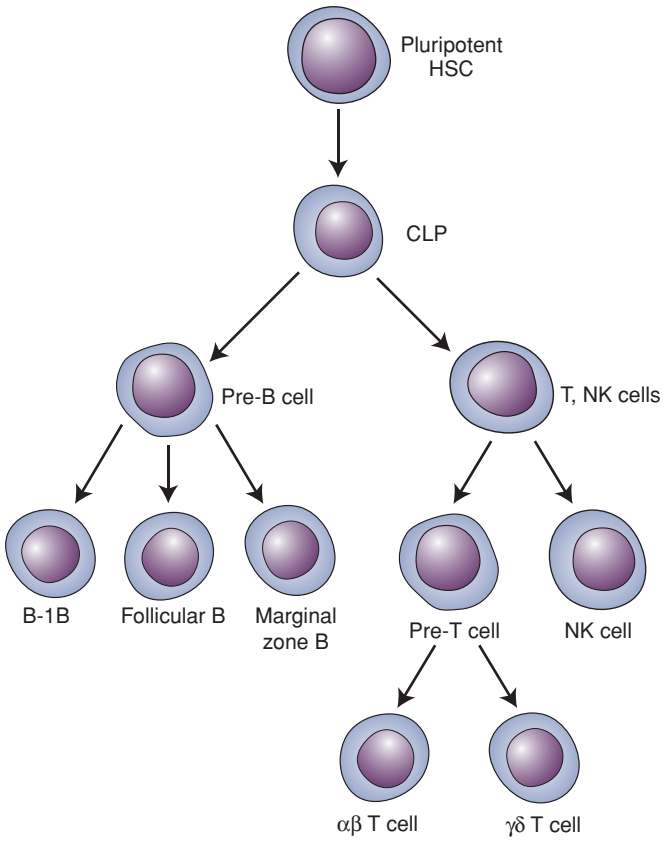

FIGURE 4-3. Pluripotent hematopoietic stem cells (HSCs) give rise to B and T lymphocytes—including their subsets. The common lymphoid progenitor (CLP) gives rise to B lymphocytes, T lymphocytes and NK cells. (See Fig. 4-2 to see how HSCs and CLPs fit into the larger hematopoietic and lymphopoietic development schemes.) Key transcription factors are listed within dashed-line circles. Commitment of CLPs to the B-lymphocyte lineage is triggered by *E2A* and *EBF* transcription factors followed by *Pax5*. In turn, commitment of T and NK progenitor cells to T lymphocytes is triggered by *Notch 1, GATA3* and other (not shown) transcription factors.

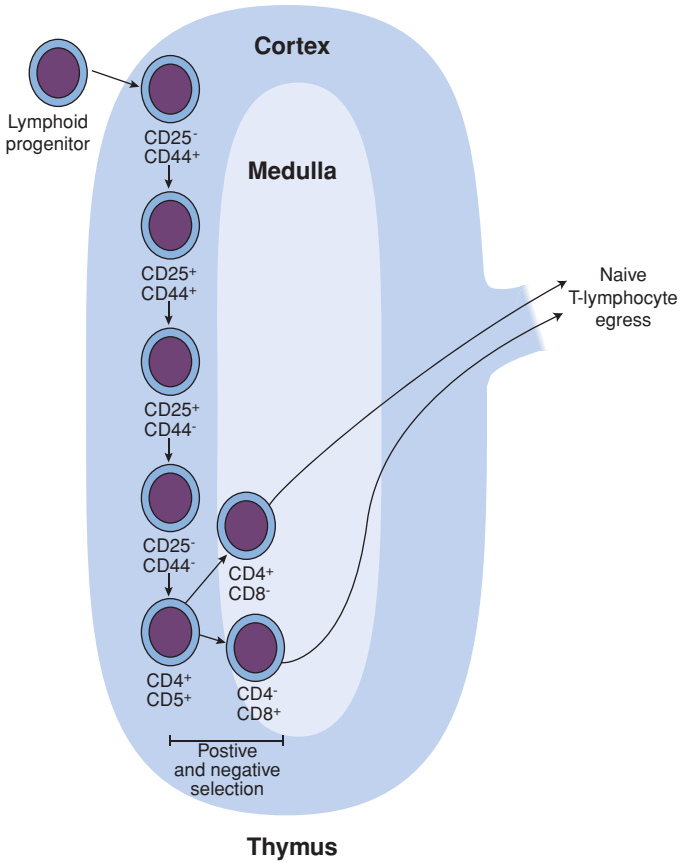

FIGURE 4-4. Lymphoid progenitors give rise to mature but naive T lymphocytes. Lymphocytes destined to become T lymphocytes migrate to the thymus where they become either α/β or γ/δ T cells. As thymocytes percolate through the cortex and then medulla, they are positively and negatively selected. Most α/β T lymphocytes emerge as either $CD4^+/CD8^-$ helper cells or $CD4^-/CD8^+$ cytotoxic cells.

T Lymphocytes

T cells can be subdivided into subpopulations by virtue of their specialized functions, surface CD molecules and, in some cases, morphologic features. Lymphoid progenitor cells destined to become T cells exit the bone marrow and migrate to the thymus. There, both α/β and γ/δ T lymphocytes are formed (Fig. 4-4), referring to the two major classes of heterodimeric TCRs that specifically recognize and bind antigens. The thymic microenvironment is determined by its epithelial stroma. The early thymus is colonized by progenitors that give rise to T cells, macrophages and dendritic cells. The thymic cortex is composed of a meshwork of epithelial cell processes that surround groups of immature thymocytes that bear *both* $CD4^+$ and $CD8^+$ surface molecules. As T lymphocytes mature, they percolate into thymic medulla where, in close proximity to nested groups of epithelial cells, they form more mature cells that are *either* $CD4^+$ or $CD8^+$ (Fig. 4-4).

The thymic corticomedullary junction contains marrow HSC-derived macrophages and dendritic cells. Much of the **positive selection** of thymocytes occurs in the cortex; **negative selection** tends to occur through exposure of developing thymocytes to corticomedullary dendritic cells. In positive thymic selection, transient, low-affinity binding of cell surface TCRs to a person's own MHC class I or II molecules

prevents cell death. Negative thymic selection is the converse process in which high-affinity TCR-mediated binding to one's own MHC class I or II molecules results in cell death by apoptosis. These complementary processes are pivotal to T lymphocyte development, so that T cells can interact with the host's own cells but not in a manner that results in excessive self-reactivity (see below).

Lineage-specific differentiation and thymic selection of T lymphocytes are fundamental to understanding the immune response and autoimmunity, respectively. Thymic T-lymphocyte maturation includes several processes. Developing T cells recombine dispersed gene segments that encode the heterodimeric α/β or γ/δ TCRs. α/β T lymphocytes progress through stages of development that are characterized as $CD4^-/CD8^-$, then $CD4^+/CD8^+$ and then *either* $CD4^+/CD8^-$ *or* $CD4^-/CD8^+$ (Fig. 4-4). Most $CD4^+/CD8^-$ T cells act as **helper cells**, while most $CD4^-/CD8^+$ T cells are **cytotoxic**.

Naive T lymphocytes exit the thymus and populate secondary lymphoid tissues. In the thymus, antigen-specific TCRs are formed and expressed in conjunction with CD3, an essential accessory molecule. Nearly 95% of circulating T lymphocytes express α/β TCRs plus either CD4 or CD8. A smaller population (5%) of T cells express γ/δ TCRs and CD3 but neither CD4 nor CD8.

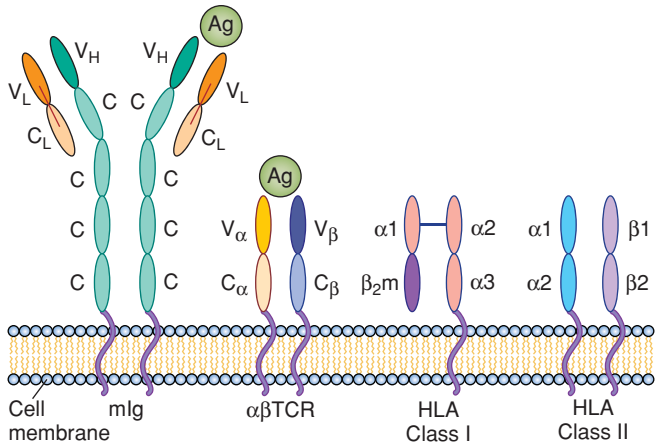

FIGURE 4-5. Alignment of two N-terminal variable domains of membrane immunoglobulin and two N-terminal variable domains of T-cell receptors (TCRs) forms the respective antigen-binding sites of B lymphocytes and T lymphocytes, respectively. Each variable (V) domain is derived from disparate recombined gene segments. The antigen-binding grooves of human leukocyte antigen (HLA) molecules are formed by the alignments of α_1 and α_2 domains in class I and α_1 and β_1 domains in class II. β_2m is β_2–microglobulin, which is encoded outside of the major histocompatibility complex (MHC).

B Lymphocytes

The maturation of B cells from CLP cells occurs in the bone marrow where several maturation stages can be identified. These include, in sequence, pro-B lymphocytes, which exhibit unrecombined (germline) DNA and no surface immunoglobulin; pre-B lymphocytes, which express an "early" antigen receptor (μ heavy chain plus an invariant surrogate light chain); immature B cells, which express a recombined H chain gene plus κ or λ messenger RNA (mRNA) and membrane IgM κ or λ; and finally, mature but naive B lymphocytes, which coexpress surface IgM **and** IgD. B-1 and marginal zone B cells develop from immature B lymphocytes via a different program than do B cells that coexpress IgM and IgD. B cells differentiate in the bone marrow into mature B cells and in some cases further into antibody-secreting plasma cells. Similar to T-lymphocyte development, the microenvironments of fetal liver and bone marrow are critical to B-cell development. In both sites, only B lymphocytes that survive pass through the multiple steps necessary to produce surface immunoglobulin. Conversely, when surface immunoglobulin binds too avidly to self-antigens, developing B cells are negatively selected and eliminated.

Analogous to T cells, B lymphocytes express a surface antigen-binding receptor, **membrane immunoglobulin** (mIg), with the same antigen-binding specificity as the soluble immunoglobulin that will ultimately be secreted by the corresponding terminally differentiated plasma cells. Like T cells, B lymphocytes are also heterogeneous (e.g., $CD5^+$ [B1] and $CD5^-$ [B2]). TCRs, along with immunoglobulins and MHC class I and class II molecules (see below), confer specificity to the immune system by virtue of their capacity to bind specifically to foreign antigens and interact with histocompatible self-cells. TCRs, Ig and a portion of the MHC class I molecule are encoded by members of the immunoglobulin supergene family (Fig. 4-5). The structural variability and, in turn, great specificity of TCRs and Igs are achieved by recombination of TCR and Ig genes. An individual TCR is a heterodimer that forms an antigen-binding site (Fig. 4-5). TCRs and Igs each possess an amino-terminal antigen-binding variable (V) domain and a carboxy-terminal constant (C) domain (Fig. 4-5). TCRs anchor antigen to the cell surface, while Igs either anchor the receptor to the B-cell surface as mIg or, in the case of soluble Ig, mediate its biological function.

NK Cells

NK cells recognize target cells mainly via antigen-independent mechanisms. They form in both thymus and bone marrow and bear several types of receptors that bind class I MHC molecules. NK receptors *inhibit* the cell's capacity to secrete cytolytic products. Certain tumor cells and virus-infected cells express reduced numbers of MHC class I molecules and thus fail to inhibit NK cells. Such NK cells engage virus-infected or tumor cells and secrete a complex of complement-like pore-forming cytolytic proteins (perforin), as well as granzymes A and B and other lytic molecules. NK cells also secrete granulysin, a cationic protein that induces target cell apoptosis.

In another example of linkage between different facets of the immune system, NK cells can also lyse target cells via antibody-dependent cellular cytotoxicity (ADCC). In ADCC, NK-cell Fc receptors engage the Fc domain of IgG that has specifically bound to antigen on surfaces of target cells. As with T and B cells, NK cells exhibit a degree of heterogeneity (e.g., $CD16^+$, $CD16^-$).

Mononuclear Phagocytes, Antigen-Presenting Cells and Dendritic Cells

Mononuclear phagocytes, chiefly **monocytes,** make up 10% of white blood cells. Circulating monocytes give rise to resident tissue macrophages including, among others, Kupffer cells (liver), alveolar macrophages (lung) and microglial cells (brain). Monocytes and macrophages express specific cell surface host defense molecules. These include MHC class II

molecules, CD14 (which binds bacterial lipopolysaccharide and can trigger cell activation), several types of Fc Ig receptors, TLRs and other PRRs, adhesion molecules and a variety of cytokine receptors that participate in regulating monocyte/macrophage function. Activated macrophages produce a variety of cytokines and soluble mediators of host defense (e.g., interferon [IFN-γ], interleukin-1β [IL-1β], tumor necrosis factor-α [TNF-α] and complement components).

Antigen-presenting cells (APCs), defined by their function and derived from HSCs, acquire the capacity to present antigen to T lymphocytes in the context of histocompatibility, after cytokine-driven upregulation of MHC class II molecules. Monocytes, macrophages, dendritic cells and, under certain conditions, B lymphocytes, endothelial cells and epithelial cells can function as APCs. In some locations, APCs are highly specialized for this function. For instance, in B-cell–rich follicles of lymph nodes and spleen, specialized APCs are termed follicular dendritic cells. In these sites, through engagement of antibody and complement via Fc and C3b receptors, APCs trap antigen–antibody complexes. In the case of lymph nodes, immune complexes arrive via afferent lymphatics, and in spleen, via blood. Antigen presentation by follicular dendritic cells leads to generation of memory B lymphocytes.

Dendritic cells are specialized APCs whose name, "dendritic," reflects their spider-like appearance. They are present in B-lymphocyte–rich lymphoid follicles, thymic medulla and many peripheral sites, including intestinal lamina propria, lung, genitourinary tract and skin. Peripherally located dendritic cells are less mature than APCs found in lymphoid follicles and express lower levels of accessory cell activation molecules (CD80 [B7-1], CD86 [B7-2]) than do mature dendritic cells. An example of a peripheral APC is the epidermal Langerhans cell. Upon exposure, Langerhans cells engulf antigen, migrate to regional lymph nodes through afferent lymphatics and differentiate into more mature dendritic cells. Langerhans cell–derived dendritic cells express high densities of MHC class I and II molecules and costimulatory molecules (CD80, CD86) and present antigens efficiently to T cells. This latter act occurs through TCRs in the context of histocompatibility determined by MHC class II molecules.

The Structure of the Tissues of the Immune System Plays a Key Role in the Biology of the Adaptive Immune System

Lymph Nodes

Lymph nodes are distributed throughout the body along thin-walled lymphatic vessels that ultimately drain into the vascular system via the superior vena cava. Individual nodes are encapsulated, vascularized and internally structured in a manner that facilitates antigen processing and presentation by follicular dendritic cells to B cells in the B-lymphocyte–rich cortical follicles and by dendritic cells to T cells in the T-lymphocyte–rich parafollicular cortex. The anatomic organization of the B-cell–rich and T-cell–rich areas of a lymph node is dictated by the region-specific structure of reticular fibers, the composition of stromal cells and complementary sets of locally produced chemokines and lymphocyte-specific chemokine receptors. Naive B and T cells circulate to a lymph node, exit the vascular space through high endothelial venules (HEVs) and then migrate to their designated areas. Lymphocytes home to HEVs where they engage in specific receptor–ligand binding interactions (see below). Naive B cells express a chemokine receptor, CXCR5 ("R" denotes receptor), which binds specifically to chemokine CXCL13 ("L" denotes ligand) that is produced by follicular dendritic cells. B lymphocytes follow the follicle-centric CXCL13 gradient and are thus concentrated in this region. In an analogous process, naive T cells express CCR7, which binds CCL19 and CCL21 produced by stromal and dendritic cells in the paracortical T region.

Antigen processing in lymph nodes is initiated by an ingenious size-dependent sorting process that is dependent on microanatomic features depicted in Fig. 4-6. First, dendritic cells that have phagocytized proteins, microbes and so forth elsewhere (e.g., skin) migrate via afferent lymphatics into regional lymph nodes and then to the T-cell zone of the node where antigens are processed and presented. Soluble lymph-borne substances such as intact viruses or high–molecular-weight particles/molecules also enter lymph nodes via afferent lymphatics. Within the subcapsular sinus, viruses, particles and high–molecular-weight molecules are engulfed by macrophages/dendritic cells that process and present antigen to cortical B cells that make antibody. Finally, lower–molecular-weight molecules (which cannot penetrate the impermeable lymph node sinus floor) flow down tubular

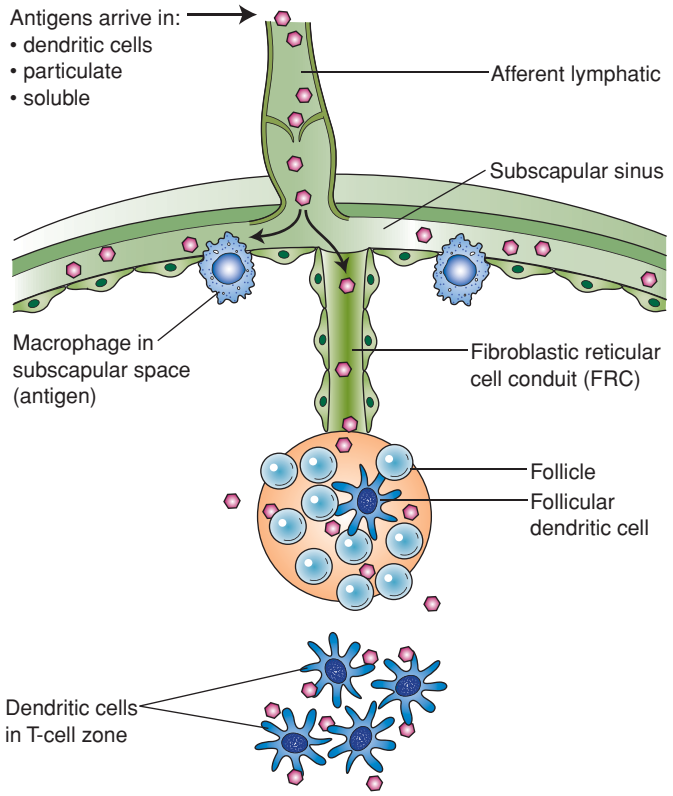

FIGURE 4-6. Potential antigens (viruses, higher–molecular-weight particles/molecules and lower–molecular-weight molecules) enter lymph nodes via afferent lymphatic vessels. Entry may occur via migratory dendritic cells or as free soluble structures. Within the subcapsular sinus, higher–molecular-weight particles/molecules are engulfed by subcapsular macrophage/dendritic cells, while lower–molecular-weight molecules flow down fibroblastic reticular cell conduits (FRCs) where they are pinocytosed dendritic cell processes.

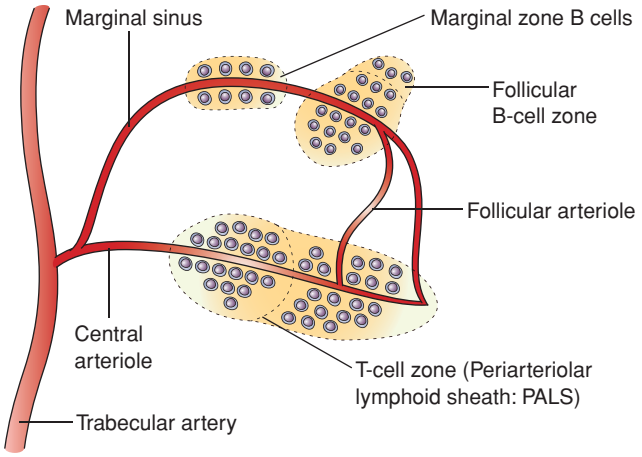

FIGURE 4-7. Splenic white pulp includes a sheath of T lymphocytes wrapped around and along the central arteriole, collections of B lymphocytes around and along the marginal sinuses (marginal zone B cells) and follicular B-cell aggregates.

structures called fibroblastic reticular cell (FRC) conduits where they encounter dendritic cell processes intercalated between FRC cells along the conduits. Here, molecules are taken up, processed by the dendritic cells and presented to T lymphocytes (Fig. 4-6). The structure and function of lymph nodes allows the "sorting" of incoming agents/molecules in a manner that optimizes antigen presentation to either B or T cells, which, in turn, constitute key pivot points to the development of adaptive immune responses.

Spleen

The spleen initiates adaptive immune responses to blood-borne antigens and removes aged and damaged red blood cells, circulating immune complexes and opsonized microbes. As evidenced by the increased susceptibility of asplenic patients to infection by encapsulated bacteria, the spleen is particularly important to the development of antibody-mediated immunity. Induction of adaptive immunity in the spleen occurs in the lymphocyte-rich white pulp, while particle clearance occurs within the red pulp (Fig. 4-7). White pulp lymphocyte aggregates are organized into T-cell– and B-cell–rich zones based on the local stromal cell and APC elaboration of the same chemokines (CXCL13 for B cells, CCL19 and CCL21 for T cells) that direct analogous lymph node structure. Periarteriolar T-cell zones of the splenic white pulp contain filtration conduits lined by FRC-like cells. Marginal zone B cells have a limited antigen receptor repertoire, while follicular B cells possess the whole range of receptor antibody diversity. Blood-borne particles (including microbes) may be delivered to marginal zone B cells via circulating plasmacytoid dendritic cells, and soluble antigens (particularly polysaccharides) may bind marginal zone macrophages directly and then are engaged by nearby B cells.

Thymus

The bilobed thymus is located in the anterior mediastinum before it undergoes involution during puberty. As noted above, the thymus is the site of T-lymphocyte maturation. Individual thymic lobules are organized into highly cellular cortical areas and less cellular medullary areas. Thymic lymphocytes (thymocytes) originate from the bone marrow as progenitors committed to T-lymphocyte development. Maturation occurs as the cells percolate first through the cortex and then the medulla before egress.

Antibodies and T-Cell Receptors Mediate Adaptive Immunity

Antibodies

Antibody function was recognized over a century ago when serum from animals previously exposed to attenuated diphtheria toxin specifically protected naive animals from diphtheroid bacteria. Secreted by plasma cells and B lymphocytes, soluble Ig molecules bind a wide variety of complementary antigens with high degrees of specificity and affinity. They recognize a variety of biological (and nonbiological) molecules including proteins, carbohydrates, lipids, nucleic acids and others. The portion of an antigen that is bound by an Ig molecule is called an "epitope." Antibody–antigen interactions differ from TCR–antigen interactions in that the latter, with few exceptions, involve only protein antigens and occur in the context of MHC molecule compatibility. The various Ig isotypes exhibit different effector functions. Membrane-bound Igs serve as receptors that can mediate B-lymphocyte activation upon antigen binding. Both secreted and membrane Igs consist of paired light chains and heavy chains that together form antigen-binding sites (Fig. 4-8). An individual's repertoire of Ig molecules entails tremendous ranges of antigen-binding specificity (10^7–10^9) and binding affinity ($K_d = 10^{-7}$–10^{-11} M). The broad range of specificities is determined by hypervariablity of amino acid sequence

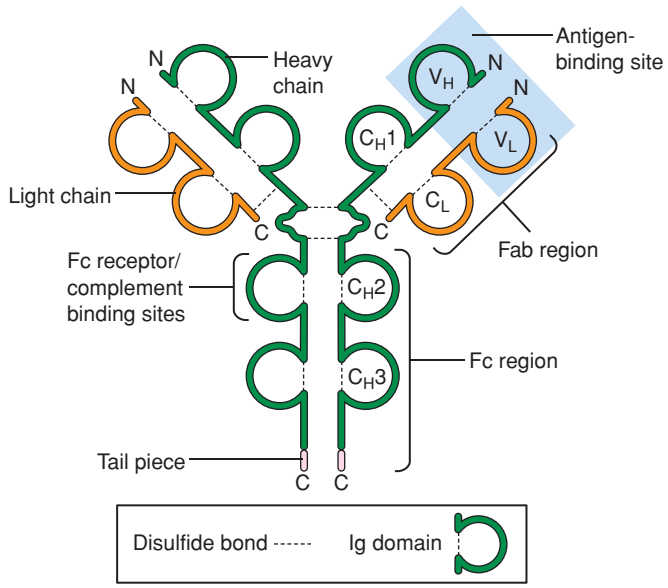

FIGURE 4-8. Schematic structure of immunoglobulin molecule (IgG). Immunoglobulin molecules consist of disulfide-linked pairs of heavy chains and light chains. Antigen-binding sites (2 for IgG) are determined by the highly variable VH and CH Ig domains located at the N-terminal portions of the structure. "Fab" refers to antigen-binding fragment and "Fc" refers to crystallizable fragment.

TABLE 4-3
IMMUNOGLOBULIN ISOTYPES AND FUNCTIONS

Isotype	Subtypes	Secreted Form	Functions
IgG	IgG 1, 2, 3, 4	Monomer	Complement fixation Opsonization ADCC Neutralization
IgA	IgA 1, 2	Dimer, monomer	Mucosal immunity
IgM	None	Pentamer	Naive B cell Complement fixation
IgE	None	Monomer	Immediate hypersensitivity
IgD	None	Not secreted	Naive BCR

ADCC = antibody-dependent cellular cytotoxicity; BCR = B-cell receptor; Ig = immunoglobulin.

within the so-called complementarity-determining regions (CDRs) of the antigen-binding V_L and V_H domains (Fig. 4-8). The high degree of variability is made possible through the highly regulated and stereotyped somatic recombination of physically separated germline segments of DNA that encode different portions of the variable domains. Additional variability is generated by addition and/or deletion of nucleotides at sites where the above-mentioned gene segments are joined together.

Ig isotypes include IgG, IgA, IgM, IgE and IgD, which are each determined by their heavy-chain gene segments. Antibodies also include light chains, either κ or λ, which are determined by light-chain gene segments (Table 4-3). Heavy chains guide function (and isotype) (Table 4-3). The role of secreted antibodies (e.g., complement fixation, Fc receptor binding, etc.) is determined by Fc region interactions (Fig. 4-8).

Ig molecules are clonally expressed. That is, a given B cell or plasma cell produces one identical set of intact immunoglobulin molecules. During T-cell–dependent humoral immune responses to protein antigens, high-affinity antibody molecules can be generated through somatic mutation of V-region genes in antigen-stimulated B cells. As a humoral immune response evolves, subsets of B lymphocytes that bind a particular antigen with high affinity proliferate and differentiate into plasma cells. Thus, the subsequent selection of B cells (via antigen binding) produces high-affinity antibody. This process results in a population of antibody molecules that exhibit higher average affinity over time. This phenomenon is called "affinity maturation" and is important in the development of an effective humoral immune response.

T Cells

Most TCRs consist of paired α- and β-chains that each have an N-terminal variable (V) domain, a constant (C) region, a transmembrane region and a cytosolic C-terminus (Fig. 4-9). TCRs bind peptide–MHC complexes where the Vα and Vβ domains of the TCR recognize and bind peptide (antigen), which fits into the α_1/α_2 peptide–binding cleft of

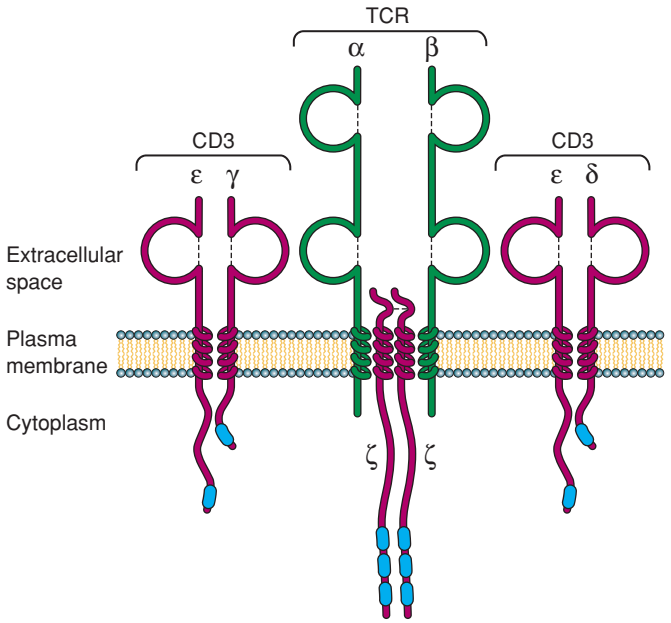

FIGURE 4-9. The T-cell receptor (TCR) consists of noncovalently linked α- and β-chains that each contain a transmembrane domain. The TCR complex includes two ζ-chains and two CD3 subunits ε/γ and ε/δ. TCRs recognize antigen presented in the context of class I human leukocyte antigen (HLA) or class II HLA.

MHC class I molecules or the α_1/β_1 peptide-binding cleft of MHC class II molecules. (As noted above, $CD4^+$ T cells bind processed peptide presented by an APC in the context of MHC class II and $CD8^+$ T cells bind surface peptide presented by a target cell in the context of MHC class I.) In turn, the **TCR complex** is composed of the TCR α- and β-chains, which contribute to antigen recognition and the CD3 γ, δ and ε signaling chains as well as the ζ homodimer. Engagement of the TCR complex leads to signal transduction and cell activation.

Lymphocyte Trafficking and Recirculation

The segments of DNA that encode antigen-binding domains of TCRs and Ig are rearranged in developing T cells and B cells, respectively, to form "new" genes. Through this combinatorial process and several other diversity-generating mechanisms, a large number of different antigen receptors is generated. Adults possess about 10^{12} lymphocytes, of which only 10% are in circulation at a given time. Despite the large aggregate number of lymphocytes, the subset with any specific antigen receptor is relatively small. Body surfaces that serve as portals of entry for foreign invaders are very large (e.g., skin, 2 m^2; respiratory tract, 100 m^2; gastrointestinal tract, 400 m^2). Lymphocyte trafficking is a necessary aspect of host defense because it allows relatively small numbers of any subset of antigen-specific lymphocytes to move to sites of "need." Lymphocyte trafficking, which entails homing and recirculation, has evolved to provide rapid, flexible and widespread distribution of lymphocytes and a means of focusing specific immunologic processes in anatomically discrete sites (e.g., lymph node cortex). Lymphocyte trafficking is a high-flux process whereby individual lymphocytes pass through each lymph node, on average, one time per day!

Following completion of early development, naive B and T lymphocytes circulate via the vascular system to secondary lymphoid tissues (e.g., spleen, lymph nodes and mucosa-associated lymphoid tissues [e.g., Peyer patches]). Lymphocyte trafficking through lymph nodes occurs through specialized postcapillary **high endothelial venules** so-named because of the high cuboidal shape of the endothelial cells (Fig. 4-6). HEVs express cellular adhesion molecules that mediate lymphocyte binding. The cuboidal shape of HEV cells reduces flow-mediated shear forces, and specialized intercellular connections facilitate egress of lymphocytes from the vascular space. Lymphocytes that do not find their cognate antigen as they percolate through secondary lymphoid tissues reenter the circulation through efferent lymphatics and the thoracic duct. Naive lymphocytes have a finite life span maintained by receptor-mediated signals. For example, B cells are engaged via B-cell receptors (surface Ig) and BAFF receptors. (BAFF is B-cell activity factor, a member of the TNF family.)

In contrast, lymphocytes that have engaged an antigen leave the secondary lymphoid tissue, enter the circulation via lymphatics and thoracic duct and then preferentially bind and migrate into peripheral tissues (e.g., lymph nodes or mucosa-associated lymphoid tissue) from which the activating antigen was introduced. Hence, there are at least two major circuits, namely, lymph node and mucosa associated. Within the mucosa-associated system, nonnaive lymphocytes can distinguish among the gastrointestinal, respiratory and genitourinary tracts. Lymphocyte (and neutrophil) homing into sites of inflammation is mediated by different sets of leukocyte and endothelial cell adhesion molecules (see Chapter 2). The best-understood adhesion molecules involved in lymphocyte-lymphoid tissue trafficking include L-selectins (on lymphocytes) and peripheral lymph node addressin (PNAds) that serve as attachment sites for lymphocytes. Among others, the addressins include mucosal addressin cell adhesion molecule-1 (MadCAM-1), glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1) and CD34.

MAJOR HISTOCOMPATIBILITY COMPLEX

The discovery that sera of multiparous women and multiply transfused patients contain antibodies against foreign blood leukocytes led to identification of a system of cell surface proteins known as **human leukocyte antigens (HLAs)** because they were first identified on leukocytes and are expressed in high concentrations on lymphocytes.

HLAs (also known as **histocompatibility** antigens) orchestrate many cell–cell interactions fundamental to immune responses. Conversely, these antigens are major immunogens and thus targets in transplant rejection. The MHC encodes these cell surface proteins, which include class I, II and III antigens. (Class III antigens represent certain complement components and are not histocompatibility antigens per se.)

Molecules structurally like "traditional" MHC class I and II molecules are encoded beyond the specific MHC region on the short arm of chromosome 6. Among these, MHC-1b and CD1d can activate so-called NK T cells. The latter resemble both NK cells and T lymphocytes. Other nontraditional MHC class I molecules (e.g., HLA-E, -F and -G) are not well understood. They may regulate NK-cell activity.

Class I MHC Molecules Are Encoded by A, B and C MHC Regions

Class I MHC loci (Fig. 4-10) encode similarly structured molecules that are expressed in virtually all tissues. Class I molecules are heterodimers consisting of a 44-kd polymorphic transmembrane glycoprotein and a 12-kd nonpolymorphic molecule, β_2-microglobulin. The latter lacks a membrane component and is noncovalently associated with the larger heavy chain. Structural polymorphism occurs primarily in the extracellular domains of the α-chain. *MHC class I alleles are codominantly expressed,* so tissues bear class I molecules inherited from each parent. Antigens are recognized by cytotoxic T cells during graft rejection and T-lymphocyte–mediated killing of virus-infected host cells in the context of histocompatibility.

Class II MHC Molecules Are Encoded in MHC D

Multiple MHC D region loci encode class II MHC: DP, DN, DM, DO, DQ and DR. These are structurally similar molecules expressed primarily on cells involved in antigen presentation. Noted above, APCs include monocytes, macrophages, dendritic cells and B lymphocytes. Class II molecules, also called "Ia" (immunity-associated) antigens, are heterodimers of two noncovalently linked transmembrane glycoproteins. A 29-kd α-chain has two disulfide bonds. The 34-kd β-chain has a single disulfide bond; its extracellular domain is the major site of class II variability. Like class I antigens, D alleles are codominantly expressed.

Nomenclature for MHC genes and antigens was revised by the World Health Organization (WHO) in 2010, to allow high-resolution designations. For example, the old HLA-B27 became B*2701-2725, where B*2701, B*2702, B*2703, . . . encompass 25 different B27 molecules.

IMMUNE CELL EFFECTOR MECHANISMS

Cell-Mediated Immunity

Cellular immunity encompasses adaptive responses triggered by microorganisms within host cells. These responses are mediated by $CD4^+$ and $CD8^+$ T cells. $CD4^+$ Th17 cells recognize microbial antigens and in turn secrete cytokines (interferon-γ) that activate macrophages. Activated macrophages ingest microorganisms and kill through a series of chemical reactions that involve enzymes and both reactive oxygen and nitrogen intermediates. $CD4^+$ T_H2 cells recognize microbial (and other) antigens and promote B-cell differentiation and immunoglobulin production, immunoglobulin isotype switching and the production of IgE. Finally, $CD4^+$ Th17 cells induce a neutrophilic response whereby the neutrophils kill microorganisms by phagocytosis, enzymatic digestion and reactive oxygen species. $CD8^+$ cytotoxic T cells (CTLs) kill host target cells that express surface foreign antigen (in MHC I context). CTL-mediated killing occurs via the perforin/granzyme pathway and/or via IFN-γ production and subsequent macrophage activation (see above).

Humoral Immunity

Antibodies produced by B lymphocytes and plasma cells are integral to the effector branch of humoral immunity. Antibodies exhibit very high degrees of antigen specificity and

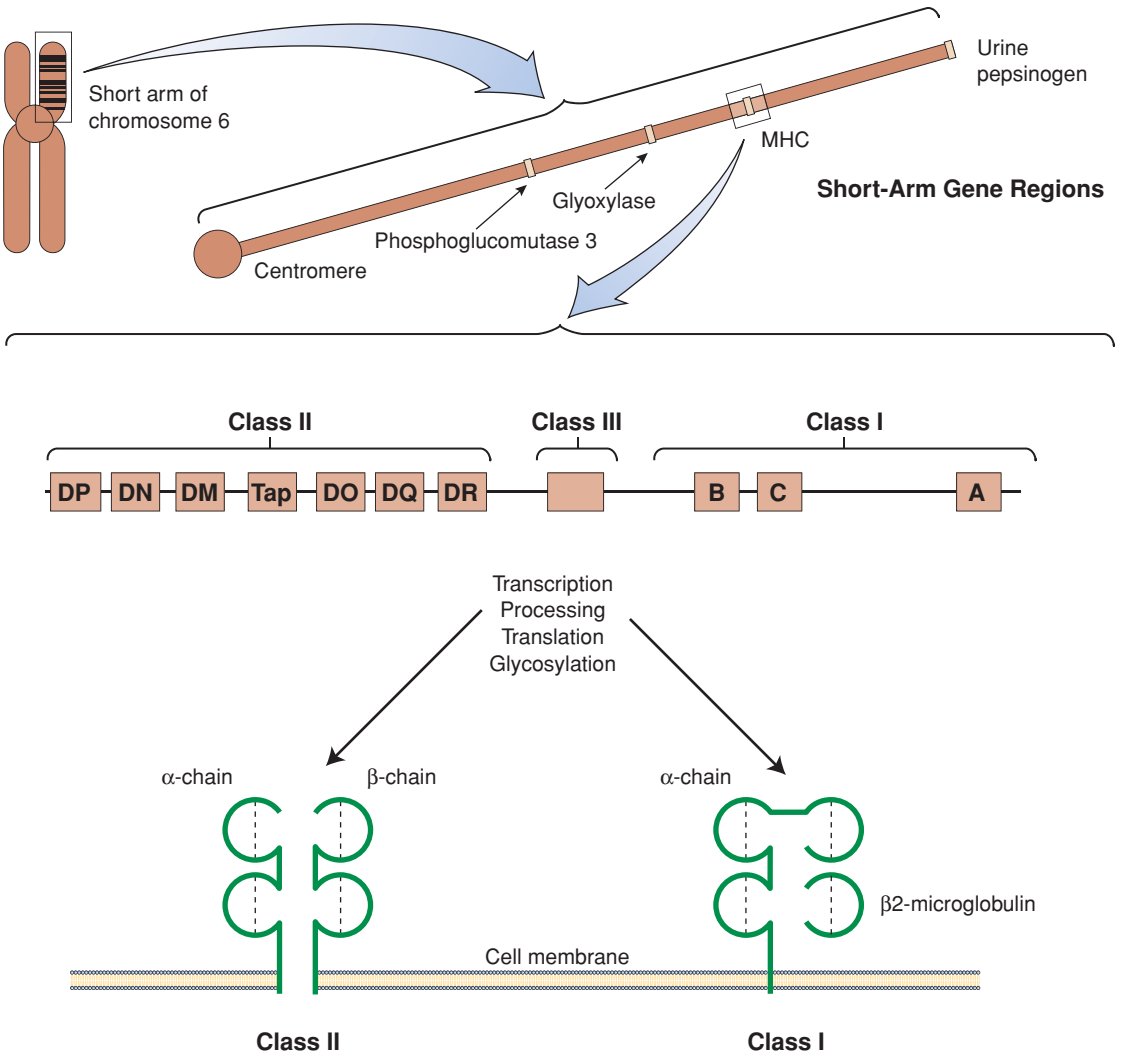

FIGURE 4-10. The highly polymorphic loci that encode major histocompatibility antigens are located on the short arm of chromosome 6. Class I and class II molecules exhibit different structures, but each participates in fundamentally important cell–cell interactions. Class III genes encode some complement components that are not formally histocompatibility antigens.

binding affinity. As noted, the various immunoglobulin isotypes determine effector function (Table 4-3). Immunoglobulin effector functions include steric blockade (e.g., antibody to human immunodeficiency virus type 1 prevents binding to CD4 molecules on T cells), binding and Fc-mediated clearance by the mononuclear phagocyte system, binding and Fc-mediated ADCC, Fc binding and cell activation (e.g., IgE antibody tightly bound to most cells via Fcε receptor) and mast cell activation triggered by allergen binding to cytophilic IgE and immunoglobulin/antibody-mediated complement fixation. Pentavalent IgM and properly spaced IgG molecules (IgG subclasses 1, 2 and 3) effectively bind (fix) C1qrs, leading to activation of the classical complement cascade and generation of its attendant proinflammatory mediators (e.g., C3a, C3b, C5a, membrane attack complex).

INTEGRATED IMMUNE RESPONSES

T-Lymphocyte Interactions

T lymphocytes recognize specific antigens, usually proteins or haptens bound to proteins. T cells undergo activation when engaged via the TCR in the context of antigen presentation by a histocompatible (i.e., MHC-matched) APC. Exogenous signals are delivered by cytokines. $CD4^+$ and $CD8^+$ T-cell subsets exhibit a variety of regulatory and effector functions. Regulatory functions include augmentation or suppression of immune responses, usually via secretion of specific helper or suppressor cytokines. Effector functions include secretion of proinflammatory cytokines and killing of cells that express foreign or altered membrane antigens.

$CD4^+$ T cells, and possibly $CD8^+$ T cells, can be further distinguished by the types of cytokines they produce. Helper type 1, or "Th1," cells produce IFN-γ and IL-2, while helper type 2, or "Th2," cells secrete IL-4, IL-5 and IL-10. Th1 lymphocytes have been associated with cell-mediated phenomena and Th2 cells with allergic responses. In general, $CD4^+$ T cells promote antibody and inflammatory responses. $CD8^+$ T cells largely exert suppressor and/or cytotoxic functions. Suppressor cells inhibit the activation phase of immune responses; cytotoxic cells kill target cells that express foreign antigens. However, there is some overlap, as some $CD8^+$ T cells secrete helper cytokines and $CD4^+$ Th1 and Th2 cells can exhibit cross-regulatory suppression.

A key aspect of T-cell antigen recognition is the requirement for antigen to be presented on the surfaces of other cells in association with a histocompatible membrane protein (Figs. 4-5, 4-9 and 4-10). As noted, T cells bear membrane receptor complexes (α/β TCRs plus CD3 accessory molecules) on their surfaces (Figs. 4-5 and 4-9). For maximal immune response, the TCR–CD3 complex must interact with a foreign antigen in the context of cell-to-cell histocompatibility. Antigens may also be presented to T cells by cells that do not "present" antigens but rather express on their surface a foreign or altered self-protein in association with an appropriate histocompatibility molecule.

$CD8^+$ cells (cytotoxic T cells) recognize antigens in conjunction with HLA class I molecules, while $CD4^+$ cells (T helper cells) recognize antigens together with class II molecules. The membrane CD4 and CD8 molecules of α/β T cells help stabilize binding interactions. γ/δ T cells may also acquire CD8 outside the thymus and then use class I antigens for binding target cells. Foreign class I and class II molecules, which are histoincompatible with the host (e.g., histocompatibility molecules in transplanted tissues), are themselves potent immunogens and can be recognized by host T cells. *This is why optimal tissue transplantation requires that donor and recipient be HLA matched.* In addition to binding foreign peptides presented by MHC molecules to the TCR complex, several other receptor–ligand interactions must occur for maximal lymphocyte activation. A $CD4^+$ T cell becomes an activated effector cell when stimulated via the TCR complex and "accessory" receptors (CD28 and cytotoxic lymphoid line [CTLL]-4), which engage costimulatory molecules (e.g., CD80 [B-7.1] and CD86 [B-7.2]). In turn, an activated T helper cell recognizes an antigen-specific B cell via its receptor. The T helper cell then provides costimulatory and regulatory signals, such as CD40 ligand and "helper" cytokines (e.g., IL-4, IL-5).

B-Lymphocyte Interactions

Mature B cells exist primarily in a resting state, awaiting activation by foreign antigens. Activation requires cross-linking of mIg receptors via antigens presented by accessory cells and/or interactions with membrane molecules of helper T cells via a mechanism called cognate T-cell–B-cell help. The initial stimulus leads to B-cell proliferation and clonal expansion, a process amplified by cytokines from both accessory cells and T cells. If an insufficient additional signal is provided, proliferating B cells return to a resting state and enter the memory cell pool. These events take place largely in lymphoid tissues. B-lymphocyte proliferation can be seen as germinal centers, within which B cells undergo further somatic gene rearrangements to generate cells that produce the various immunoglobulin isotypes and subclasses (Table 4-3). T cells also influence B-cell differentiation. In the presence of antigen, T cells produce helper cytokines that stimulate isotype switching or induce proliferation of previously committed isotype populations. For example, IL-4 induces switching to the IgE isotype.

The final stage of B-cell differentiation into antibody-synthesizing plasma cells requires exposure to additional products of T lymphocytes (e.g., IL-5, IL-6), especially in the case of protein antigens. However, some polyvalent agents directly induce B-cell proliferation and differentiation into plasma cells, bypassing the requirements for B cell growth and differentiation factors. Such agents are called "polyclonal B-cell activators" because they do not interact with antigen-binding sites; they are not specific antigens. Such polyclonal B-cell activators include bacterial products (lipopolysaccharide, *Staphylococcus* protein A) and certain viruses (Epstein-Barr virus [EBV], cytomegalovirus [CMV]).

The predominant type of Ig produced during an immune response changes with age. Newborns produce mainly IgM. Older children and adults initially produce IgM following antigenic challenge but rapidly shift toward IgG synthesis.

IMMUNOLOGICALLY MEDIATED TISSUE INJURY

There are many diseases in which an immunologically triggered inflammatory response attacks the body's own tissues. A variety of foreign substances (e.g., dust, pollen, viruses, bacteria) provoke protective responses. In certain situations, the protective effects of an immune response lead to harmful consequences, which can range from temporary discomfort to substantial injury. For example, in the process of ingesting and destroying bacteria, phagocytic cells (neutrophils and macrophages) often cause injury to surrounding tissue. An immune response that leads to tissue injury is broadly called a **hypersensitivity** reaction. Many diseases are categorized as immune disorders or immunologically mediated conditions, in which an immune response to a foreign or self-antigen causes injury. Immune- or hypersensitivity-mediated diseases are common and include hives (urticaria), asthma, hay fever, hepatitis, glomerulonephritis and arthritis.

Hypersensitivity reactions are classified according to immune mechanism (Table 4-4). Type I, II and III hypersensitivity reactions all involve antibodies specific for exogenous (foreign) or endogenous (self) antigens. (An exception includes a subset of type I reactions.) Antibody isotype influences the mechanism of tissue injury.

- **Type I, or immediate-type hypersensitivity, reactions:** IgE antibody is formed and binds high-affinity receptors on mast cells and/or basophils via its Fc domain. Subsequent antigen binding and cross-linking of IgE trigger rapid (immediate) release of products from these cells, leading to the characteristic manifestations of urticaria, asthma and anaphylaxis.
- **Type II hypersensitivity reactions:** IgM or IgG antibody is formed against an antigen, usually a cell surface protein. Less commonly, the antigen is an intrinsic structural component of the extracellular matrix (e.g., basement membrane). Such antigen–antibody coupling activates complement, which in turn lyses the cell (cytotoxicity) or damages the extracellular matrix. In some type II reactions, other antibody-mediated effects are operative.
- **Type III hypersensitivity reactions:** The antibody responsible for tissue injury is also usually IgM or IgG, but the mechanism of tissue injury differs. Antigen circulates in the vascular compartment until it is bound by antibody. Resulting immune complexes deposit in tissue where complement activation leads to recruitment of leukocytes, which mediate tissue injury. In some type III reactions, antigen is bound by antibody in situ.
- **Type IV, cell-mediated** or **delayed-type, hypersensitivity reactions:** Antigen activation of T lymphocytes, usually with the help of macrophages, causes release of products by these cells, leading to tissue injury.

TABLE 4-4
MODIFIED CELL AND COOMBS CLASSIFICATION OF HYPERSENSITIVITY REACTIONS

Type	Mechanism	Examples
Type 1 (anaphylactic type): immediate hypersensitivity	IgE antibody–mediated mast cell activation and degranulation Non–Ig mediated	Hay fever, asthma, hives, anaphylaxis Physical urticarias
Type II (cytotoxic type): cytotoxic antibodies	Cytotoxic (IgG, IgM) antibodies formed against cell surface antigens; complement usually involved Noncytotoxic antibodies against cell surface receptors	Autoimmune hemolytic anemias, Goodpasture disease Graves disease
Type III (immune complex type): immune complex disease	Antibodies (IgG, IgM, IgA) formed against exogenous or endogenous antigens; complement and leukocytes (neutrophils, macrophages) often involved	Autoimmune diseases (SLE, rheumatoid arthritis), many types of glomerulonephritis
Type IV (cell-mediated type): delayed-type hypersensitivity	Mononuclear cells (T lymphocytes, macrophages) with interleukin and lymphokine production	Granulomatous disease (tuberculosis), delayed skin reactions (poison ivy)

Ig = immunoglobulin; SLE = systemic lupus erythematosus.

Many immunologic diseases are mediated by more than one type of hypersensitivity reaction. For example, in hypersensitivity pneumonitis, lung injury from inhaled fungal antigens involves types I, III and IV reactions.

IgE-Mediated Hypersensitivity Reactions (Type I)

Immediate-type hypersensitivity entails localized or generalized reactions that occur immediately (within minutes) after exposure to an antigen or "allergen" to which the person has been previously sensitized. Clinical manifestations depend on the site of antigen exposure and extent of sensitization. For example, when a reaction involves the skin, the characteristic local reaction is a "wheal and flare," or urticaria. When the conjunctiva and upper respiratory tract are involved, sneezing and conjunctivitis result and we speak of hay fever (allergic rhinitis). In its generalized and most severe form, immediate hypersensitivity reactions are associated with bronchoconstriction, airway obstruction and circulatory collapse, as seen in anaphylactic shock. There is a high degree of genetically determined variability in susceptibility to type I hypersensitivity reactions, and susceptible individuals are said to be "atopic."

Type I reactions usually feature IgE antibodies formed by a $CD4^+$, Th2 T-cell–dependent mechanism that bind avidly to Fcε receptors on mast cells and basophils. High avidity ($K_d = 10^{-15}$ M) of IgE binding accounts for the term **cytophilic** antibody. Once exposed to a specific allergen that elicits IgE, a person is sensitized; subsequent exposures to that allergen or a cross-reacting epitope induce immediate hypersensitivity reactions. Once IgE is elicited, repeat exposure to antigen typically induces additional IgE antibody, rather than antibodies of other classes.

Bound to Fcε receptors on mast cells and basophils, IgE can persist for years. Upon reexposure, recognition of the soluble antigen or allergen by IgE coupled to its surface Fcε receptor activates the mast cell or basophil. Released inflammatory mediators cause type I hypersensitivity reactions. As shown in Fig. 4-11, the antigen (allergen) binds the Fab region of the IgE antibody. To activate the cell, antigen must cross-link at least two adjacent IgE antibody molecules.

Mast cells and basophils can also be activated by agents other than antibodies. For example, some individuals develop urticaria after exposure to an ice cube (physical urticaria) or pressure (dermographism). The complement-derived anaphylatoxic peptides, C3a and C5a, can directly stimulate mast cells by a different receptor-mediated process (Fig. 4-11). These cell-activating events trigger release of stored granule constituents and rapid synthesis and release of other mediators. Some compounds, such as melittin (from bee venom), and some drugs (e.g., morphine) activate mast cells directly.

Regardless of how mast cell activation is initiated, a rise in cytosolic free calcium triggers an increase in cyclic adenosine monophosphate (cAMP), activation of several metabolic pathways within the mast cell and subsequent secretion of both preformed and newly synthesized products. Stored in granules, mediators are released within minutes and act rapidly. Of the granule constituents listed in Fig. 4-11, histamine is particularly important. It induces constriction of vascular and nonvascular smooth muscle, causes microvascular dilation and increases venule permeability. These effects are largely mediated through H_1 histamine receptors. Histamine also increases gastric acid secretion through H_2 histamine receptors and provokes the cutaneous wheal-and-flare reaction. In the lungs, it causes the early manifestations of immediate hypersensitivity, including bronchospasm, vascular congestion and edema. Other preformed products released from mast cell granules include heparin, a series of neutral proteases (trypsin, chymotrypsin carboxypeptidase and acid hydrolases) and both neutrophil and eosinophil chemotactic factors. The latter is responsible for the accumulation of eosinophils, a characteristic finding in immediate hypersensitivity. The synthesis and secretion of cytokines by mast cells, by other recruited inflammatory cells and even by indigenous cells (e.g., epithelium) are important in the so-called "late-phase" reaction of immediate hypersensitivity. Late-phase responses typically last 2–24 hours, are marked by a mixed inflammatory infiltrate and are mediated by many cytokines including IL-1, IL-3, IL-4, IL-5, IL-6, TNF, granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage inflammatory protein (MIP)-1α and MIP-1β.

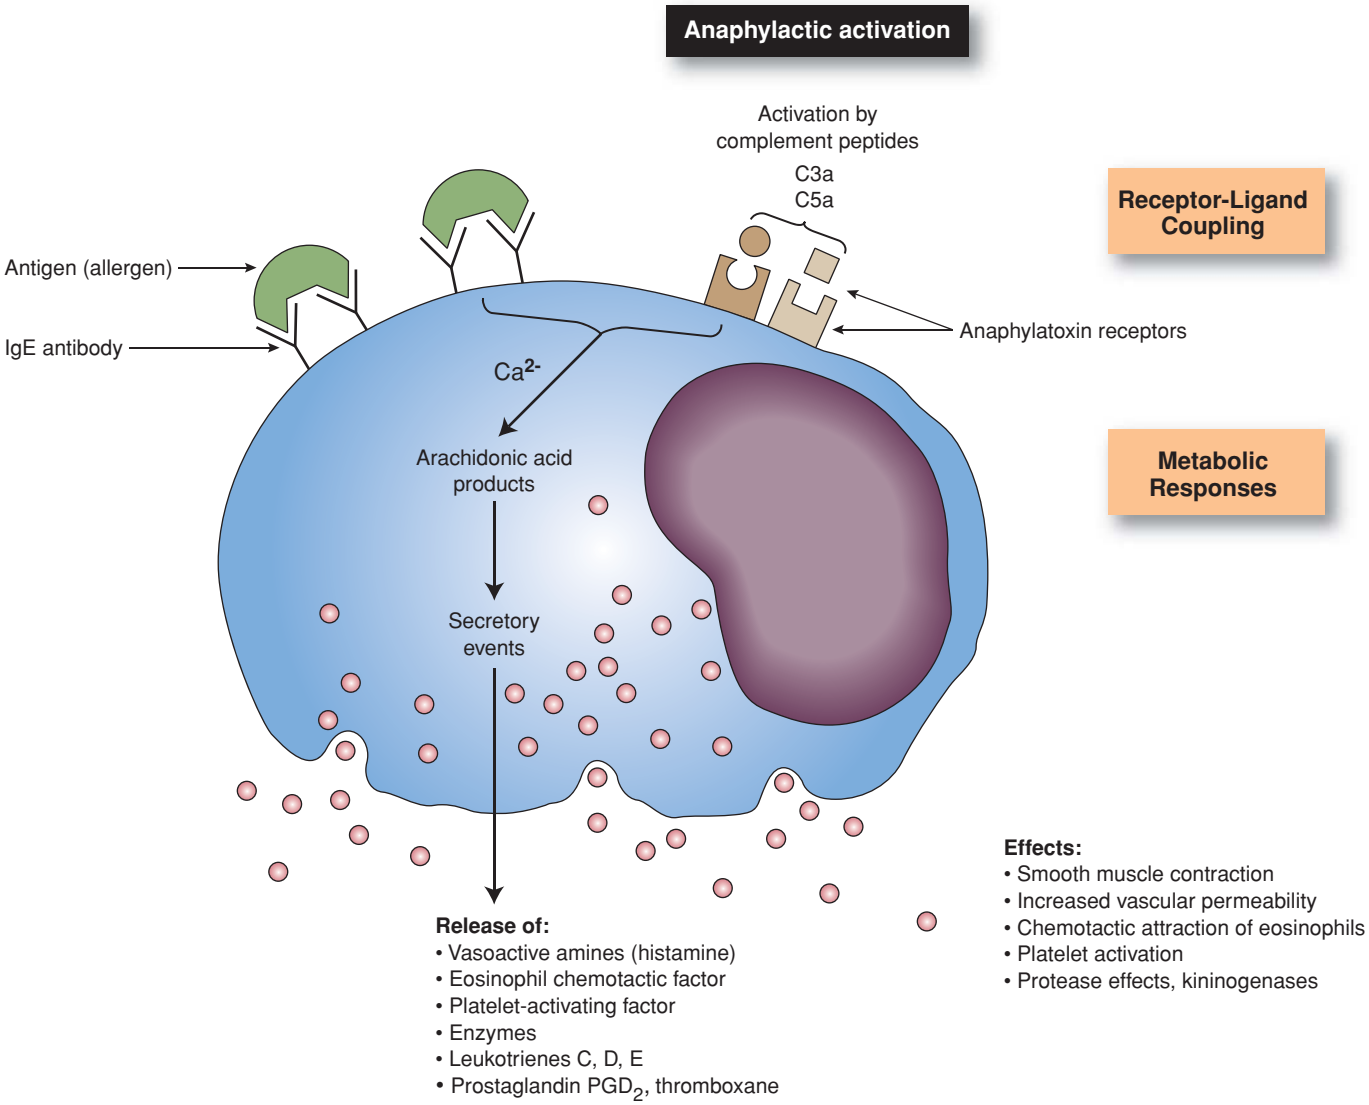

FIGURE 4-11. In a type I hypersensitivity reaction, antigen (allergen) binds to cytophilic surface IgE antibody on a mast cell or basophil and triggers cell activation and the release of a cascade of proinflammatory mediators. Mast cells and basophils can also be activated by anaphylatoxins like C3a and C5a, as well as some physical stimuli (e.g., cold). These mediators are responsible for smooth muscle contraction, edema formation and the recruitment of eosinophils. Ca^{2+} = calcium ion; *Ig* = immunoglobulin; PGD_2 = prostaglandin D_2.

Mast cell activation also increases synthesis of arachidonic acid pathway products formed after activation of phospholipase A_2. Products of cyclooxygenase (prostaglandins D_2, E_2 and F_2 and thromboxane) and lipoxygenase (leukotrienes B_4, C_4, D_4, E_4) are also produced. Arachidonic acid derivatives, generated by a variety of cell types, induce smooth muscle contraction, vasodilation and edema. Leukotrienes C_4, D_4 and E_4, previously known as "slow-reacting substances of anaphylaxis" (SRS-As), are important in the delayed bronchoconstriction phase of anaphylaxis. Leukotriene B_4 is a potent chemotactic factor for neutrophils, macrophages and eosinophils.

Another inflammatory mediator synthesized by mast cells is **platelet-activating factor** (PAF), a lipid derived from membrane phospholipids. PAF is a potent inducer of platelet aggregation and release of vasoactive amines as well as a potent neutrophil chemotaxin. PAF can activate all types of phagocytic cells.

Activated T cells, specifically Th2 cells, produce cytokines that have important roles in allergic responses. This subset releases IL-4, IL-5 and IL-13, leading to IgE production and increased numbers of mast cells and eosinophils. In allergy-prone people, a similar response occurs via T cells that produce IL-4, IL-6 and IL-2, concentrations of which are also increased in allergic individuals. These individuals also have reduced levels of IFN-γ, which suppresses development of Th2 cells and subsequent production of IgE.

In summary, type I (immediate) hypersensitivity reactions are characterized by specific cytophilic antibody (IgE) that binds to high-affinity Fcε receptors on basophils and mast cells and reacts with a specific antigen (allergen). Activated mast cells and basophils release preformed (granule) products and synthesize mediators that cause the classic manifestations of immediate hypersensitivity and the late-phase reaction.

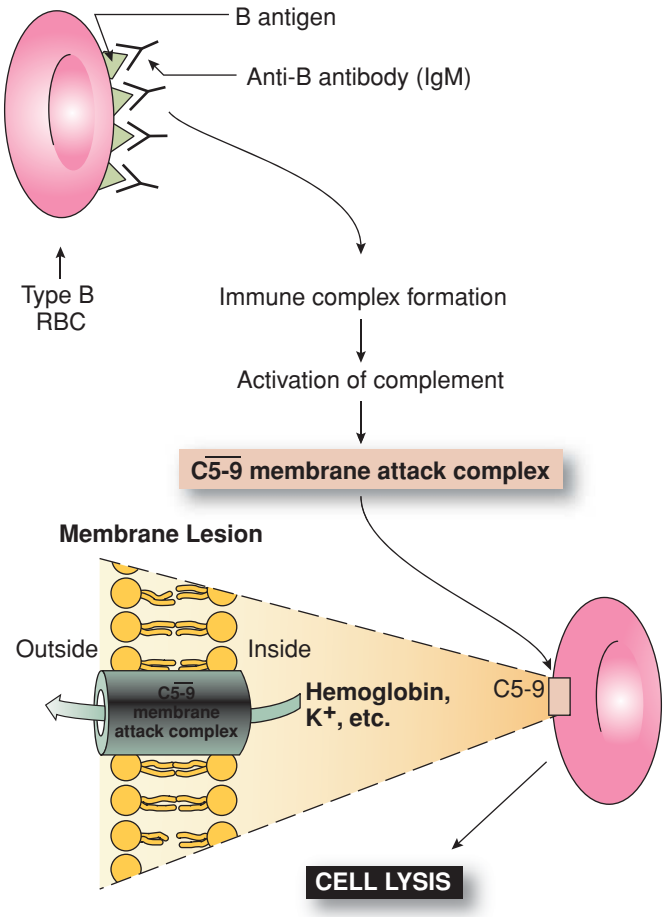

FIGURE 4-12. In a type II hypersensitivity reaction, binding of IgG or IgM antibody to an immobilized antigen promotes complement fixation. Activation of complement leads to amplification of the inflammatory response and membrane attack complex (MAC)-mediated cell lysis. *Ig* = immunoglobulin, K^+ = potassium ion; *RBC* = red blood cell.

Non-IgE Antibody-Mediated Hypersensitivity Reactions (Type II)

IgM and IgG mediate most type II reactions. These Ig isotypes activate complement via their Fc domains. There are several antibody-dependent mechanisms of tissue injury. Prototypic antibody-mediated erythrocyte cytotoxicity is illustrated in Fig. 4-12. IgM or IgG antibody binds an antigen on the erythrocyte membrane. At sufficient density, bound Ig fixes complement via C1q and the classical pathway (see Chapter 2). Activated complement can destroy target cells directly, via C5b-9 complexes (Fig. 4-12). The C5b-9 **membrane attack complex** inserts like the staves of a barrel into the plasma membrane and forms holes or ion channels, destroying the permeability barrier and inducing cell lysis. This type of cell lysis is exemplified by certain autoimmune hemolytic anemias resulting from antibodies against erythrocyte blood group antigens. In some transfusion reactions that result from major blood group incompatibilities, intravascular hemolysis occurs through activation of complement.

Complement and antibody molecules can also destroy target cells by **opsonization**. Target cells coated (opsonized) with immunoglobulin and/or C3b molecules are bound by phagocytes that express Fc or C3b receptors. Complement activation near a target cell surface leads to formation and covalent bonding of C3b (Fig. 4-13). Many phagocytic cells, including neutrophils and macrophages, express cell membrane Fc and C3b receptors. By binding to these receptors, Ig or C3b bridges the target and effector (phagocytic) cells, thereby enhancing phagocytosis and subsequent intracellular destruction of the antibody- or complement-coated cell.

Some transfusion reactions, autoimmune hemolytic anemias and drug reactions occur via antibody- and complement-mediated opsonization.

Antibody-dependent cell-mediated cytotoxicity does not require complement, but rather involves cytolytic leukocytes that attack antibody-coated target cells after binding via Fc receptors. Phagocytic cells and NK cells can act as effector cells in ADCC. Effector cells synthesize homologs of terminal complement proteins (e.g., perforins), which participate in cytotoxic events (see preceding discussion of NK cells). *Only rarely is antibody alone directly cytotoxic.* In cases involving primarily lymphoid cells, apoptosis is activated. ADCC is implicated in the pathogenesis of some autoimmune diseases (e.g., autoimmune thyroiditis).

In some type II reactions, antibody binding to a specific target cell receptor does not lead to cell death but rather to change in function. For example, in Graves disease and myasthenia gravis, autoantibodies against cell surface hormone receptors and postsynaptic neurotransmitter receptors, respectively (Fig. 4-14), may activate or inhibit cell activation

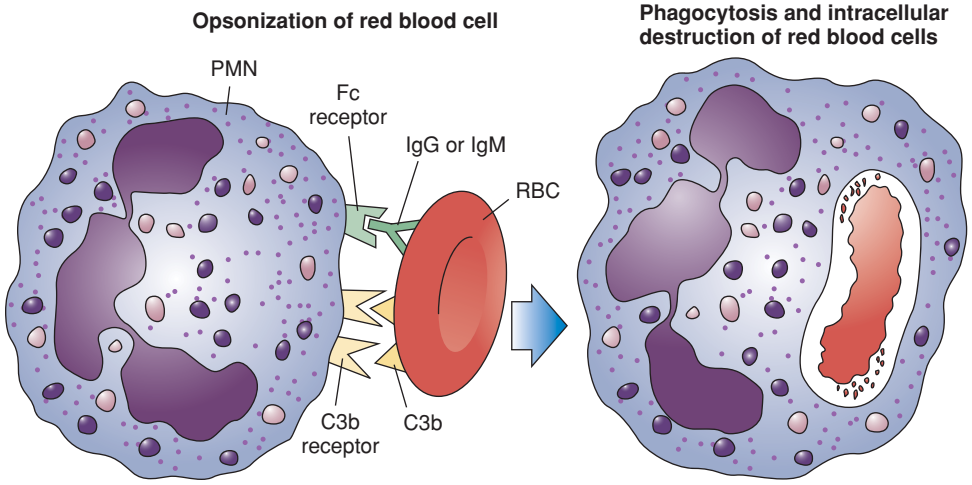

FIGURE 4-13. In a type II hypersensitivity reaction, opsonization by antibody or complement leads to phagocytosis via either Fc or C3b receptors, respectively. *Ig* = immunoglobulin; *PMN* = polymorphonuclear leukocyte; *RBC* = red blood cell.

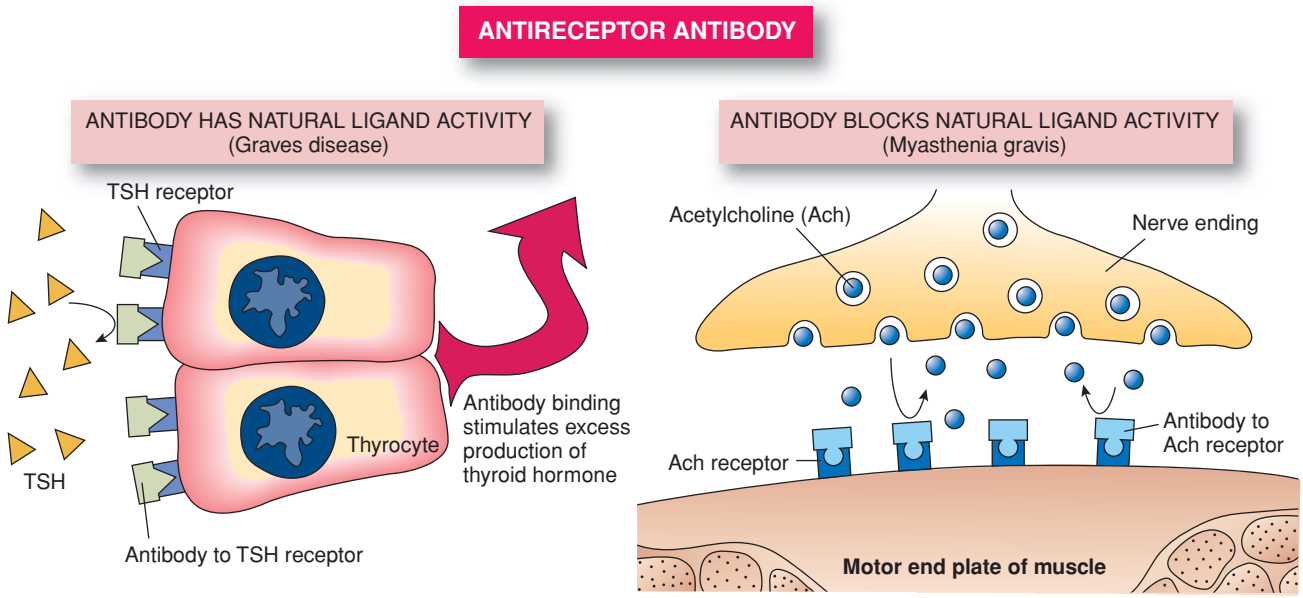

FIGURE 4-14. In a type II hypersensitivity reaction, antibodies bind to a cell surface receptor and induce activation (e.g., thyroid-stimulating hormone [TSH] receptors in Graves disease) or inhibition/destruction (e.g., acetylcholine receptors in myasthenia gravis).

(see below). In Graves disease, autoantibody against thyroid-stimulating hormone (TSH) receptors elicits thyroxin production, leading to thyrotoxicosis. In myasthenia gravis, autoantibodies to acetylcholine receptors on postsynaptic membranes block acetylcholine binding and/or mediate internalization or destruction of receptors, thereby preventing effective synaptic transmission. Patients with myasthenia gravis suffer from muscle fatigue.

Some type II reactions result from antibody against a structural connective tissue component. Classic examples are Goodpasture syndrome and the bullous skin diseases, pemphigus and pemphigoid. In these disorders, circulating antibodies bind intrinsic connective tissue antigens and evoke destructive local inflammatory responses. In Goodpasture syndrome, antibody binds the noncollagenous domain of type IV collagen, which is a major structural component of pulmonary and glomerular basement membranes (Fig. 4-15). Local complement activation results in neutrophil chemotaxis and activation, tissue injury and pulmonary hemorrhage and glomerulonephritis. Direct complement-mediated damage to glomerular and alveolar basement membranes via membrane attack complexes may also be involved.

In summary, type II hypersensitivity reactions are directly or indirectly cytotoxic through action of antibodies against antigens on cell surfaces or in connective tissues. Complement participates in many of these events. It may directly mediate lysis, or it may act indirectly by opsonization and phagocytosis or chemotactic attraction of phagocytic cells, which produce a variety of tissue-damaging products. Complement-independent reactions, such as ADCC, also play a role in type II hypersensitivity.

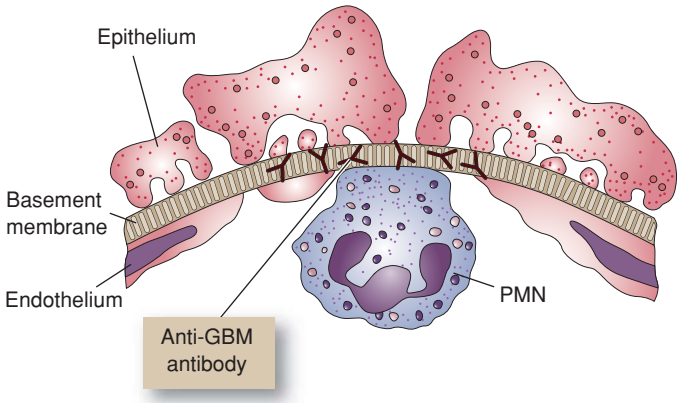

FIGURE 4-15. Goodpasture syndrome involves a type II hypersensitivity reaction in which antibody binds to a structural antigen, activates the complement system and leads to the recruitment of tissue-damaging inflammatory cells. Several complement-derived peptides (e.g., C5a) are potent chemotactic factors. *GBM* = glomerular basement membrane; *PMN* = polymorphonuclear leukocyte.

Immune Complex Reactions (Type III)

IgM, IgG and occasionally IgA against a circulating antigen that deposits or is planted in a tissue can cause a type III response. Physicochemical characteristics of the immune complexes, such as size, charge and solubility, in addition to Ig isotype, determine whether an immune complex deposits in tissue and fixes complement. "Phlogistic" (inflammatory) immune complexes elicit inflammatory responses by activating complement, thus recruiting neutrophils and monocytes. These activated phagocytes release tissue damage mediators, such as proteases and reactive oxygen species.

Immune complexes have been implicated in many human diseases. The most compelling cases are those in which demonstration of immune complexes in injured tissue correlates with development of injury. Examples include cryoglobulinemic vasculitis associated with hepatitis C infection, Henoch-Schönlein purpura (in which IgA deposits are found at sites of vasculitis) and systemic lupus erythematous (SLE) (anti–double-stranded DNA in vasculitic lesions). In many diseases, immune complexes can be detected in plasma but

are not associated with tissue injury. The physicochemical properties of circulating immune complexes frequently differ from those deposited in tissues. In some cases, vascular permeability may determine the localization of circulating immune complexes. Diseases that seem to be most clearly attributable to immune complex deposition are autoimmune diseases of connective tissue, such as SLE and rheumatoid arthritis, some types of vasculitis and many varieties of glomerulonephritis.

Serum sickness is an acute, self-limited disease that typically occurs 6–8 days after administration of a foreign protein or a compound that binds to and thus modifies a native protein. Human serum sickness is uncommon but can occur in patients given foreign proteins as a therapeutic agent (e.g., antilymphocyte globulin). It is characterized by fever, arthralgias, vasculitis and acute glomerulonephritis. In experimental acute serum sickness, serum levels of exogenously injected antigen remain constant until about day 6, after which they fall rapidly (Fig. 4-16). At the same time, immune complexes (containing IgM or IgG bound to antigen) appear in the circulation. Some circulating complexes deposit in tissues such as renal glomeruli and blood vessel walls. They are rendered more soluble by their interaction with the complement system, which enhances tissue deposition. Immune complexes fix complement, leading to generation of C3a and C5a, which increase vascular permeability.

Once phlogistic immune complexes are deposited in tissues, they trigger an inflammatory response. Local activation of complement by immune complexes results in formation of C5a, which is a potent neutrophil chemoattractant. Other neutrophil chemotactic mediators include leukotriene B_4 and IL-8. Neutrophil adherence and migration into sites of immune complex deposition involve a series of cytokine-mediated adhesive interactions (see Chapter 2). Several cytokines have been implicated in this response. Early production of IL-1 and TNF-α upregulates

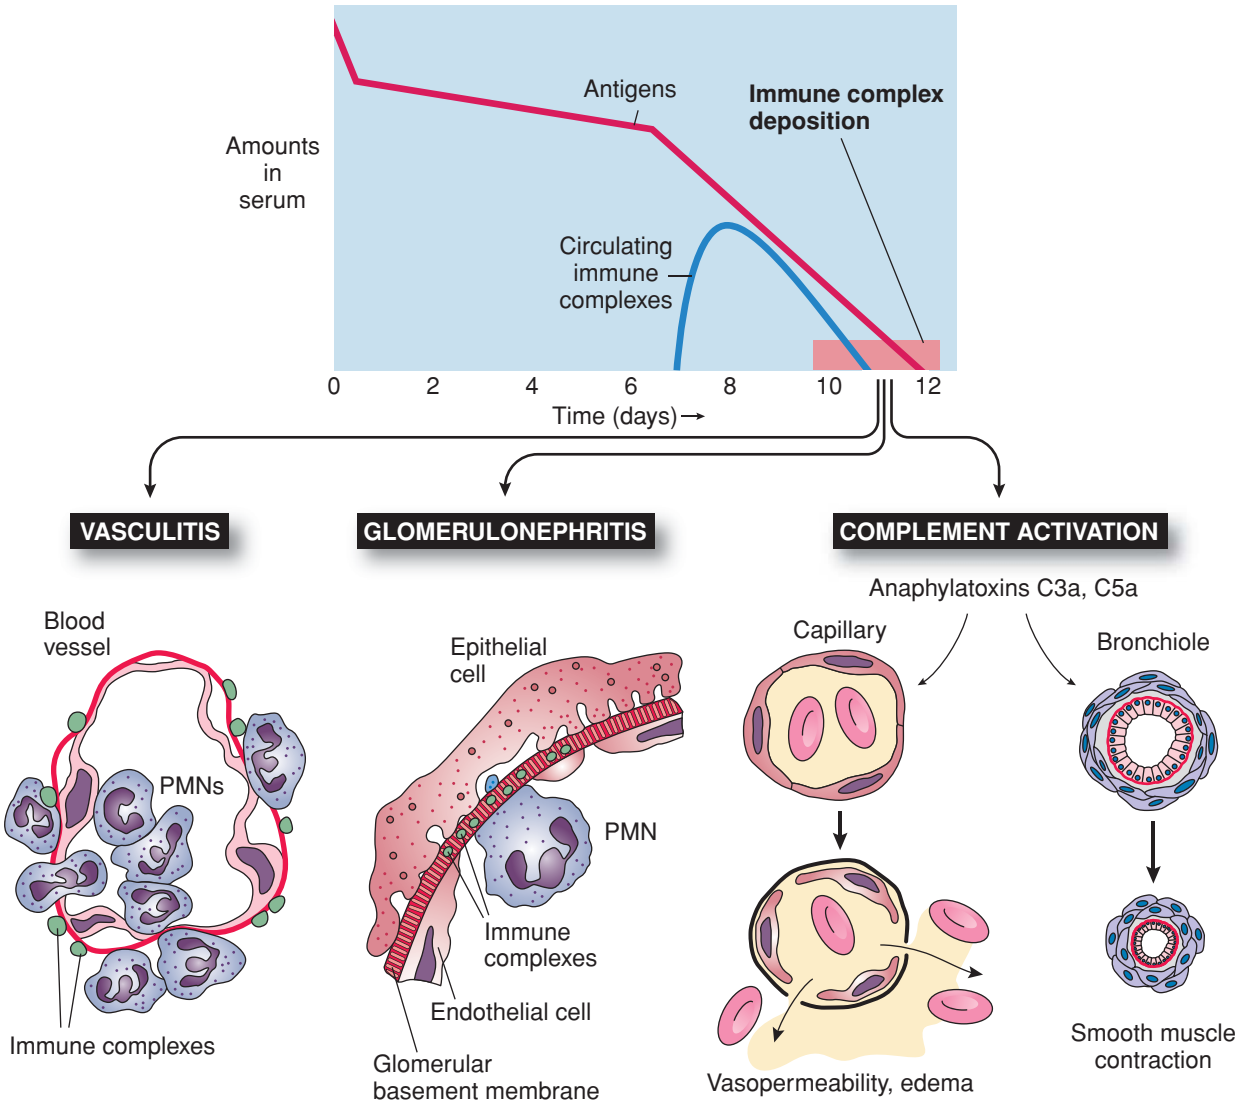

FIGURE 4-16. In type III hypersensitivity, immune complexes are deposited and can lead to complement activation and the recruitment of tissue-damaging inflammatory cells. This schematic illustrates the series of events that occur in acute serum sickness. The ability of immune complexes to mediate tissue injury depends on size, solubility, net charge and ability to fix complement. *PMN* = polymorphonuclear leukocyte.

adhesion molecules on endothelial cells and production of other proinflammatory cytokines that include platelet-derived growth factor (PDGF); transforming growth factor-β (TGF-β); and IL-4, IL-6 and IL-10, which modulate activation of leukocytes and fibroblasts. Not all cytokines are proinflammatory; IL-10, in particular, downregulates inflammatory responses.

Recruited neutrophils are activated through contact with, and ingestion of, immune complexes. Activated cells release inflammatory mediators, including proteases, reactive oxygen intermediates and arachidonic acid products, which collectively produce tissue injury. Tissue injury associated with experimental serum sickness mimics that seen in human vasculitis and glomerulonephritis.

The **Arthus reaction** has been studied using an experimental model of vasculitis in which localized injury is induced by immune complexes (Fig. 4-17). This reaction is classically seen in dermal blood vessels after local injection

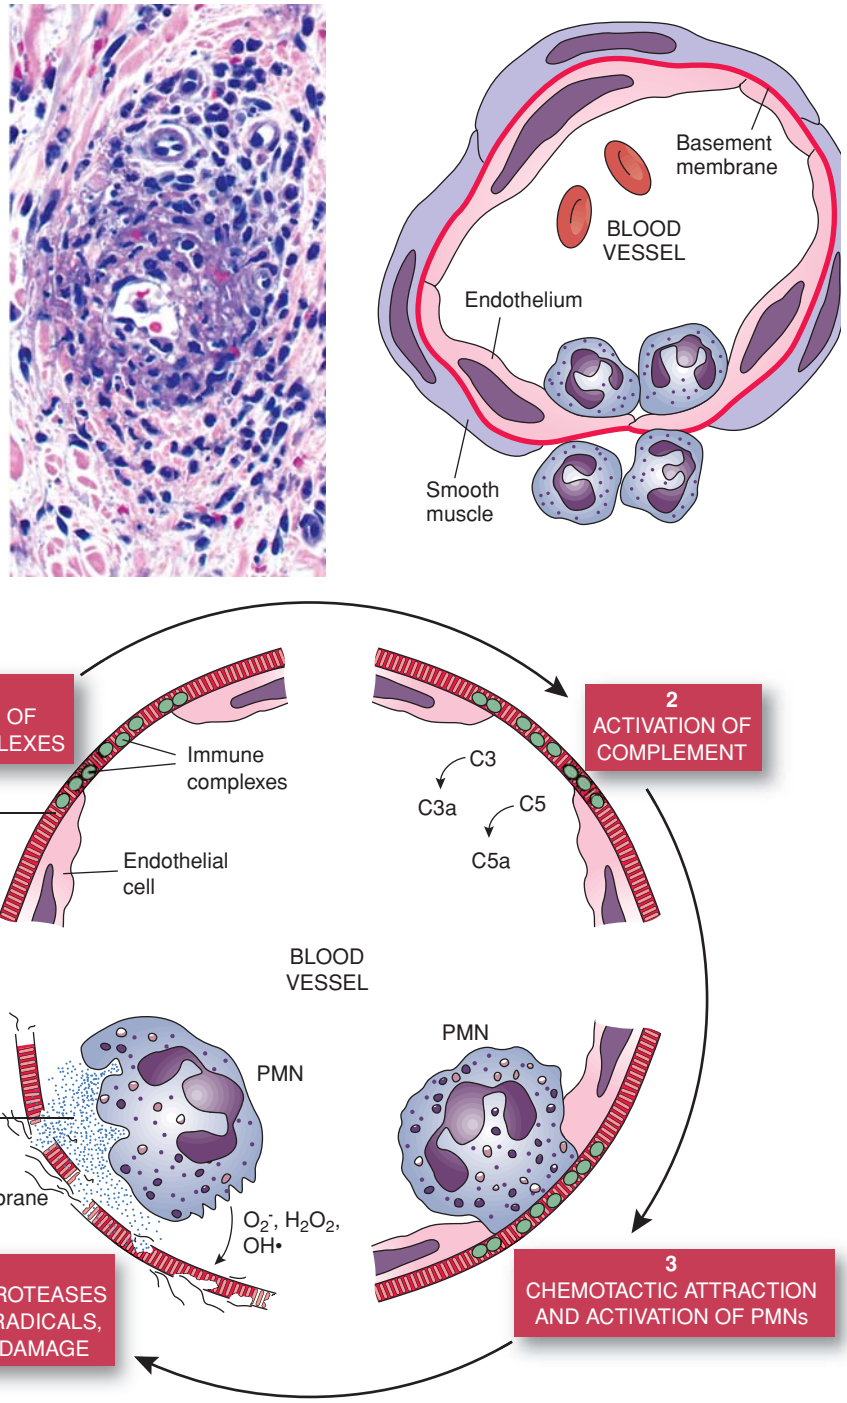

FIGURE 4-17. The Arthus reaction is a type III hypersensitivity reaction characterized by the deposition of immune complexes and the induction of an acute inflammatory response within blood vessel walls. Some vasculitic lesions exhibit fibrinoid necrosis. H_2O_2 = hydrogen peroxide; O_2^- = superoxide anion; $OH\bullet$ = hydroxyl radical; *PMN* = polymorphonuclear leukocyte.

of an antigen to which an individual was previously sensitized. The circulating antibody and locally injected antigen diffuse down concentration gradients toward each other to form complex deposits in walls of small blood vessels. Resulting vascular injury is mediated by complement activation, recruited neutrophils and their proinflammatory mediators. In contrast to type I (immediate) hypersensitivity, these lesions develop over a period of 2–10 hours. Walls of affected vessels contain numerous neutrophils and show evidence of damage, with edema and hemorrhage into surrounding tissue. The presence of fibrin creates the classic appearance of immune complex–induced vasculitis, namely, fibrinoid necrosis. This experimental model of localized vasculitis is a prototype for many forms of vasculitis seen in humans (e.g., cutaneous vasculitides that characterize certain drug reactions).

Type III hypersensitivity reactions are immune complex–mediated injuries. Antigen–antibody complexes may be formed either in the circulation and then deposited in the tissues, or in situ. Immune complexes fix complement, which leads to recruitment of neutrophils and monocytes. Activation of inflammatory cells by immune complexes and complement, with consequent release of potent inflammatory mediators, is directly responsible for injury (Fig. 4-17). Many human diseases, including autoimmune diseases such as SLE and many types of glomerulonephritis, are mediated by this mechanism.

Cell-Mediated Hypersensitivity Reactions (Type IV)

Type IV reactions often occur together with antibody reactions, which can make it difficult to distinguish them. The type of tissue response is largely determined by the nature of the inciting agent. *Classically, delayed-type hypersensitivity is a tissue reaction, mainly involving lymphocytes and mononuclear phagocytes, occurring in response to a soluble protein antigen and reaching peak intensity after 24–48 hours.* A classic type IV reaction is the contact sensitivity response to poison ivy. Although the chemical ligands in poison ivy (e.g., urushiol) are not proteins, they bind covalently to cell proteins, the products of which are recognized by antigen-specific lymphocytes.

In delayed-type hypersensitivity reactions (Fig. 4-18), foreign protein antigens or chemical ligands first interact with accessory cells that express class II HLA molecules (Fig. 4-18A). Accessory cells (macrophages, dendritic cells) secrete IL-12, which, along with processed and presented antigen, activate $CD4^+$ T cells (Fig. 4-18B). Activated $CD4^+$ T cells secrete IFN-γ and IL-2, which respectively activate more macrophages and elicit T-lymphocyte proliferation (Fig. 4-18C). Protein antigens are actively processed into short peptides within phagolysosomes of the macrophages and presented on the cell surface in conjunction with class II HLA molecules. Processed and presented antigens are recognized by MHC-restricted, antigen-specific $CD4^+$ T cells, which become activated and, as Th1 cells, synthesize various cytokines. In turn, the cytokines recruit and activate lymphocytes, monocytes, fibroblasts and other inflammatory cells. If the antigenic stimulus is eliminated, the reaction spontaneously resolves after about 48 hours. If the stimulus persists (e.g., poorly biodegradable mycobacterial cell wall components), an attempt to sequester the inciting agent may result in a granulomatous reaction.

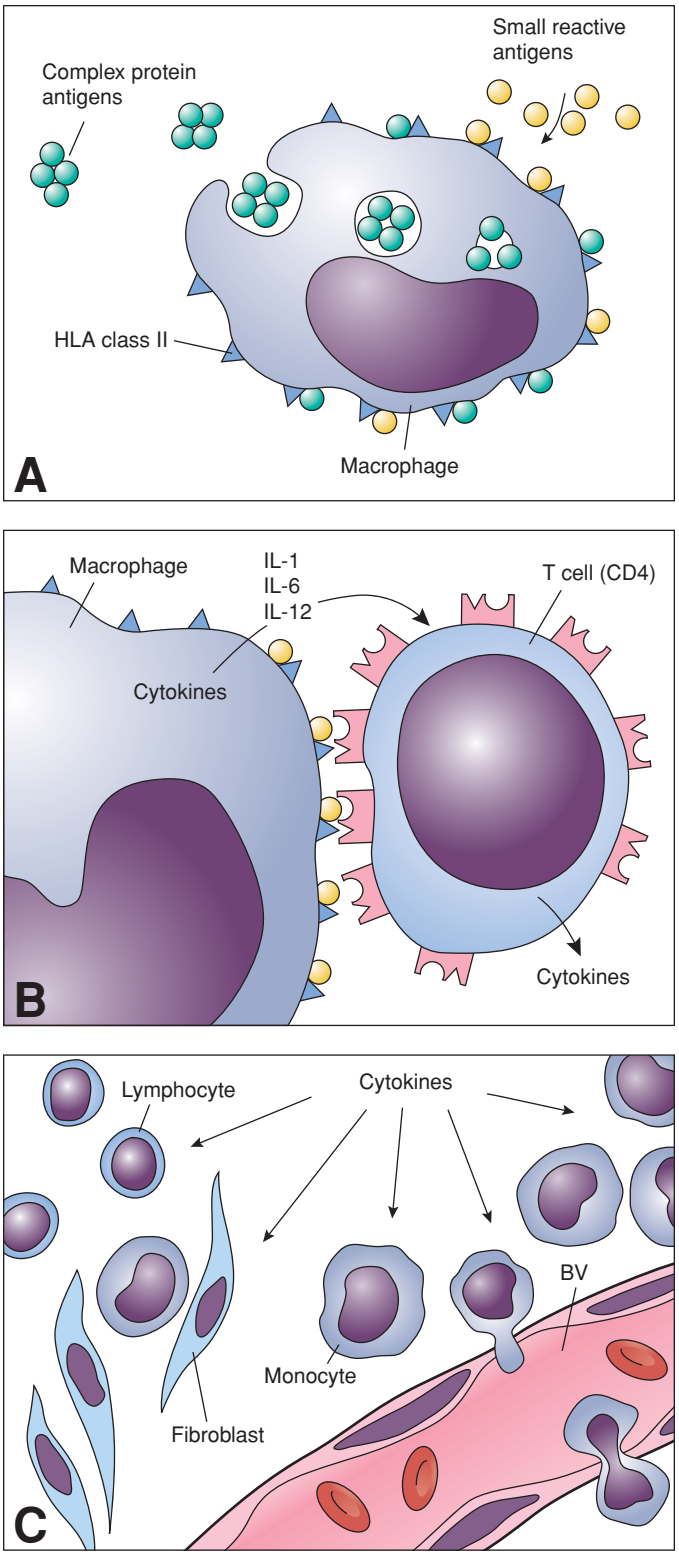

FIGURE 4-18. In a type IV (delayed-type) hypersensitivity reaction, complex antigens are phagocytized, processed and presented on macrophage cell membranes in conjunction with class II major histocompatibility complex (MHC) antigens. Antigens are in turn recognized via T-cell receptors (TCRs) expressed on histocompatible T lymphocytes. **A.** Antigen-specific, histocompatible, cytotoxic T lymphocytes bind presented antigens and are activated. **B, C.** Activated cytotoxic T cells secrete cytokines that amplify the response. *BV* = blood vessel.

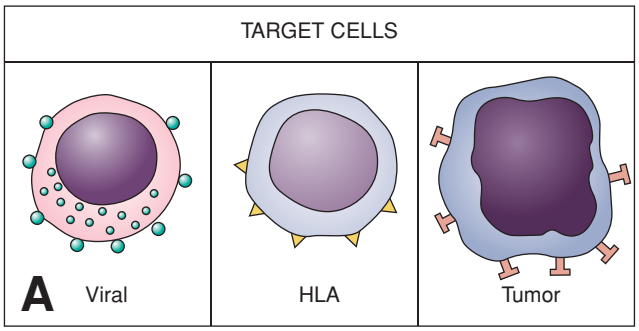
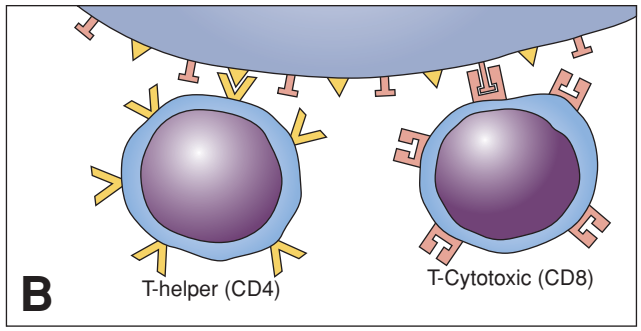
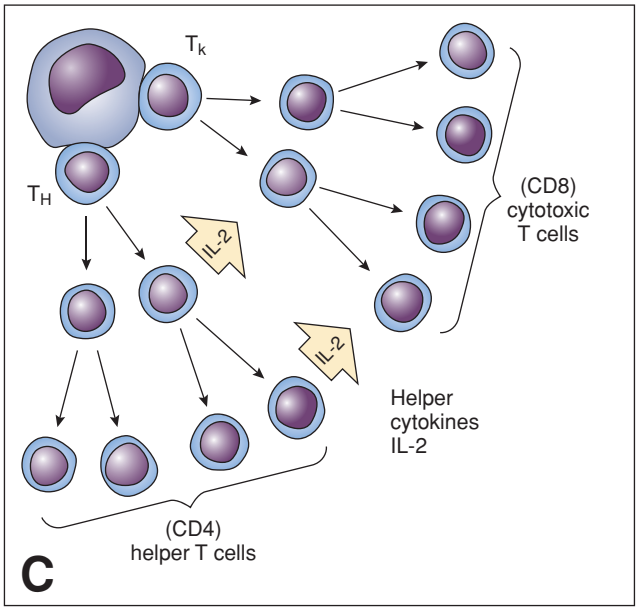


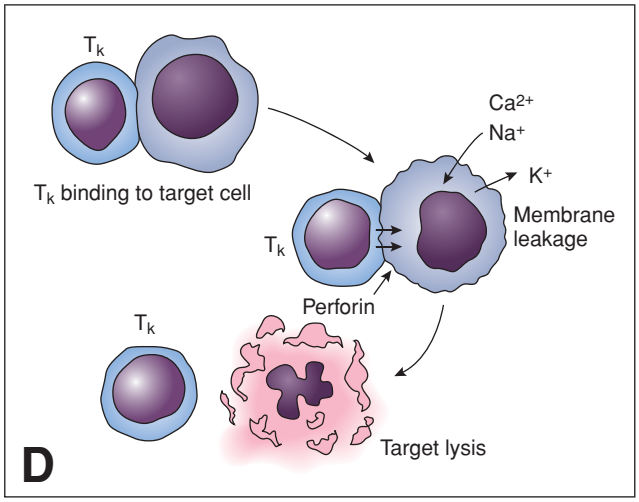
TARGET ANTIGENS
- Virally coded membrane antigen
- Foreign or modified histocompatibility antigen
- Tumor-specific membrane antigens



RECOGNITION OF ANTIGEN BY T CELLS
- T-helper cells recognize antigen plus class II molecules
- T-cytotoxic/killer cells recognize antigen plus class I molecules



ACTIVATION AND AMPLIFICATION
- T-helper cells activate and proliferate, releasing helper molecules (e.g., IL-2)
- T-cytotoxic/killer cells proliferate in response to helper molecules



TARGET CELL KILLING
- T-cytotoxic/killer cells bind to target cell
- Killing signals perforin release and target cell loses membrane integrity
- Target cell undergoes lysis

FIGURE 4-19. In T-cell–mediated cytotoxicity, potential target cells include (A) virus-infected host cells, malignant host cells and foreign (histoincompatible transplanted) cells. B. Cytotoxic T lymphocytes recognize foreign antigens in the context of human leukocyte antigen (HLA) class I molecules. **C.** Activated T cells secrete lytic compounds (e.g., perforin and other mediators) and cytokines that amplify the response. **D.** Apoptosis (target cell killing) is mediated by perforin and involves influx of Ca^{2+} (calcium ion) and Na^+ (sodium ion) and efflux of K^+ (potassium ion). *IL* = interleukin.

Another mechanism by which T cells (especially $CD8^+$) mediate tissue damage is direct lysis of target cells (Fig. 4-19). This mechanism is important in destroying and eliminating cells infected by viruses, transplanted tissues and, possibly, tumor cells.

In contrast to delayed-type hypersensitivity reactions, cytotoxic $CD8^+$ T cells specifically recognize target antigens in the context of class I MHC molecules. Foreign antigens are actively presented together with self-MHC antigens. In graft rejection, foreign MHC antigens are themselves potent activators of $CD8^+$ T cells. Once activated by antigen, cytotoxic cell proliferation is aided by helper cells and mediated by soluble growth factors such as IL-2 (Fig. 4-19C), and the population of antigen-specific cytotoxic cells thus expands. Cell killing occurs via several mechanisms (Fig. 4-19D; see also Chapter 1). Cytolytic T cells (CTLs) secrete perforins that form pores in target cell membranes and introduce granzymes that activate intracellular caspases, leading to apoptosis. CTLs can also kill targets by engaging Fas ligand (FasL, on the CTL) and Fas (on the target). FasL–Fas interaction triggers apoptosis of the Fas-bearing cell.

The defining characteristics of NK cells have been described, but the extent to which they participate in tissue-damaging reactions is unclear. Some evidence indicates that NK cells exert both effector and immunoregulatory functions. Fig. 4-20 illustrates target cell killing by an NK cell. NK

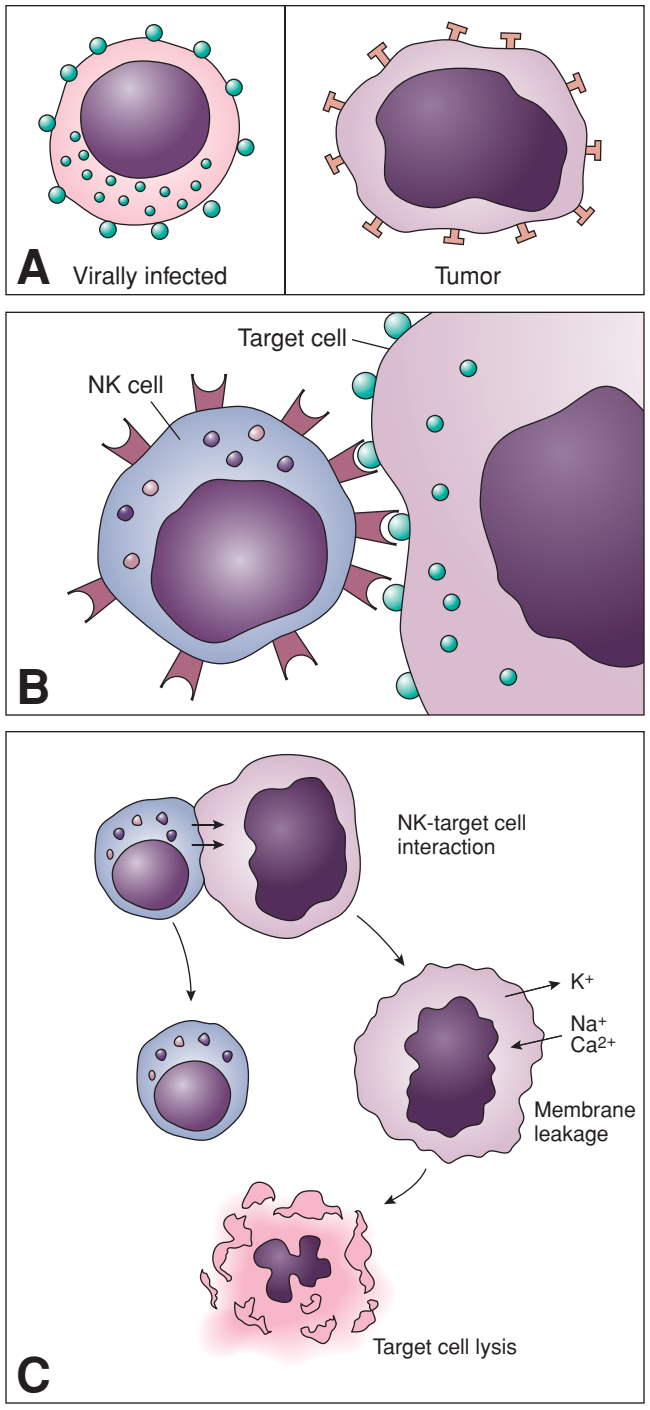


FIGURE 4-20. In natural killer (NK)-cell–mediated cytotoxicity, potential target cells include virus-infected and neoplastic cells. NK cells bind target cells **(A)**, are activated **(B)**, and secrete lytic compounds **(C)**. NK cells bind to target cells that express decreased numbers of surface human leukocyte antigen (HLA) class I molecules. Ca^{2+} = calcium ion; K^+ = potassium ion; Na^+ = sodium ion.

cells can recognize a variety of targets including membrane glycoproteins expressed by some virus-infected cells and tumor cells. Similar to events described for cytotoxic T cells, NK cells bind to target cells through membrane receptors and deliver molecular signals that result in lysis. NK cells also express membrane Fc receptors, which can bind antibodies that mediate cell killing by ADCC. NK cell activity is influenced by a variety of mediators. For example, it is increased by IL-2, IL-12 and IFN-γ and decreased by several prostaglandins.

In type IV hypersensitivity reactions, antigens are processed by macrophages and presented to antigen-specific T lymphocytes. These lymphocytes become activated and release mediators that recruit and activate lymphocytes, macrophages and fibroblasts. Injury is caused by T cells, macrophages or both. No antibodies are involved. Chronic inflammation associated with autoimmune diseases—including type 1 diabetes, chronic thyroiditis, Sjögren syndrome and primary biliary cirrhosis—is largely the result of type IV hypersensitivity.

IMMUNODEFICIENCY DISEASES

Immunodeficiency diseases are classified as congenital (primary) or acquired (secondary), and by defective host defense system. The former are genetically determined. **Primary immunodeficiencies are classified as B cell or humoral, T cell or cellular, defects of phagocytes or abnormalities of the complement system.** This scheme is useful, but it should be recognized that a primary defect within one aspect of the immune system may have farther-reaching effects. Complement deficiencies are associated with recurrent and/or severe bacterial infections (encapsulated pyogens and *Neisseria*) as well as lupus-like disorders. Phagocyte defects are generally associated with cutaneous, soft tissue and visceral bacterial and fungal infections. Disorders of complement and primary defects of phagocytes are discussed in detail elsewhere (see Chapter 2). In contrast to the low prevalence of congenital immunodeficiencies, acquired immune deficits, like AIDS, are common.

Functional defects in lymphocytes can be localized to particular stages in the ontogeny of the immune system, or the interruption of discrete immune activation events (Fig. 4-21). A detailed classification scheme for primary immunodeficiency disorders is available via the WHO.

People with Antibody Deficiency Diseases Are Inordinately Susceptible to Recurrent Bacterial Infections

Several specific types of viral infections may also occur (e.g., central nervous system [CNS] echovirus infections in patients with Bruton agammaglobulinemia) and subnormal serum concentrations of either all or specific isotypes of Igs. There are a variety of immunoglobulin isotype and subclass deficiencies including selective deletions of immunoglobulin heavy chains and selective loss of light-chain expression (Table 4-5). Some patients have normal immunoglobulin levels but fail to make antibodies against specific antigens, usually polysaccharides. The clinical manifestations of these entities are highly variable; some patients suffer from life-threatening bacterial infections, varying from meningitis to mucosal infections, while other patients are asymptomatic.

Bruton X-Linked Agammaglobulinemia

Bruton X-linked agammaglobulinemia (XLA) often presents in boys younger than 1 year old, when protective maternal antibody levels have declined. Up to 10% of XLA patients do

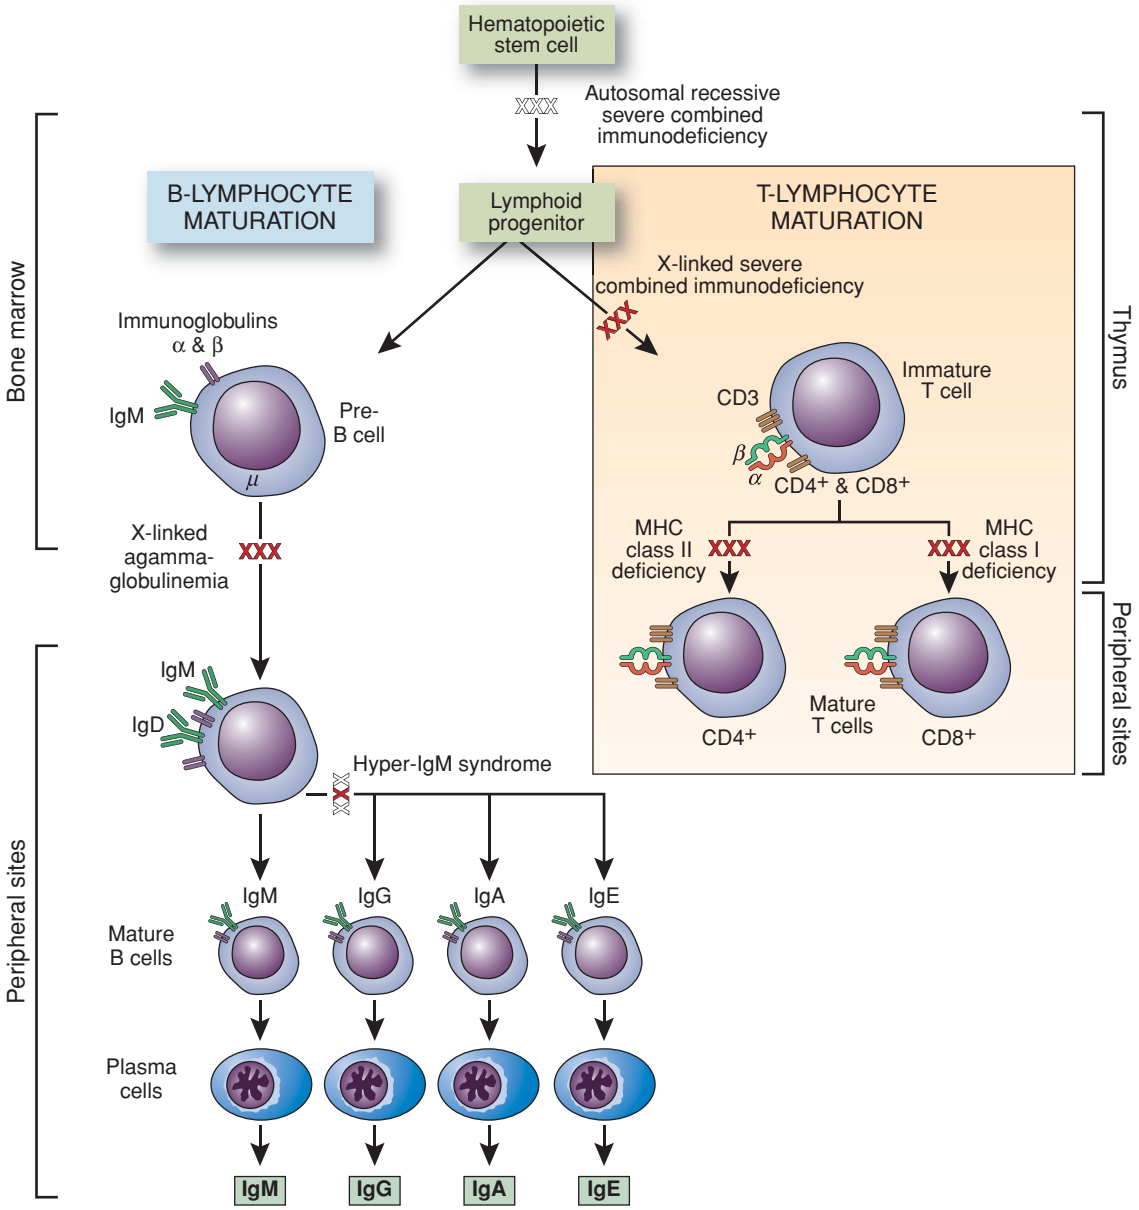

FIGURE 4-21. Hematopoietic stem cells give rise to lymphoid progenitor cells that, in a predetermined manner, populate either the bone marrow or thymus. More than 100 primary immunodeficiency disorders have been characterized at the genetic and/or molecular levels. In a number of immunodeficiency disorders, a discrete molecular defect results in a form of "maturational arrest" in the development of fully differentiated and functional lymphocytes. The identification of specific molecular lesions has hastened diagnostic evaluation and mechanistic understanding.

not present until they are teenagers, and recent studies suggest that perhaps 10% of adults diagnosed with "common variable immunodeficiency (CVID)" (see below) actually have XLA. Patients develop recurrent infections of mucosal surfaces (e.g., sinusitis, bronchitis), pyoderma, meningitis and septicemia. Severe hypogammaglobulinemia involves all Ig isotypes. Some patients develop viral hepatitis or chronic enterovirus infections of the CNS or large joints. Immunization with live attenuated poliovirus can lead to paralytic poliomyelitis. About 1/3 of XLA patients suffer from a poorly understood form of arthritis, possibly caused by enteroviruses or *Ureaplasma*.

There are no mature B cells in peripheral blood or plasma cells in lymphoid tissues. Pre-B cells, however, can be detected. The genetic defect, on the long arm of the X chromosomes (Xq21.22), inactivates the gene for B-cell tyrosine kinase (Bruton tyrosine kinase), an enzyme critical to B-lymphocyte maturation (Table 4-5).

Selective IgA Deficiency

This is the most common primary immunodeficiency syndrome. It is characterized by normal serum levels of IgM and IgG and low serum (<7 mg/dL) and secretory concentrations of IgA. Incidence ranges from 1:18,000 in Japan to 1:400 among northern Europeans. Patients are often asymptomatic but may present with chronic or recurrent respiratory or gastrointestinal infections. They often develop allergies,

TABLE 4-5
PRIMARY HUMORAL IMMUNODEFICIENCY DISORDERS

Disease	Mode of Inheritance	Locus/Gene
Agammaglobulinemia	XL	Xq21.3/BTK
Selective Antibody Class/Subclass Deficiencies

Common Variable Immunodeficiency	Varied	—

AR = autosomal recessive; *BTK* = Bruton tyrosine kinase; Ig = immunoglobulin; XL = X-linked.

autoimmune diseases and collagen vascular disorders and are at risk for allergic, occasionally anaphylactic, reactions to IgA-containing transfused blood products.

Patients with IgA deficiency have peripheral blood B cells that coexpress IgA, IgM and IgD; their varied and poorly understood defects result in an inability to synthesize and secrete IgA (Table 4-5). There may be a common origin with CVID (see below). Some cases have been associated with drug exposures (e.g., phenytoin, D-penicillamine) and some with deletions or defects in chromosome 18. Patients with concomitant IgG subclass deficiencies are more likely to be clinically affected.

Common Variable Immunodeficiency

CVID is a heterogenous group of disorders with severe hypogammaglobulinemia and attendant infections (Table 4-5), apparently due to a variety of defects in B-lymphocyte maturation or T cells that regulate B-lymphocyte maturation. Some relatives of patients with CVID have selective IgA deficiency. Affected patients present with recurrent severe pyogenic infections, especially pneumonia and diarrhea, the latter often due to infection with *Giardia lamblia*. Recurrent attacks of herpes simplex virus are common; herpes zoster develops in 1/5 of patients. CVID appears years to decades after birth, with a mean age at onset of 25 years. It occurs in between 1:50,000 and 1:200,000 people. Inheritance patterns vary. CVID features several maturational and regulatory defects of the immune system. Cancers are increased in CVID, including a 50-fold greater incidence of gastric cancer. Interestingly, lymphoma is 300 times more common in women with this disease than in affected men. Malabsorption due to lymphoid hyperplasia and inflammatory bowel diseases occurs more frequently than in the general population. Patients are also more susceptible to other autoimmune disorders, including hemolytic anemia, neutropenia, thrombocytopenia and pernicious anemia.

Transient Hypogammaglobulinemia of Infancy

In infants with this disease, prolonged hypogammaglobulinemia occurs once maternal antibodies reach their nadir. Some affected children develop recurrent infections and require therapy, but all eventually produce antibodies. The infants have mature B cells that are temporarily unable to produce antibodies. The defect is not well understood but may represent delayed helper T-cell signal-generating capacity.

Hyper-IgM Syndrome

Hyper-IgM (HIM) syndrome is often classified as a humoral immunodeficiency because Ig production is disordered. Patients have subnormal IgG, IgA and IgE levels and elevated IgM concentrations. There is an X-linked form that results from defects in CD40 ligand (type 1 hyper-IgM) and an autosomal recessive form due to defects in CD40 (type 3 hyper-IgM). Infants with X-linked disease suffer pyogenic and opportunistic infections, especially with *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*), and also tend to develop autoimmune diseases involving the formed elements of blood, especially autoimmune hemolytic anemia, thrombocytopenic purpura and recurrent, severe neutropenia.

Circulating B cells bear only IgM and IgD. The "switch" to other heavy-chain isotypes from IgD/IgM is defective. Interaction of CD40 receptor on B-cell membranes with CD40 ligand is required for isotype switching (Fig. 4-21).

T-Cell Immunodeficiencies Are Often Part of a Constellation of Abnormalities

DiGeorge Syndrome

In its complete form, DiGeorge syndrome is a severe T-cell immunodeficiency disorder in which serum Igs are reduced due to lack of T-helper activity. Although variable, some infants present with conotruncal great vessel and cardiac defects and severe hypocalcemia (due to hypoparathyroidism). Others show characteristically abnormal facial features. Infants who survive the neonatal period are subject to recurrent and/or chronic viral, bacterial, fungal and protozoal infections.

DiGeorge syndrome is caused by defective development of the third and fourth pharyngeal pouches, which give rise to thymic epithelium and parathyroid glands and influence conotruncal cardiac development. Most patients have a deletion in the long arm of chromosome 22; thus, DiGeorge syndrome is considered to be a form of the "22q11 deletion syndrome." In the absence of functional thymus, T-cell maturation is interrupted at the pre–T-cell stage. The immunologic defect has been corrected by transplanting thymic tissue. Most affected patients have "partial" DiGeorge syndrome, in which a small remnant of thymus is present. With time, many individuals recover T-cell function without

treatment. Some individuals with 22q11 mutations suffer only from conotruncal cardiac defects.

Chronic Mucocutaneous Candidiasis

This disease results from impaired T-cell function and is characterized by susceptibility to candidal infections and endocrinopathy (hypoparathyroidism, Addison disease, diabetes mellitus). Most T-cell functions are intact, but the response to *Candida* antigens is deficient.

A series of defects in T-cell development underlie this syndrome. Patients with this disorder react to *Candida* antigens differently from normal individuals. Unlike normal responses in which Th1 (IL-2/IFN-γ) cells predominate and effectively control candidal infections, affected patients mount a Th2 (IL-4/IL-6) helper cell response, which is ineffective in resisting the organism.

Combined Immunodeficiency Diseases Vary in Severity

Severe combined immunodeficiencies are conspicuously heterogenous and are often life-threatening (Table 4-6).

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) encompasses over 20 disorders associated by deficiencies in T-cell and B-cell development and function. Affected patients present in the first few months of life with recurrent, often severe infections, diarrhea and failure to thrive. Some forms of SCID have nonimmunologic developmental defects. SCID is usually fatal within the first year of life unless an immune system can be provided by HSC transplantation.

SCID is consistently marked by defective T-cell development and/or function. In some types, B-cell development is also affected. Since B cells require T-cell–derived signals for optimal antibody production, most patients have defective cellular and humoral immunity. NK-cell development and function are variably affected. Current classifications of SCID include several categories (Table 4-6).

The most common form of SCID in the United States (50% of cases) is due to mutations within *IL2RG; IL2RG* encodes the cytokine receptor common γ-chain, which is shared by receptors for IL-2, IL-4, IL-7, IL-9, IL-15 and IL-21. Defects result in complete absence of T cells and NK cells (90% of cases) but normal numbers of B cells. Immunoglobulin production is severely impaired because of the T-cell defect. Signaling downstream of the IL receptors with the common γ-chain requires activation of JAK3 tyrosine kinase (Janus kinase 3). Not surprisingly, T–/–B+/–NK– SCID patients with mutations in *JAK3* have been identified.

MOLECULAR PATHOGENESIS: More than a dozen molecular lesions have been described in T–/–B+/–NK+ SCID patients. For instance, mutations in genes (*CD3D, CD3E, CD3G*) that encode each subunit (δ, ε, γ) of the TCR-associated CD3 complex have been described. These patients all show defects in T-lymphocyte function, but clinical features have varied. Another group of

TABLE 4-6
SEVERE COMBINED IMMUNODEFICIENCY (SCID): MOLECULAR LESIONS[a]

Disease	Locus/Gene
T–/–B+/–NK–/–	
IL2RG	Cytokine receptor common γ-chain
JAK3	Tyrosine kinase JAK3
T–/–B+/–NK+/–	
CD3D	CD3 complex, δ subunit
CD3E	CD3 complex, ε subunit
CD3G	CD3 complex, γ subunit
CIITA	MHC class II transactivator
RFXANK	MHC class II transactivator
FRX5	MHC class II transactivator
RXAP	MHC class II transactivator
ZAP70	TCR-associated protein of 70 kd
TAP1	Transporter-associated antigen processing 1
TAP2	Transporter-associated antigen processing 2
T–/–B–/–NK–/–	
ADA	Adenosine deaminase
PNP	Purine nucleoside phosphoacylase
T–/–B–/–NK+/–	
RAG1	Recombinase-activating gene 1
RAG2	Recombinase-activating gene 2

[a]This is a partial list of SCID disorders.
MHC = major histocompatibility complex; TCR = T-cell receptor.

T–/–B+/–NK+ SCID patients lack $CD4^+$ T cells in association with various defects in expression of MHC class II molecules. Yet another group of T–/–B+/–NK+ SCID patients are deficient in $CD8^+$ T cells. Among this group of patients, mutations in *ZAP70, TAP1* and *TAP2* have been described. *ZAP70* (TCR-associated protein of 70 kd) is a tyrosine kinase involved in TCR signaling; *TAP1* and *TAP2* are required for shuttling of cytosolic peptide onto naive HLA class I molecules for subsequent presentation to TCRs.

Mutations in the genes for enzymes in the purine nucleotide salvage pathway, adenosine deaminase (*ADA*) and purine nucleoside phosphorylase (*PNP*), result in T–/–B–/–NK– SCID. Accumulation of toxic purine metabolites leads to death of immature, proliferating lymphocytes (and other cell types). ADA deficiency accounts for 15% of all SCID patients in the United States. PNP deficiency is very rare.

Rare patients with T–/–B–/–NK+ SCID possess mutations within genes for DNA-binding proteins involved in

Ig and TCR gene rearrangement. Some patients suffer from radiation sensitivity in addition to immunodeficiency.

Molecular lesions are identified in approximately 95% of patients with SCID, suggesting that additional molecular lesions account for the remaining 5%.

AUTOIMMUNITY

The Occurrence of Autoimmune Disease Implies That the Immune System Fails to Discriminate Adequately between Self and Nonself

Once considered an abnormal response that invariably caused disease, autoimmunity is in fact a physiologic process that helps regulate the immune system. When "normal" regulatory mechanisms are in some way disrupted, uncontrolled autoantibody production or abnormal cell–cell recognition leads to tissue injury and autoimmune disease. Specific autoantibodies may be present and useful in diagnosing autoimmune diseases, but in order to conclude causality, an autoimmune reaction (humoral or cellular) must be integral to the disease process. Autoimmune diseases may be organ specific or generalized. Relatively few diseases (e.g., Hashimoto thyroiditis, type 1 diabetes, SLE) clearly fit this rigorous criterion.

Immune tolerance occurs when there is no measurable (or clinically deleterious) immune response to specific (usually self) antigen. An abnormal or injurious autoimmune response to self-antigens implies loss of immune tolerance. Tolerance to self-antigens appears to be an active process and requires contact between self-antigens and immune cells. In fetal life, tolerance is readily established to antigens that trigger vigorous immune responses in adults. Several mechanisms induce and maintain tolerance, actively and continuously. Thus, in tolerance, potentially harmful immune responses are constantly blocked or aborted. Induction of tolerance to an antigen is partly related to the dose of antigen to which cells are exposed.

Central and peripheral mechanisms both participate. In **central tolerance,** self-reactive immature T and B lymphocytes are "deleted" or changed during their maturation in the "central" thymus and bone marrow, respectively. Developing T cells that recognize self-peptides in the context of compatible MHC molecules with high binding affinity undergo apoptosis. These T cells are said to have been "negatively selected." The AIRE protein (autoimmune regulator) is involved in expression of peripheral tissue-restricted self-antigens within the thymus, and so is important in central expression of peripheral self-antigens to which the individual becomes tolerant. Mutations in *AIRE* cause an autoimmune polyendocrinopathy.

In the bone marrow, a similar negative selection process involves B cells. In addition, engagement of self-antigens by developing marrow B cells can reset antigen receptor gene rearrangement through a process called "receptor editing." These reprogrammed B cells thus do not recognize self. $CD4^+$ regulatory T cells also develop. **Peripheral tolerance** is important in regulating T cells that escape intrathymic negative selection. Mature T lymphocytes are held in check in the periphery via **anergy,** suppression and/or activation-induced cell death. Anergy occurs when T lymphocytes bind antigen presented by APCs in the absence of the "second signal," which is normally provided by CD80/B7-1 and CD86/B7-2 on the APC and CD28 on the T cell. Downstream T-cell inactivation/unresponsiveness (anergy) is mediated by at least two mechanisms. Immune responses are suppressed by the population of regulatory T cells (T_{reg}, noted above) generated in response to exposure to self-antigens. These T_{reg}s are $CD4^+$, constitutively express CD25 (β-chain of high-affinity IL-2 receptor) and express FOXp3 transcription factor. Mutations and polymorphisms affecting *CD25*, IL-2 or FOXp3 result in autoimmune disorders. Finally, $CD4^+$ T cells and self-reactive B cells can be deleted by several activation-initiated mechanisms.

Theories of Autoimmunity

There are multiple explanations for the development of autoimmune disease, which are not mutually exclusive.

Inaccessible Self-Antigens

An immune reaction may develop against self-antigens not normally "accessible" to the immune system. Intracellular antigens are generally not exposed or released until infection and/or tissue injury "releases" or "exposes" them. At that time, an immune response develops (e.g., antibodies against spermatozoa, lens tissue and myelin). Whether such autoantibodies directly induce injury is another matter. For example, there is no evidence that antisperm antibodies induce generalized injury, aside from a localized orchitis. Thus, autoantibodies may form against normally "sequestered" antigens but appear to be pathogenic infrequently.

Abnormal T-Cell Function

Autoimmune reactions may develop due to T-cell abnormalities. As noted above, several mutations and/or polymorphisms are linked to autoimmune disease. Altered numbers or functional activities of helper or suppressor T cells could thus influence one's ability to mount an immune response. Defects, particularly in suppressor T cells, occur in many autoimmune diseases (see above). Lymphocytotropic antibodies also occur in patients with SLE. Abnormal suppressor T-cell function characterizes other autoimmune diseases, including primary biliary cirrhosis, thyroiditis, multiple sclerosis, myasthenia gravis, rheumatoid arthritis and scleroderma. The key question is whether these alterations in suppressor T-cell function cause these diseases or are epiphenomena. Defects in suppressor T-cell activity also occur in people who do not have any evidence of autoimmune disease.

Helper T cells are defined by their role in antigen-specific B-cell activation, and their function may also be abnormal in autoimmune disease. Helper T-cell tolerance is most likely induced by low doses of antigen. These cells become autoreactive in autoimmune diseases.

Epigenetic modulation, as in DNA hypomethylation caused by drugs and other agents, is a type of environmentally influenced upregulation of leukocyte function antigen-1 (LFA-1) and B-cell activation and is independent of antigen. An example of T-cell autoreactivity and loss of antigen specificity is drug-induced lupus. It is also possible to "break" tolerance by altering an antigen, so that helper cells are activated and trigger B cells. This occurs when an antigen is modified by partial degradation or by complexing with a carrier protein. In some rheumatic diseases, antibodies

recognize partially degraded connective tissue proteins such as collagen or elastin. In some drug-induced hemolytic anemias, antibody against the drug causes hemolysis when the drug binds to erythrocyte membranes.

Molecular Mimicry

Helper T-cell tolerance may also be overcome if foreign antigens elicit antibodies that cross-react with self-antigens. In this case, helper T cells act "correctly": they do not induce autoantibodies. Rather, the efferent limb of the immune response is abnormal. Thus, in rheumatic heart disease, antibodies against streptococcal bacterial antigens cross-react with antigens from cardiac muscle, which is called **molecular mimicry**.

Polyclonal B-Cell Activation

In polyclonal B-cell activation, B lymphocytes are directly activated by complex substances that contain many antigenic sites (e.g., bacterial cell walls and viruses). Bacterial, viral and parasitic infections may thus stimulate development of rheumatoid factor in rheumatoid arthritis, anti-DNA antibodies in SLE and other autoantibodies. Such scattergun stimulation of antibody responses may also lead to autoantibodies.

Tissue Injury in Autoimmune Diseases

Autoimmune diseases have traditionally been considered to be prototypical immune complex diseases, with immune complexes forming in the circulation or in tissues. Thus, type II (cytotoxic) and type III (immune complex) hypersensitivity reactions are implicated in tissue injury in many. These hypersensitivity reactions explain most autoimmune tissue injury, but of course the story is more complicated. In some autoimmune diseases, T cells sensitized to self-antigens (such as thyroglobulin) cause tissue injury directly (type IV reaction), but the extent is not clear.

In addition, in ADCC, antibodies against an antigen expressed at the cell membrane lead to destruction of that cell. Thus, antibodies against parietal cell H^+/K^+-ATPase contribute to the pathogenesis of atrophic gastritis. However, many people have antiparietal cell antibodies but not gastritis.

Not all autoantibodies cause disease via cytotoxicity. In **antireceptor antibody diseases,** such as Graves disease and myasthenia gravis, antibody binds a receptor but the disease process reflects either activation or inactivation of the receptor, rather than cell loss. In Graves disease, autoantibody against the TSH receptor acts as an agonist to simulate thyroid hormone production, while in myasthenia gravis the autoantibody either prevents acetylcholine binding to its receptor or leads to damage of the receptor, thereby impairing neuromuscular synaptic transmission. Anti-insulin receptor antibodies in acanthosis nigricans and ataxia telangiectasia cause some patients to develop diabetes that entails extreme insulin resistance.

Type III hypersensitivity reactions (immune complex disease) explain tissue injury in some autoimmune diseases (e.g., SLE). DNA–anti-DNA complexes formed in the circulation (or at local sites) deposit in tissues, where they induce inflammation and injury (e.g., vasculitis, glomerulonephritis). Similarly, rheumatoid arthritis, scleroderma, polymyositis/dermatomyositis and Sjögren syndrome are all characterized by immune phenomena and classified as "collagen vascular diseases" (see Chapter 11). Their clinical manifestations are systemic, and many organs and tissues are typically involved. By contrast, cytotoxic (type II–mediated) autoimmune reactions are, for the most part, organ specific.

TRANSPLANTATION IMMUNOLOGY

Donor MHC-encoded antigens are immunogenic molecules that can stimulate rejection of transplanted tissues. Optimal graft survival occurs when recipient and donor are closely matched for histocompatibility antigens. In practice, an exact HLA match is uncommon, except between monozygotic twins. Thus, immunosuppressive therapy and vigilant monitoring of graft function are required after organ transplantation. Therapeutic advances have greatly improved transplant success rates, even when there is a degree of histoincompatibility. When host-versus-graft immune reactions (rejection) occur, a combination of immune mechanisms may injure the graft.

Both T-cell–mediated and antibody-mediated reactions participate in transplant rejection. Within the graft, antigen-presenting cells, specifically those bearing foreign MHC molecules, are recognized by host $CD8^+$ cytotoxic T lymphocytes, which mediate tissue injury, and host $CD4^+$ T helper cells, which augment antibody production, induce IFN-γ production and activate macrophages. In turn, IFN-γ enhances MHC expression, amplifying the immune response and resulting tissue injury. Host APCs also process foreign donor antigens, leading to $CD4^+$-mediated delayed-type hypersensitivity and $CD4^+$-mediated antibody production.

Solid organ transplant rejection reactions are usually categorized as "hyperacute," "acute" and "chronic" based on the clinical tempo of the response and pathophysiologic mechanism involved. However, in practice, features often overlap, creating diagnostic ambiguity. Categorization of transplant rejection is further complicated by the toxicity of immunosuppressive drugs, the potential for mechanical problems (e.g., vascular thrombosis) and recurrence of original disease (e.g., some types of glomerulonephritis). The next sections illustrate rejection in the context of renal transplantation. Similar responses occur in other transplanted tissues, although rejection as applied to each tissue type has its own unique features.

Hyperacute Rejection Is a Sudden Reaction That Occurs within Minutes of Transplantation

Hyperacute rejection of a kidney may be so rapid as to occur intraoperatively and manifests as a sudden cessation of urine output, darkening of the graft and rapid development of fever and pain at the graft site. This form of rejection is mediated by preformed anti-HLA antibodies and complement activation products, including chemotactic and other inflammatory mediators. Hyperacute rejection is catastrophic, necessitating prompt surgical removal of the grafted kidney. Histologic features include vascular congestion, fibrin–platelet thrombi within capillaries, neutrophilic vasculitis with fibrinoid necrosis, prominent interstitial edema and neutrophil infiltrates (Fig. 4-22A). Fortunately, hyperacute rejection is distinctly uncommon when appropriate pretransplantation antibody screening has been performed.

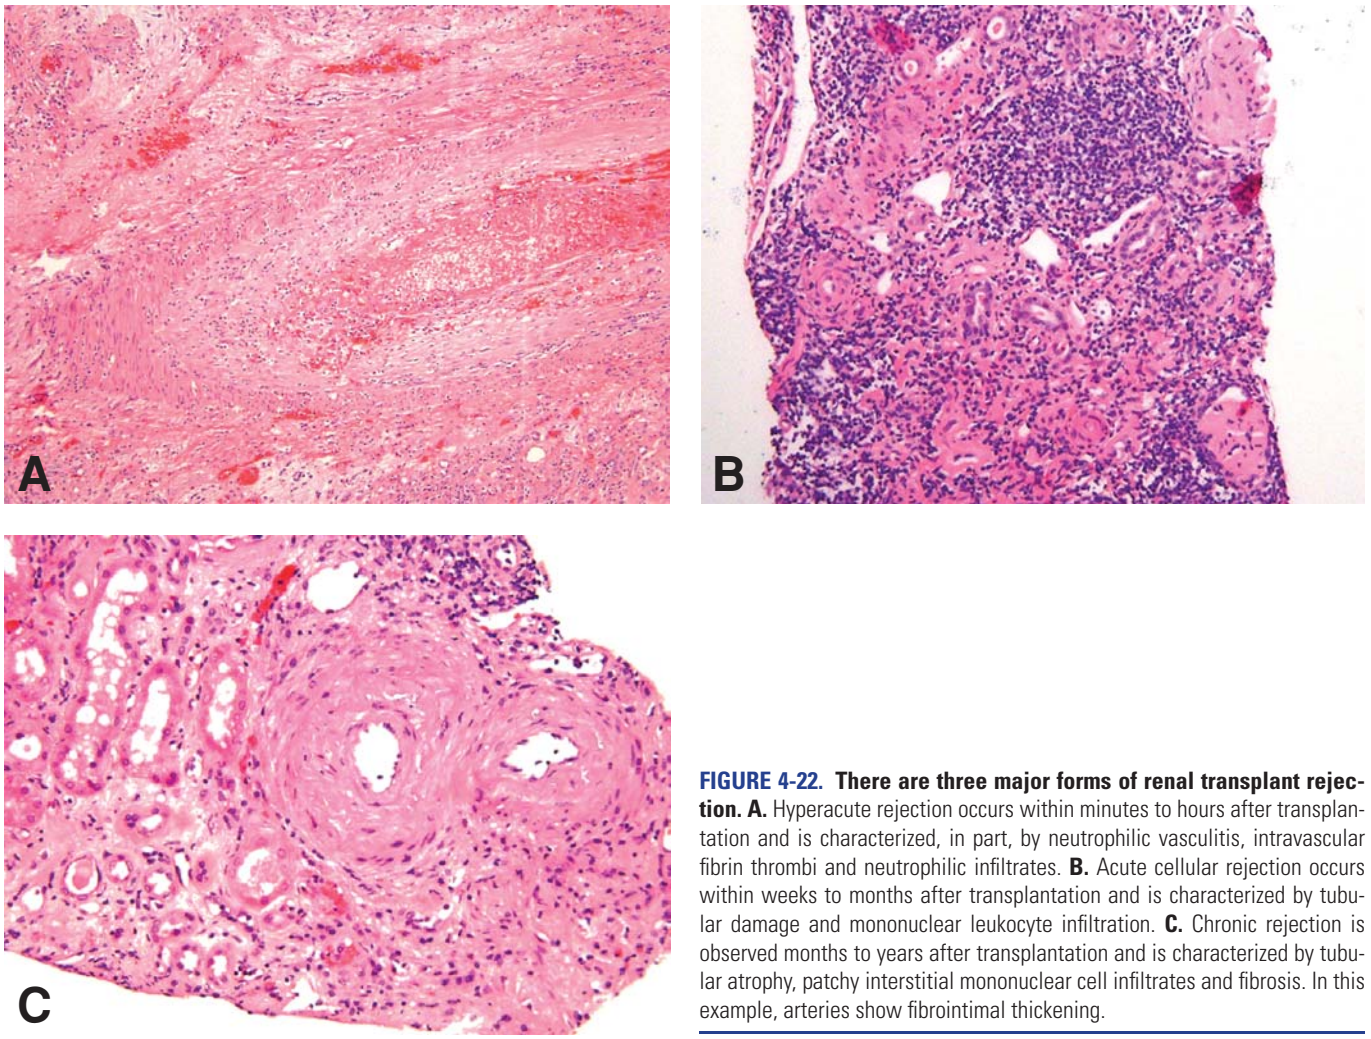

FIGURE 4-22. There are three major forms of renal transplant rejection. A. Hyperacute rejection occurs within minutes to hours after transplantation and is characterized, in part, by neutrophilic vasculitis, intravascular fibrin thrombi and neutrophilic infiltrates. **B.** Acute cellular rejection occurs within weeks to months after transplantation and is characterized by tubular damage and mononuclear leukocyte infiltration. **C.** Chronic rejection is observed months to years after transplantation and is characterized by tubular atrophy, patchy interstitial mononuclear cell infiltrates and fibrosis. In this example, arteries show fibrointimal thickening.

Acute Rejection Usually Occurs Weeks to Months after Organ Transplantation

It is characterized by the abrupt onset of azotemia and oliguria, which may be associated with fever and graft tenderness. Acute rejection typically involves both cell-mediated and humoral mechanisms of tissue damage. If detected early, acute rejection can be reversed with immunosuppressive therapy. Needle biopsy is often needed to differentiate acute rejection from acute tubular necrosis or toxicity associated with immunosuppressive drugs. Findings vary depending on whether the process is mainly cellular or humoral. In acute cellular rejection, interstitial lymphocyte and macrophage infiltration, edema, lymphocytic tubulitis and tubular necrosis occur (Fig. 4-22B). In the acute humoral form, which is sometimes called "rejection vasculitis," vascular damage predominates, with arteritis, fibrinoid necrosis and thrombosis. Blood vessel involvement is an ominous sign since it usually signifies resistance to therapy.

Chronic Rejection Follows Transplantation by Months to Years

Affected patients typically develop progressive azotemia, oliguria, hypertension and weight gain over a period of months. Chronic rejection may be due to repeated episodes of cellular rejection, either asymptomatic or clinically apparent. Arterial and arteriolar intimal thickening cause vascular stenosis or obstruction, thickened glomerular capillary walls, tubular atrophy and interstitial fibrosis (Fig. 4-22C). There are scattered interstitial mononuclear infiltrates. Tubules contain proteinaceous casts. Chronic rejection represents an advanced state of organ injury and does not respond to therapy. Acute and chronic rejection may overlap histologically and they may vary in degree, so that unambiguous pathologic distinction may not be possible.

In Graft-Versus-Host Disease, Donor Lymphocytes React against the Graft Recipient

The advent of transplantation of allogeneic (donor) bone marrow or HSCs harvested from peripheral blood makes possible treatment of diseases that had previously been considered terminal or untreatable. In order for the transplanted marrow/HSCs to engraft in the new host, the recipient's bone marrow and immune system must be "conditioned" (usually ablated) by cytotoxic drugs, sometimes plus radiation. If the graft includes immunocompetent lymphocytes, these donor cells may react to—"reject"—host tissues, causing

graft-versus-host disease (GVHD). GVHD can also occur if a severely immunodeficient patient receives a solid organ containing many "passenger" lymphocytes or is transfused with blood products containing viable HLA-incompatible lymphocytes.

The major organs affected in GVHD are skin, gastrointestinal tract and liver. The skin and intestine show mononuclear cell infiltrates and epithelial cell necrosis. The liver displays periportal inflammation, damaged bile ducts and liver cell injury. Clinically, acute GVHD manifests as rash, diarrhea, abdominal cramps, anemia and liver dysfunction. Chronic GVHD is characterized by dermal sclerosis, sicca syndrome (see above: dry eyes and mouth due to chronic inflammation of lacrimal and salivary glands) and immunodeficiency. Treatment of GVHD requires immunosuppression. Patients, especially those with chronic GVHD, may be at a higher risk for potentially life-threatening opportunistic infections (e.g., invasive aspergillosis).

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

THE APPEARANCE OF AIDS

AIDS is the most common immunodeficiency state worldwide. It is mainly caused by human immunodeficiency virus type 1 (HIV-1), although a small minority of patients, primarily in western Africa, are infected with HIV-2. People infected with HIV-1, if untreated, develop many immunologic defects, the most devastating of which is severely impaired cellular immunity, leading to catastrophic opportunistic infections. HIV-1 infection progresses from an initial asymptomatic state to severe immune depletion in overt AIDS. This continuum is called HIV/AIDS. Infection of $CD4^+$ (helper) T lymphocytes by HIV-1 causes depletion of this cell population, leading to impaired immune function and dysregulation. Because they cannot mount new immune responses, especially cell-mediated immune responses, patients with AIDS usually die of opportunistic infections, principally with mycobacteria, viruses or fungi. There is also a high incidence of malignant tumors, mainly B-cell lymphomas and Kaposi sarcoma. Finally, HIV-1 infection in the CNS causes HIV-associated neurologic disease (HAND), which ranges from minor cognitive or motor disorders to frank dementia.

Early Human HIV Infections Were Unreported

The onset of this human epidemic is uncertain, but unreported human HIV infections almost certainly occurred at least as early as 1902. The North American epidemic probably began in Haiti in 1966 and a single transmission event led to its spread to the United States about 5 years later. By the late 1970s, clusters of strange infectious diseases in New York and Miami among men who have sex with men (MSM), intravenous drug users and Haitians are now recognized as having been caused by HIV. AIDS was first reported in the United States in 1981, as *P. carinii* (now called *P. jiroveci*) pneumonia in MSM. By 1982, these unusual infections were linked to Kaposi sarcoma (KS) and understood to reflect an acquired immune defect. Thus, "AIDS" was coined.

It became clear that AIDS was spread by contact with blood or body fluids from infected people: largely MSM and intravenous drug users who shared needles, but also recipients of blood and blood products, especially hemophiliacs, and heterosexual contacts and infants born to female drug users. Once the responsible virus, now called HIV-1, was identified (1983), it became possible to develop a serologic test to detect antibodies to HIV-1 (1985), which in turn allowed accurate diagnosis and screening of donated blood to prevent transmission by blood and its derivatives.

EPIDEMIOLOGY: AIDS originated in sub-Saharan Africa, and at least 3 different viral strains were transmitted from chimpanzees to humans. It is now a worldwide pandemic due to the ease of international travel and enhanced population mobility, which in many societies coincided with a rapid increase in sexual activity and sexually transmitted diseases. Presently, the WHO estimates that 34 million people carry HIV worldwide, with 2.7 million new infections and 1.8 million deaths yearly. The death rate peaked in 2005 and has declined since then. Annual new infections peaked in 1997, at 3.3 million, and have dropped subsequently. As antiretroviral therapy (ART) reaches more people, the total number of people living with HIV infection continues to increase.

The highest prevalence is in sub-Saharan Africa, but no country is free of HIV-1. MSM once were by far the largest group of HIV-positive people in the United States and still account for most newly infected cases. In some other parts of the world, transmission may be largely by heterosexual contact or via intravenous drug users. Most AIDS patients in the United States are men, although the prevalence of HIV-1 infection in women continues to increase.

Sub-Saharan Africa, which has suffered more from the ravages of AIDS than other regions, has made progress in lowering the rate of new infections and AIDS-related deaths. However, in some parts of sub-Saharan Africa, 20% of the population is HIV positive. African patients largely acquire HIV infection by heterosexual intercourse or via maternal–child transmission.

Further, although new HIV infections and HIV-related deaths have declined in the Western world and sub-Saharan Africa, the AIDS epidemic continues to grow in the Middle East, Eastern Europe and parts of central and eastern Asia. Multiple factors contribute to the sustained increases in HIV/AIDS in these areas.

As the epidemic matures and stabilizes in many parts of the world, new issues arise. Thus, the affected (i.e., infected) populations are aging. Already, 15% of new infections occur in people over 50, and by 2015, it is estimated that half of HIV-positive patients will be 50 years old or older. These changing demographics, which reflect both lifestyles and improvements in therapies, present their own challenges as CNS infections and therapy-related complications become increasingly important.

HIV Is Transmitted by Contact with Blood and Certain Body Fluids, and through Sexual Activity

HIV is present in blood, semen, vaginal secretions, breast milk and cerebrospinal fluid of infected patients. HIV is present in most of these fluids in lymphocytes and as free virus. It is transmitted via these fluids to sexual partners, drug users who share needles and recipients of blood products and via breast milk to nursing infants.

Infection is transmitted by a single virus or virus-infected cell in about 80% of cases, the remainder of new infections reflecting multiple viruses or infected cells. Virus in semen enters through tears in the rectal mucosa, particularly in anal-receptive MSM partners. It can also infect rectal epithelial cells directly. In heterosexual contact, male-to-female transmission is more likely than the reverse, perhaps because there is more HIV in semen than in vaginal fluid. Additionally, genital lesions facilitate virus entry. HIV infections are lower in circumcised men, perhaps because the foreskin is less well keratinized than other parts of the penis and has a higher concentration of cutaneous dendritic cells (Langerhans cells).

HIV-1 is not transmitted by nonsexual, casual exposure to infected people. Further, fewer than 1% of health care workers who sustained "needle sticks" or other accidental exposures to blood from HIV-positive patients became infected with HIV-1. Immediate postexposure antiretroviral prophylaxis is available (see http://www.cdc.gov/hiv/resources/guidelines for details).

HIV-1 BIOLOGY AND BEHAVIOR

The Biology of HIV-1 Determines Its Success as a Pathogen

MOLECULAR PATHOGENESIS: HIV-1 is a member of the lentivirus family of retroviruses. Animal lentiviruses have been recognized for a century, but human lentiviruses have been known for less than three decades.

HIV-1 virions carry two identical 9.7-kb copies of the virus single-stranded RNA genome plus some key enzymes, such as reverse transcriptase (RNA-dependent DNA polymerase, RT) and integrase (IN), that are needed early in the infectious cycle (see below). These are packaged in a core of viral proteins. The outermost layer, the envelope, is derived from the host cell membrane, in which are found virally encoded Env glycoproteins (gp120 and gp41). In addition to the *gag*, *pol* and *env* genes present in all replication-competent RNA viruses, HIV-1 has six other genes that code for proteins that control viral replication and certain host cell functions. Mononuclear phagocytes and $CD4^+$ helper T lymphocytes are the virus's main targets, although B lymphocytes, astrocytes, endothelial cells and intestinal epithelium can also be infected.

The replicative cycle of HIV-1 is depicted in Fig. 4-23.

1. **Binding:** Free HIV or an infected lymphocyte can transmit the virus to an uninfected cell. HIV gp120, either on a free virus or on the surface of an infected cell, binds the CD4 molecule on the surface of helper T lymphocytes and other cells, plus specific β-chemokine receptors. The most important of these chemokine receptors are CCR5 (on many phagocytic cells) and CXCR4 (on T lymphocytes). Virus binding to both CD4 and a chemokine receptor mediates HIV entry. However, HIV-1 can enter dendritic cells (DCs) via C-type lectin receptors (e.g., DC-SIGN). There is also evidence that CCR3 may be important in HIV-1 infection in the CNS (see below) and elsewhere.
2. **Internalization:** Upon binding to CD4, gp120 undergoes a conformational change, to uncover its CCR5 (or CXCR4) binding domain. Thereupon, viral gp41 forms a loop, fusing virus and cell membranes. The virus capsid, genome and those enzymes needed for the early phase of the infectious cycle enter the cell.
3. **DNA synthesis:** The virus genome and viral RT and IN enter the cytosol and reverse transcription occurs. HIV-1 RT has several functions and is a key target for ART. It reverse-transcribes HIV-1 RNA into a complementary DNA (cDNA) copy. As it does this, it digests the RNA it has just reverse-transcribed. RT then acts as a DNA-dependent DNA polymerase and synthesizes a second DNA strand complementary to the first. The resulting double-stranded DNA version of the HIV-1 genome is called the provirus. ***One critical function that this versatile RT lacks is an editing capacity. There is, consequently, a very high error rate in this whole process***. Consequently, viral replication entails an extremely high mutation rate. While this results in a high percentage of defective or noninfectious virus particles, it also results in rapid viral adaptation—and so resistance—to therapies. This characteristic of HIV also leads to rapid evolution of the virus after it enters the host. Thus, coreceptor usage, envelope antigenicity and other features of the virus may change substantially, allowing adaptation to a changing host environment.
4. **Integration:** Once proviral DNA has entered the nucleus, HIV-1 IN catalyzes provirus cDNA integration into the host genome. HIV-1 genomes therefore remain in the cell as long as the cell survives and are replicated along with host chromosomes. As tissue phagocytes and memory T cells are very long-lived, some experts estimate that even if total suppression of HIV-1 replication were achieved, over 60 years would be needed for infected cells to die off. Also, some replication occurs even with the most effective ART regiments.
5. **Replication:** Viral RNA is reproduced by transcriptional activation of the integrated HIV provirus, a process that, for example, for T cells, requires "activation" of the infected cell plus certain inducible host transcription factors, especially nuclear factor-κB (NFκB).
6. **Dissemination:** To complete its cycle, nascent virus is assembled in the cytoplasm just beneath the cell membrane and disseminated to other target cells. This is accomplished either by fusion of an infected cell with an uninfected one or by budding of virions from the plasma membrane of infected cells (Fig. 4-24).

The mechanism by which HIV kills infected T lymphocytes is incompletely understood. Virus-induced apoptosis and autophagy may be involved. Other possibilities include immune clearance of infected cells and the actions of secondary mediators such as cytokines. Whatever the mechanism(s), there is a clear association between increasing viral burden and declining $CD4^+$ lymphocyte counts.

HIV-1 persists, effectively, for the lifetime of the host. Even in the face of low or undetectable plasma virus levels (see below), a latent or quiescent form of the virus remains

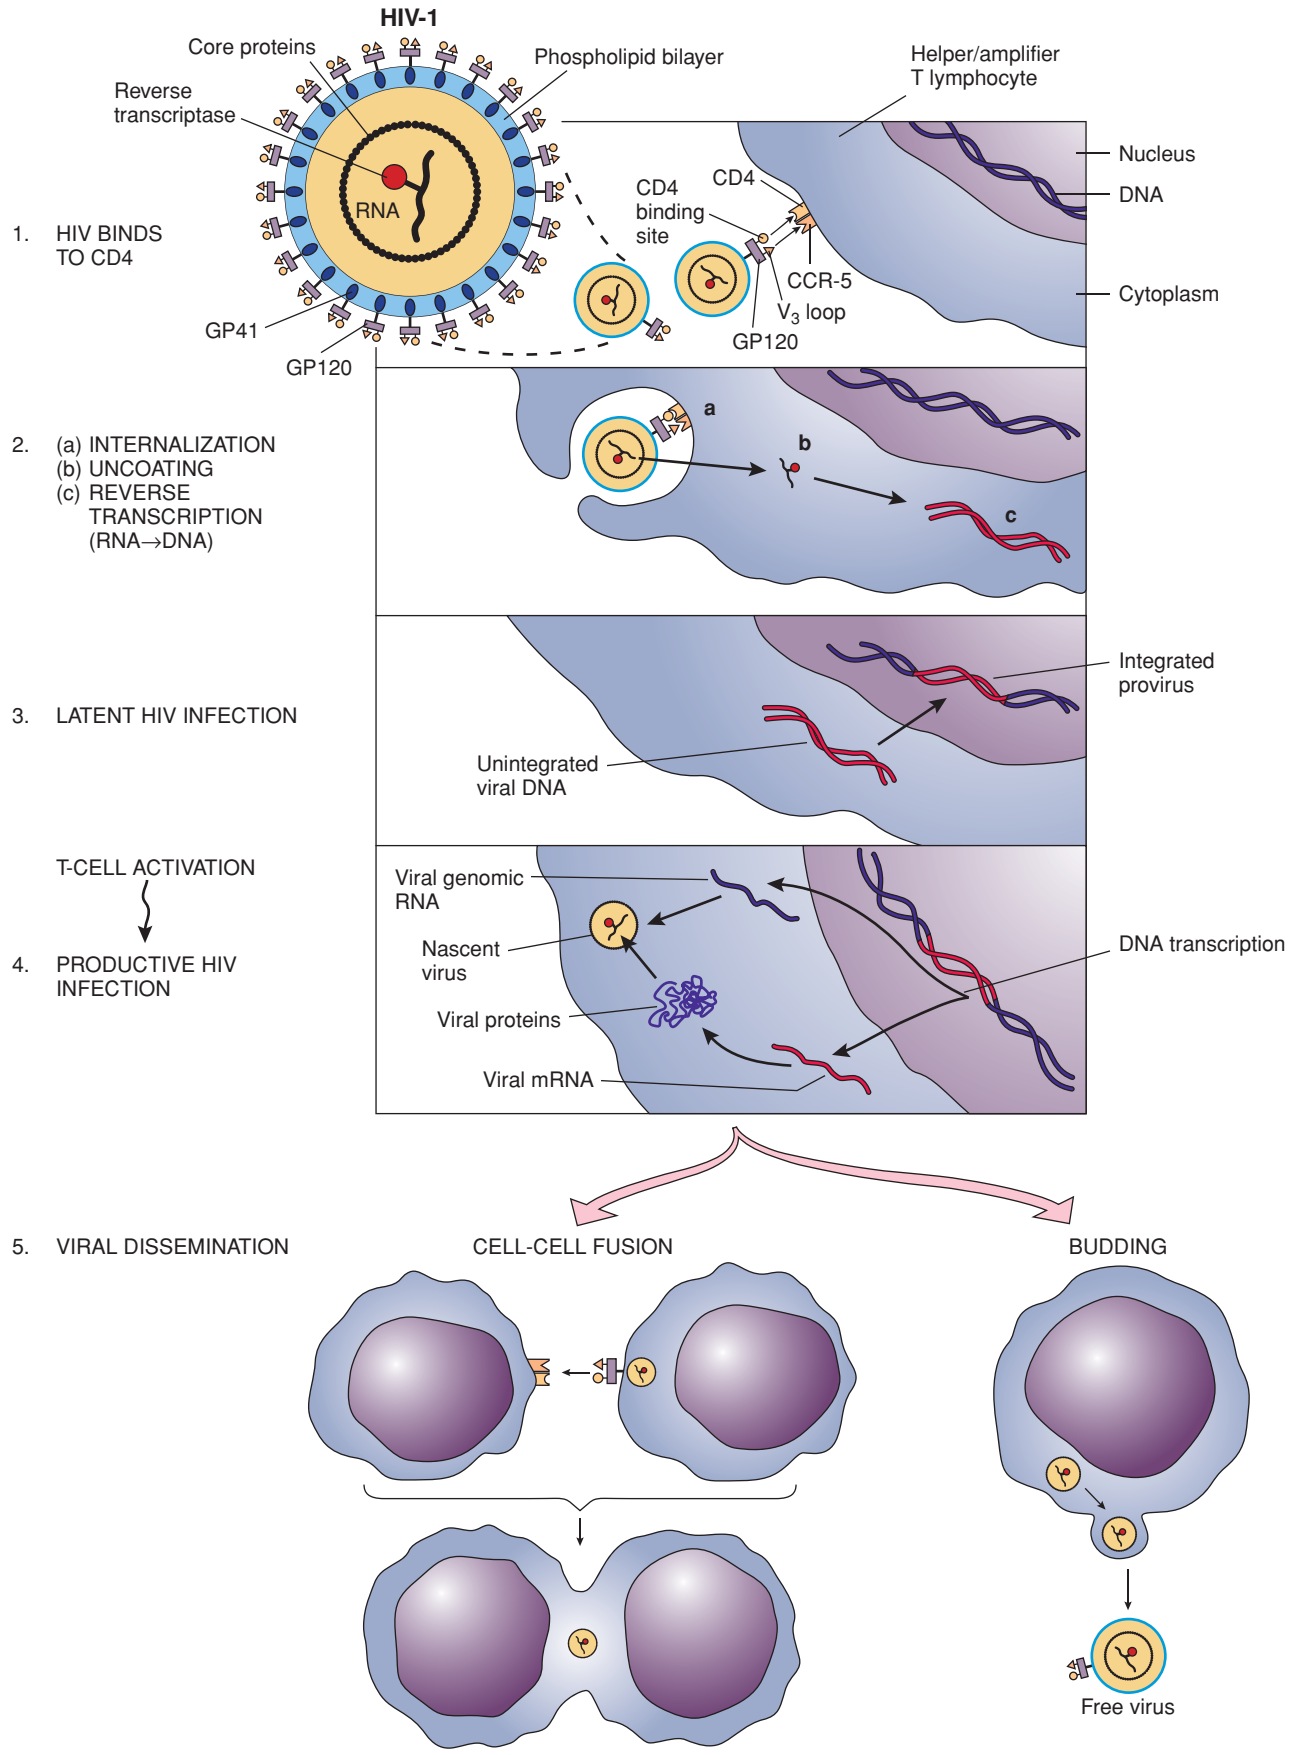

FIGURE 4-23. **The life cycle of human immunodeficiency virus-1 (HIV-1) is a multistep process that includes (1) binding CD4 receptor in conjunction with chemokine receptor (e.g., CCR5); (2) internalization, uncoating and reverse transcription; (3) integration into host DNA as a provirus where it persists in a state of latency; (4) replication in concert with host T-cell activation; and (5) dissemination.**

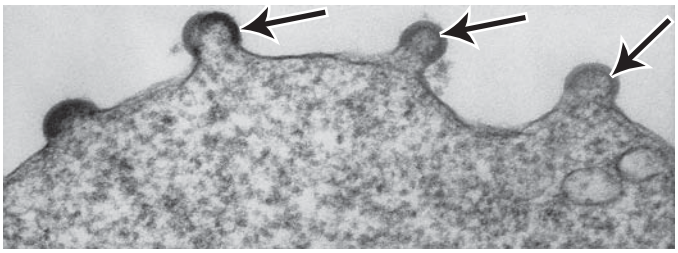

FIGURE 4-24. Human immunodeficiency virus-1 (HIV-1) virions can be seen budding from infected cells (*arrows*).

in long-lived memory T cells and tissue phagocytes. There is also evidence that the CNS and possibly other organs may serve as a reservoir for potential reseeding of the periphery.

Initiation of viral replication in latent HIV-1 infection depends on induction of host proteins during T-cell activation. Viral transcription may be activated by many T-cell mitogens and cytokines produced by monocyte/macrophages, including TNF-α and IL-1, and, in addition, by proteins produced by other viruses that infect patients with AIDS, such as herpesvirus, EBV, adenovirus and CMV. Thus, immune system activation by a variety of infectious agents may promote HIV replication.

PATHOPHYSIOLOGY: The destruction of $CD4^+$ T cells by HIV-1 can essentially disable the entire immune system because this subset of lymphocytes exerts critical regulatory and effector functions that involve both cellular and humoral immunity. ***Thus, in typical AIDS patients, all elements of the immune system are eventually crippled, including T cells, B cells, NK cells, the monocyte/macrophage lineage of cells and immunoglobulin production.***

Of the two functional types of $CD4^+$ T lymphocytes (i.e., helper and amplifier [or inducer] cells), those affected first in HIV infection are the amplifier subset. Eventually, total $CD4^+$ lymphocyte counts fall to less than 500 cells/μL, and helper-to-suppressor T-cell ratios decline from a normal of 2.0 to as little as 0.5. Numbers of $CD8^+$ (cytotoxic/suppressor) cells are variable, although in AIDS, most of these cells seem to be of the cytotoxic variety.

Defects in T-cell function are manifested by weak responses in skin testing with a variety of antigens (delayed hypersensitivity) and impaired proliferative responses to mitogens and antigens in vitro. Moreover, the deficiency of $CD4^+$ cells reduces levels of IL-2, the cytokine produced in response to antigens that stimulate cytotoxic T-cell killing. ***Thus, patients with AIDS cannot generate the antigen-specific cytotoxic T cells that are required to clear viruses and other infectious agents.***

Humoral immunity is also abnormal. Production of antibodies in response to specific antigenic stimulation is markedly decreased, often to less than 10% of normal. B cells also show poor proliferative responses in vitro to mitogens and antigens. Yet, sera of patients with AIDS usually show high levels of polyclonal immunoglobulins, autoantibodies and immune complexes. This apparent paradox is probably explained by the concurrent infection with polyclonal B-cell–activating viruses (e.g., EBV or CMV), which constantly stimulate B cells nonspecifically to produce immunoglobulins. Lack of $CD4^+$ lymphocytes impairs the cytotoxic T-cell proliferation that normally would eliminate B cells infected with EBV.

NK-cell activity is severely decreased in AIDS as well. Since these cells kill both virus-infected cells and tumor cells, this defect may contribute to the malignant tumors and viral infections that plague these patients. Suppression of NK-cell activity is related both to a decrease in NK-cell number and to reduction in IL-2 levels, owing to a loss of $CD4^+$ cells.

Lentiviruses tend to target macrophages, and infected macrophages may serve as reservoirs for dissemination of the virus. Interestingly, some macrophages express CD4 on their surfaces. Unlike T lymphocytes, which are killed by HIV, infected macrophages generally survive. Macrophages from patients with AIDS phagocytose immune complexes and opsonized particles poorly and show impaired chemotaxis and responsiveness to antigenic challenges.

PATHOLOGY; CLINICAL FEATURES: Patients recently infected with HIV-1 may have an acute, usually self-limited flu-like illness termed the **acute retroviral syndrome**. It clinically resembles infectious mononucleosis. This occurs 2–3 weeks after exposure to HIV, before appearance of antibodies against the virus. Less commonly, patients present with neurologic symptoms that suggest encephalitis, aseptic meningitis or a neuropathy. Fever, myalgia, lymphadenopathy, sore throat and a macular rash are common. Most of these symptoms resolve within 2–3 weeks, although lymphadenopathy, fever and myalgia may persist for a few months. Seroconversion occurs 1–10 weeks after the onset of this acute illness. Thus, the standard HIV-1 enzyme immunoassay (EIA) and Western blot testing, which depends on the presence of anti–HIV-1 *gag* antibodies, is negative during the initial stage of the infection. Most patients recover from this initial illness as their immune system mounts a cytotoxic T-cell counterattack, although a small percentage progress rapidly to frank AIDS within a few months. After the initial acute syndrome, most newly infected individuals enter a period of latency and slow immune system decline that averages approximately 10 years before they reach a state of serious immune compromise. If symptoms go unrecognized or untreated, the outcome will eventually be fulminant immunodeficiency and its fatal complications (Fig. 4-25).

Persistent generalized lymphadenopathy is palpable lymph node enlargement at two or more extrainguinal sites, persisting for more than 3 months in a person infected with HIV. The disorder develops either as part of the acute HIV syndrome or within a few months of seroconversion. Axillary, inguinal and posterior cervical nodes are most affected, although any group of lymph nodes can be involved. Many cells within the affected lymph nodes, especially follicular dendritic cells, harbor actively replicating virus. Biopsy reveals reactive changes with follicular hyperplasia, but these are not diagnostic. Persistent generalized lymphadenopathy does not have any prognostic significance with respect to progression of HIV infection to AIDS. The ability

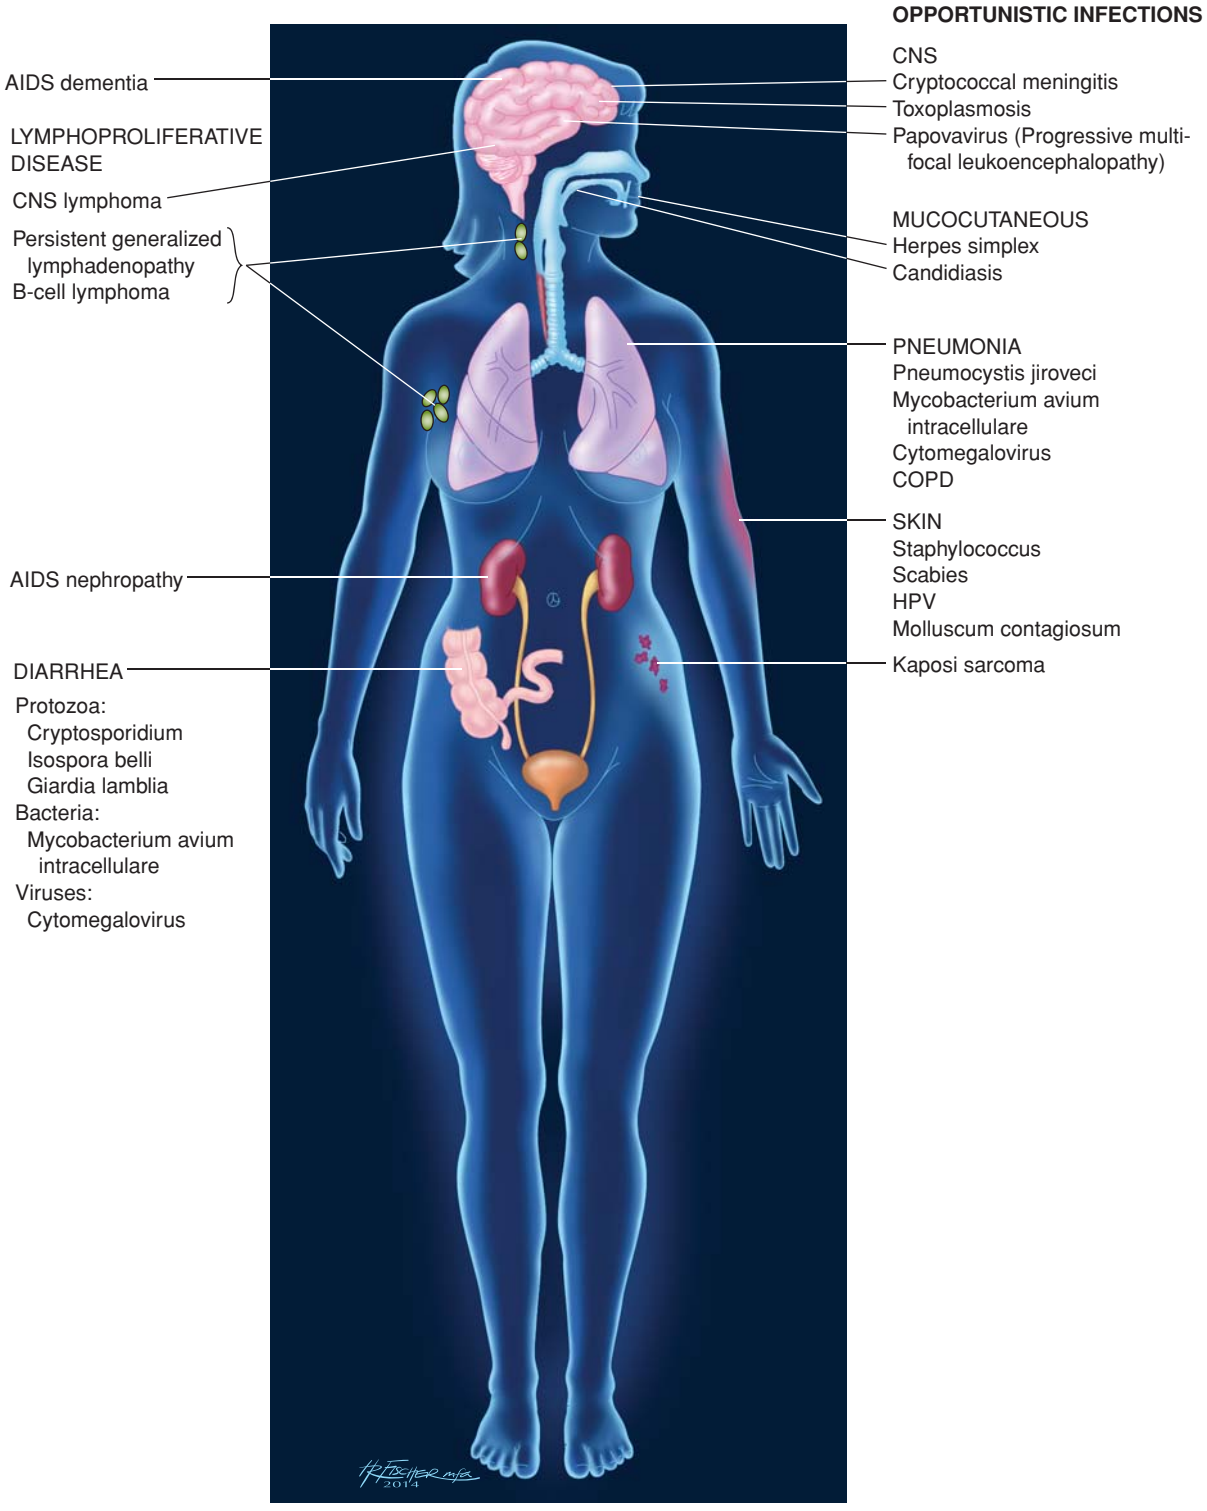

FIGURE 4-25. Human immunodeficiency virus-1 (HIV-1)-mediated destruction of the cellular immune system results in AIDS. The infectious and neoplastic complications of AIDS can affect practically every organ system. *CNS* = central nervous system; *HPV* = human papilloma virus.

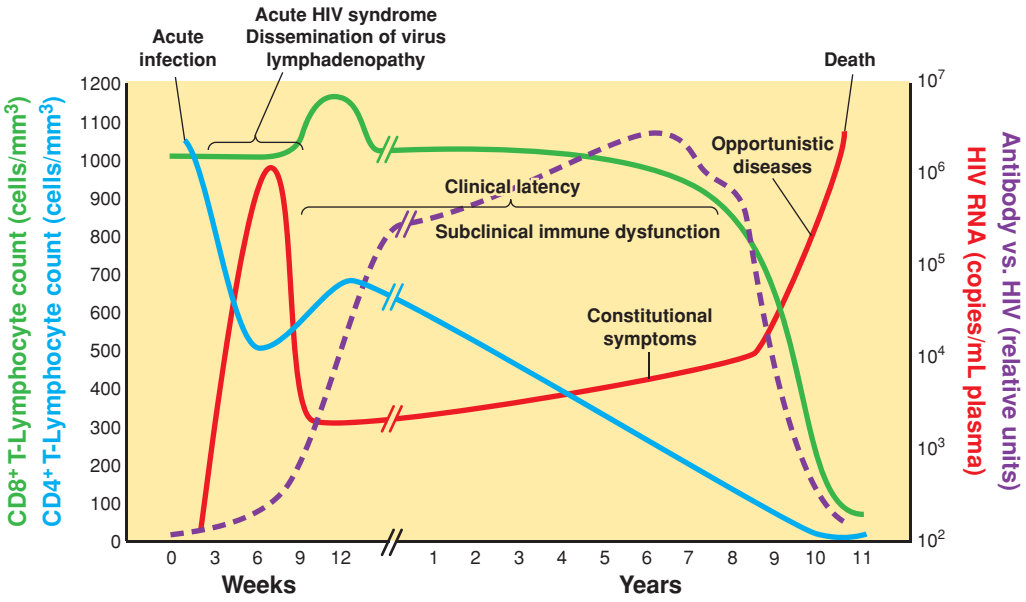

FIGURE 4-26. Generalized time course of human immunodeficiency virus-1 (HIV-1) infection. Important events in the development of HIV-1 infection are shown, including the clinical syndrome, virus loads and $CD4^+$ and $CD8^+$ lymphocyte population dynamics over time.

to persist and elicit ongoing lymphoproliferative responses is responsible for much of the long-term effects of HIV, even in patients treated with ART (see below).

Most patients infected with HIV express detectable viral antigens and antibodies within 6 months. Patients will generally experience an initial period of intense viremia with very high viral loads during the acute retroviral syndrome and a corresponding sharp drop in their absolute number of $CD4^+$ T cells (Fig. 4-26). As a patient's immune system begins to recognize the new infection, viral load drops and $CD4^+$ T-cell count begins to climb. This control of HIV-1 infection occurs via a vigorous cytotoxic T-cell response. Viral replication continues but is constrained by the immune response. The immune system and the HIV-1 load eventually enter into a sort of uneasy equilibrium, during which the HIV-1 viral RNA load stays fairly constant at the "viral set point." During this time infected individuals are generally asymptomatic. However, the rapidity with which HIV-1 evolves within each host ensures that it represents a continually moving antigenic target for the body's immune system.

The long interval between HIV-1 entry and the appearance of clinical symptoms of AIDS is related to the small number of infected T lymphocytes and viral latency and, it is now becoming clear, extensive virus replication away from the circulation in the gut-associated lymphoid tissue (GALT), and perhaps elsewhere. During this asymptomatic period, only 0.01%–0.001% of circulating T cells actively transcribe the HIV-1 genome, even though 1% contain integrated proviral DNA. Moreover, virus replication continues apace in the GALT, consuming certain $CD4^+$ T-cell populations, particularly memory T cells. When this depletion eventually exceeds the body's ability to replenish these cells, systemic HIV-1 replication supervenes.

At some time $CD4^+$ T cell counts start to decrease. Patients generally remain asymptomatic until their $CD4^+$ counts fall below 500/μL. Nonspecific constitutional symptoms may appear, along with opportunistic infections. Once $CD4^+$ levels are under 150/μL and CD4:CD8 ratios less than 0.8, the disease progresses rapidly. A variety of bacteria, viruses and fungi attack immunocompromised patients. KS and lymphoproliferative disorders, especially virus-related lymphoproliferative disorders (see Chapter 26), may appear, and neurologic disease is common.

Symptoms of CNS dysfunction occur in 1/3 of AIDS patients. Postmortem studies of patients who have died of AIDS reveal CNS pathology in more than 3/4 of cases. HIV is thought to enter the brain via infected blood monocytes shortly after it enters the body. It resides there in microglial cells and perivascular macrophages. HIV infection of neurons is not common, but HIV gene products produced by infected brain phagocytes are very toxic for neurons and cause apoptosis via several mechanisms. ART drugs cross the blood-brain barrier poorly, so CNS HIV-1 infection can progress independently of HIV-1 infection outside the CNS, and despite good control of HIV-1 in the periphery. Longer survival among the HIV-positive population has led to greater numbers of patients with discernible neurologic deficits.

About 1% of whites are homozygous for asymptomatic major deletions in the CCR5 gene (the major mutation being a 32-base-pair deletion, causing a frameshift leading to a premature stop codon and a truncated, inactive protein product). ***These people may remain uninfected despite extensive exposure to the virus.*** Heterozygosity for the mutant CCR5 allele provides partial protection against HIV infection, and if infections do occur, they usually progress more slowly. Carriage of the mutant allele is found in up to 20% of whites but is largely absent in blacks and Asians.

Opportunistic Infections, Particularly Polymicrobial Infections, Are Common in Patients with AIDS

Discussion of the diversity of infectious agents that ravage patients with AIDS is beyond the scope of this chapter, and only a few representative examples are mentioned. It is important to recognize that while most immunocompetent patients will have only one infection at a time, HIV-1–infected patients can develop multiple severe infections simultaneously.

The majority of patients with HIV-1/AIDS suffer from opportunistic pulmonary infections, although this has been greatly reduced through the use of prophylactic antibiotics. *P. jiroveci* (formerly *P. carinii*) pneumonia may occur in patients with advanced HIV-1 disease. Lung infections with CMV and *M. avium-intracellulare* are less common. Patients with AIDS are also susceptible to *Legionella* infections.

Diarrhea occurs in over 75% of patients, often representing simultaneous infections with more than one organism. The most frequent pathogens are protozoans, including *Cryptosporidium, Isospora belli* and *Giardia lamblia*. *M. avium-intracellulare* and *Salmonella* species are the most common bacterial causes of diarrhea in AIDS patients. CMV infection of the gastrointestinal tract can manifest as a colitis associated with watery diarrhea in patients whose CD4 counts are under 50 cells/mm^3.

Cryptococcal meningitis is a devastating complication and represents 5%–8% of all opportunistic infections in patients with AIDS. Other CNS infectious complications include cerebral toxoplasmosis; primary CNS lymphoma; encephalitis caused by herpes simplex, varicella or CMV; and progressive multifocal leukoencephalopathy, which is due to JC virus (see Chapter 32).

Virtually all patients with AIDS develop some form of skin disease, infections being the most prominent. *Staphylococcus aureus* is the most common, causing bullous impetigo, deeper purulent lesions (ecthyma) and folliculitis. Chronic mucocutaneous herpes simplex infection is so characteristic of AIDS that it is considered an index infection in establishing the diagnosis. Skin lesions produced by *Molluscum contagiosum* and human papilloma virus (HPV) are also common, as are scabies and infections with *Candida* species. A varicella zoster eruption in someone under the age of 50 should raise the question of a possible occult HIV-1 infection.

Among the most common causes of death in patients with HIV/AIDS is hepatitis C virus (HCV) infection (see Chapter 20). In some studies, over 1/4 of deaths among HIV-positive individuals are from hepatitis C. A very high percentage of HIV-positive intravenous drug abusers are also infected with HCV. There is evidence that coinfection with HIV and HCV accelerates the course of disease with both viruses.

Kaposi sarcoma is an otherwise rare, multicentric, malignant neoplasm (see Chapters 5 and 28). It is characterized by cutaneous and (less commonly) visceral nodules, in which endothelium-lined channels and vascular spaces are admixed with spindle-shaped cells (see Chapter 24). Patients with AIDS, especially MSM rather than intravenous drug users, are at very high risk for KS. In fact, KS in an otherwise healthy person under age 60 is strong evidence of AIDS. Unlike the classic indolent variety of KS, the tumor in AIDS is usually aggressive, often involving viscera such as the gastrointestinal tract or lungs. Lung involvement frequently leads to death.

A strain of herpesvirus—human herpes virus 8 (HHV8)—is implicated in all forms of KS, including that associated with AIDS. HHV8 is also thought to be the cause of a peculiar lymphoma associated with AIDS (**primary effusion lymphoma**) and of **AIDS-associated Castleman disease** (see Chapter 26). The virus has been detected in both KS spindle cells and endothelial cells. The finding of HHV8 in the blood strongly predicts later development of KS. In fact, 75% of HIV-infected people with HHV8 in the blood developed KS within 5 years. It is thought that HHV8 is sexually transmitted, as almost all MSM HIV carriers are infected, but only 1/4 of heterosexual drug users with HIV infection harbor HHV8.

B-cell lymphoproliferative diseases are common in AIDS patients. Congenital and acquired immunodeficiency states are associated with B-cell hyperplasia, usually manifested as generalized lymphadenopathy. This lymphoproliferative syndrome may be followed by the appearance of high-grade B-cell lymphomas. In fact, patients who have been subjected to immunosuppressive therapy for renal transplants are at a 35-times-greater risk of developing lymphoma, and in 1/3 of these cases the tumor is confined to the CNS. Lymphomas in chronically immunodeficient patients may manifest as invasive polyclonal B-cell proliferations or monoclonal B-cell lymphomas. EBV infection has been closely associated with these lesions.

B-cell hyperplasia and generalized lymphadenopathy precede malignant lymphoproliferative disease. HIV-associated lymphomas are usually the large cell variety, as in other immunodeficiency conditions, although small cell lymphomas are sometimes seen. A conspicuous feature of AIDS-associated lymphomas is their preference for extranodal primary sites, particularly the brain, gastrointestinal tract, liver and bone marrow. The EBV genome has also been demonstrated in many AIDS-related lymphomas, especially in the CNS.

Efforts at Immunization to Prevent HIV-1 Infection Have to Date Been Unsuccessful

Enormous energy and resources have been applied to developing a vaccine to protect from HIV-1 infection. To date, no approach to vaccination has provided more than a glimmer of hope. Many approaches have been tried, from killed whole virus, to isolated viral proteins, to gene delivery of viral proteins using various vectors. None has yet been successful. This failure reflects many factors, including the antigenic diversity of HIV-1 strains (Fig. 4-27). To further complicate the task, since spontaneous recovery from HIV-1 infection has not been documented, it is unclear what effective immunity to HIV-1 would look like—what part(s) of the immune system would mediate resistance and what their immunologic target(s) would be. More mundane measures, such as careful screening of transfused blood products, condoms, male circumcision (see above) and prophylactic ART treatment of babies born to HIV-positive mothers, have helped to slow the spread of the virus.

HIV-2 Causes a Clinical Syndrome Like That Caused by HIV-1

In 1985, otherwise healthy prostitutes in Senegal were discovered to harbor antibodies that cross-reacted with a monkey retrovirus, now termed **simian immunodeficiency virus** (SIV). A year later, a retrovirus similar to HIV-1 was isolated from West African patients with AIDS who were negative for antibodies against HIV-1. Antibodies to this new retrovirus, now termed HIV-2, also cross-reacted with SIV antigens. Frozen sera from West Africa dating to the 1960s have been shown to contain antibodies to HIV-2. In Guinea-Bissau, infection with HIV-2 has been shown in 8% of pregnant women, 10% of male blood donors and more than 1/3 of prostitutes. The infection has

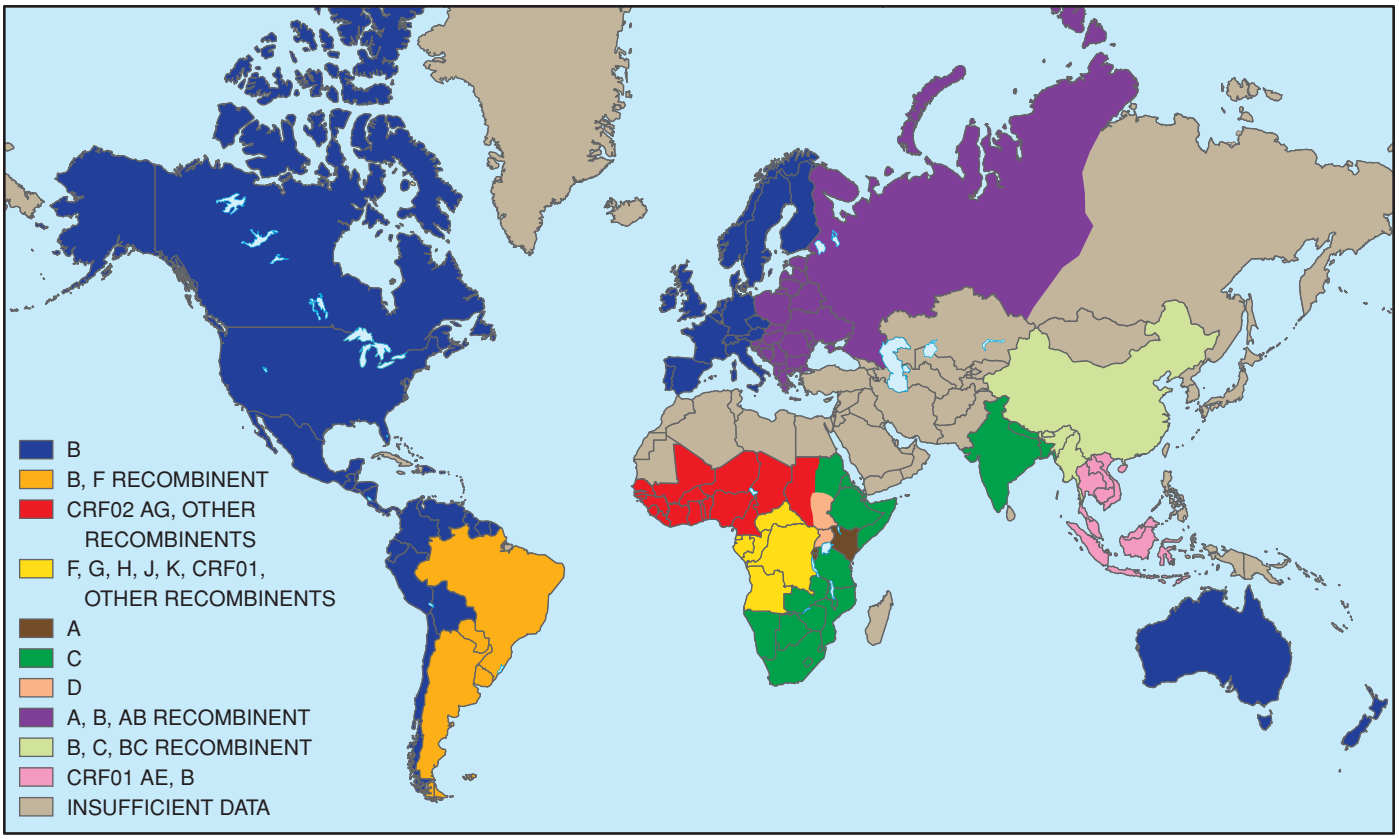

FIGURE 4-27. Diversity of human immunodeficiency virus-1 (HIV-1) antigens worldwide. The dominant HIV-1 serotypes (clades), by country; 2005 figures from the World Health Organization (WHO).

now also been reported from other parts of Africa, Europe and the United States.

HIV-2 is morphologically similar to HIV-1, and the immunodeficiency state associated with HIV-2 infection is indistinguishable from AIDS caused by HIV-1. The risk factors for infection in both diseases seem to be similar. However, HIV-2 is felt to be derived from a different nonhuman primate virus from HIV-1 and is more difficult to transmit than HIV-1. People infected with HIV-2 tend to progress to AIDS more slowly than those infected with HIV-1.

ANTIRETROVIRAL THERAPY AND ITS CONSEQUENCES

The Introduction of Combination Antiretroviral Therapy Has Helped Many HIV-Positive People Live Longer and Healthier Lives

HIV infection represents a novel challenge in treatment. Human lentivirus infections have not been therapeutic targets in the past. Thus, new strategies have had to be developed to treat patients with HIV/AIDS. Therapy focuses on HIV proteins that are obligatory for HIV replication and sufficiently different from normal cellular proteins to offer clear targets for pharmacotherapy. Initial agents were designed to inhibit the function of HIV RT and protease (PR). Combining compounds that inhibit RT with drugs that inhibit PR has been the mainstay of ART. Use of ART revolutionized AIDS treatment, reducing AIDS-related mortality and increasing all indices of health in HIV-1–infected patients. Newer medications that target CCR5 and HIV-1 IN and other HIV-1–related functions have been added to the antiretroviral therapeutic armamentarium.

As mentioned above, HIV-1 RT lacks an editing function, so that HIV mutates much more often than most other viruses. This high mutation rate facilitates avoidance of immune attack and enhances its ability to generate functional mutations that are resistant to ART. Although combining three or more drugs in most ART regimens depresses viral replication, HIV mutants resistant to multiple chemotherapeutic agents contribute now a high percentage of primary HIV isolates in the United States. Further, ART drugs do not cross the blood-brain barrier well and are less effective in inhibiting HIV-1 persistence in macrophages. Thus, the CNS and other organs—especially mononuclear phagocytes in other organs like the gut and lung—may be sanctuaries for the virus (see above). Thus, continuing development of antiretrovirals is needed to stay ahead of the virus's adaptability to the evolving therapeutic environment.

Immune Reconstitution Inflammatory Syndrome

The introduction of effective antiretroviral therapy has led to an unanticipated consequence: the complications of sudden widespread suppression of HIV-1 replication, reconstitution of immune function. This syndrome affects about 1/6 of patients, usually shortly after ART begins.

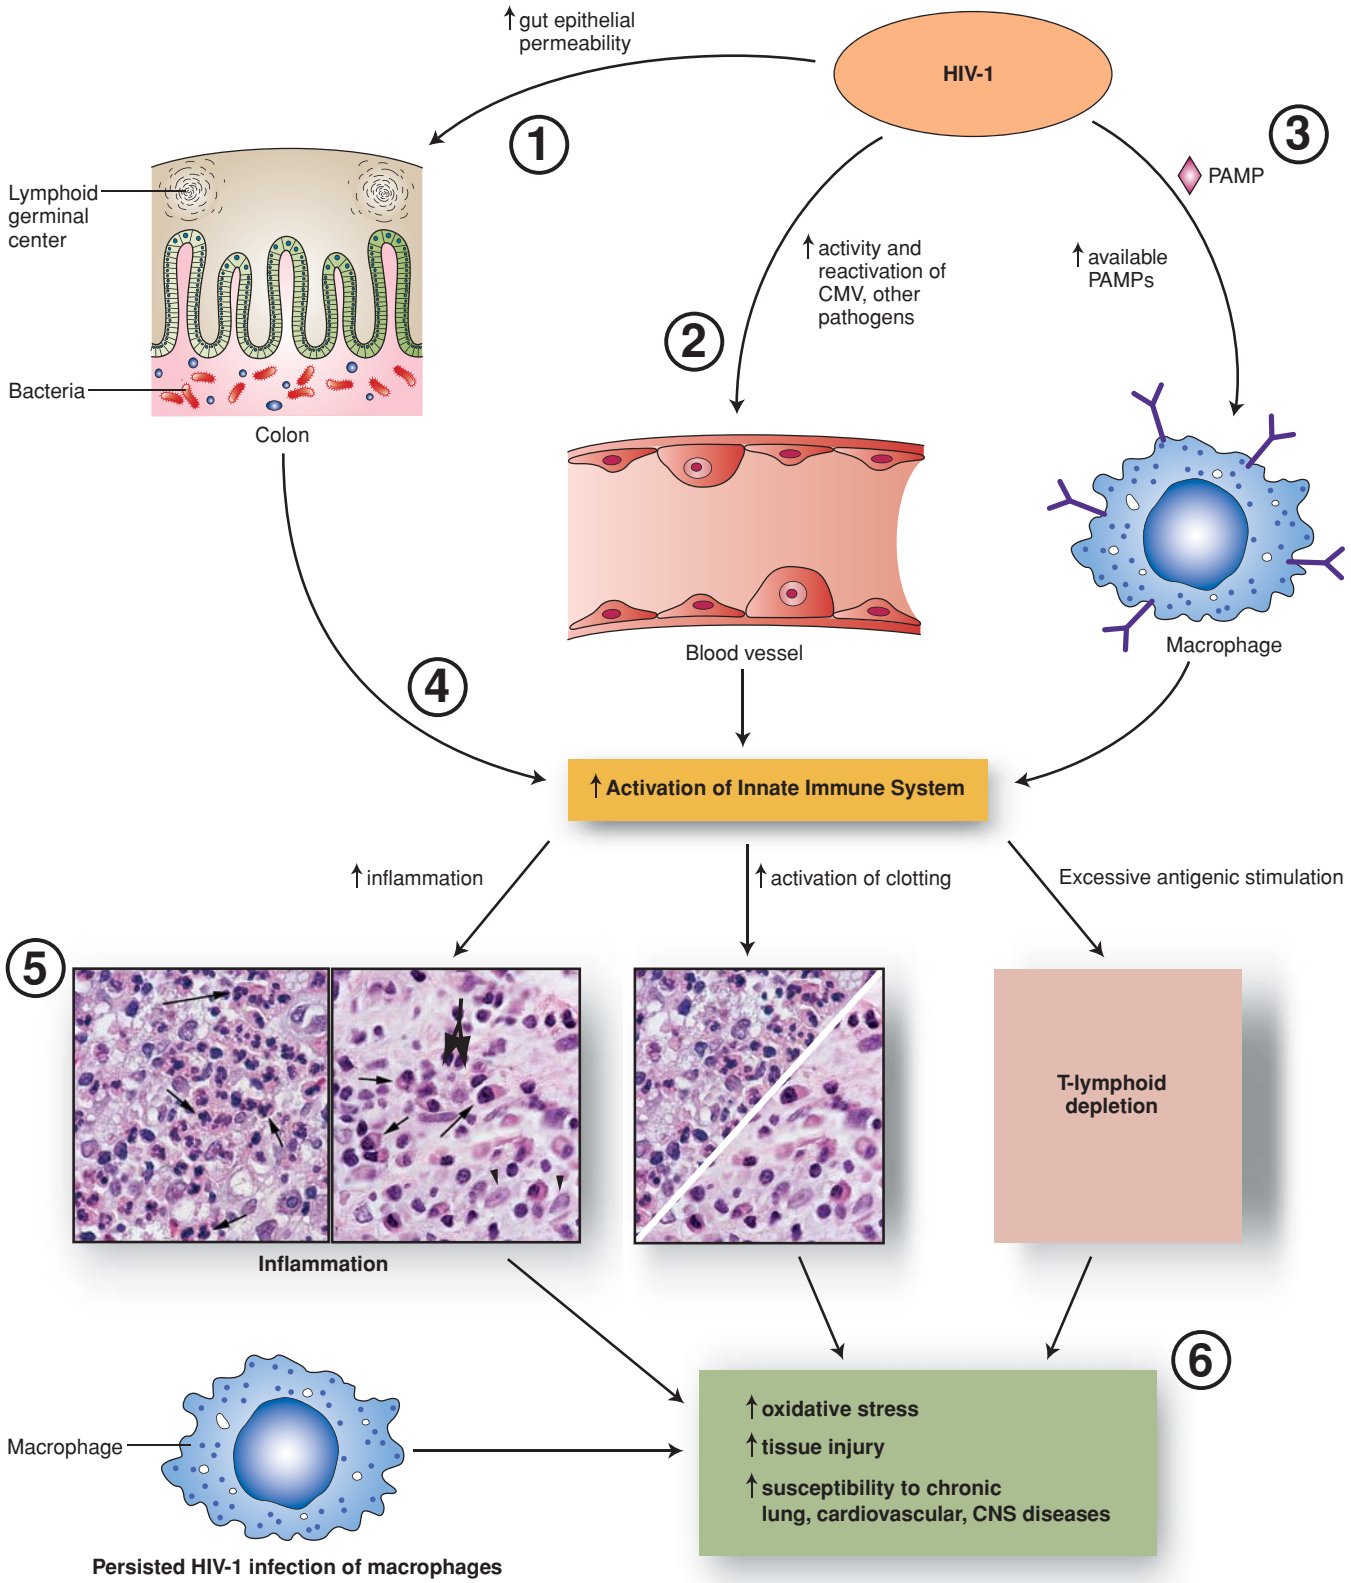

FIGURE 4-28. Probable pathogenesis of long-term complications of human immunodeficiency virus-1 (HIV-1) infection in the antiretroviral therapy (ART) era. 1. HIV-1 infection impairs the barrier function of the gut epithelium, leading to chronic antigenic stimulation by bacteria and other microbes in the gastrointestinal lumen. **2.** Impairment of ongoing surveillance immunity against resident pathogens, such as cytomegalovirus (CMV), leads to reactivation, in this case, within vasculature. **3.** Increased circulating microbial antigens present macrophages and other cells of the innate immune system with excessive levels of pathogen-associated molecular patterns (PAMPs) that stimulate their receptors (PRRs) on these cells. **4.** These factors all combine to activate the innate immune system excessively. **5.** As a consequence, systemic levels of inflammatory responses, tissue factor triggering of clotting and T-cell compartment exhaustion all contribute to tissue injury. **6.** A combination of these factors (5) with persistent macrophage infection by HIV-1, with continuing production of HIV-1 antigens and virus particles, leads to increased oxidative stress, depleting antioxidant reserves and accelerating the types of tissue injury (e.g., cardiovascular, pulmonary, etc.) most often associated with degenerative diseases of the elderly.

PATHOPHYSIOLOGY: ART allows recovery of peripheral lymphocyte populations, especially memory T cells, from HIV-1–caused suppression. These cells increase greatly in the circulation between 3 and 6 months after ART starts. This sudden increase in both CD4 and CD8 memory cells can be dangerous, as, being memory cells, their repertoire reflects previous contact with foreign antigens. The presence of unresolved infections (see below) then magnifies these populations, leading to exaggerated immune responses. A defect in immunoregulatory T_{reg} cells has been postulated, as the ensuing clinical course reflects exaggerated activation of preexisting memory cells and their conversion into effector cells.

The lurking triggers for immune reconstitution inflammatory syndrome (IRIS) are largely infectious agents. So-called paradoxical IRIS occurs in the face of what had been thought to be effectively treated opportunistic infections, when residual microbial antigens drive the T-cell responses noted above. Typically, this type of IRIS occurs 3–6 months after ART begins. A second type of IRIS, which is called the unmasking form, reflects the ability of a previously unsuspected infection to stimulate the unrestrained inflammation. In general, IRIS due to undiagnosed pathogens occurs sooner than the paradoxical form. (It should be mentioned here that IRIS may also complicate recovery of patients with hematologic malignancies, without HIV-1 infection.)

Additionally, autoimmune diseases recrudescing may trigger IRIS. The most common of these is Graves disease (see Chapter 27), but other autoimmune diseases have also been implicated. Sarcoidosis may also act as an initiator for this syndrome.

ETIOLOGIC AGENTS, CLINICAL FEATURES: Pathogens often responsible for IRIS include many of the opportunistic villains commonly associated with AIDS: mycobacteria, both *M. tuberculosis* and *M. avium* complex; fungi such as *C. neoformans;* viruses, particularly CMV, hepatitis B virus and herpes zoster and simplex viruses; and *P. jiroveci.* These may present atypically and present vexing problems in differential diagnosis.

Among the most difficult problems diagnostically is IRIS involving the CNS, particularly presenting as progressive multifocal leukoencephalopathy (PML, see Chapter 32), which is caused by JC virus.

As mentioned above, IRIS often presents atypically and may not be suspected. It tends to affect more severely those whose circulating $CD4^+$ T-cell counts were lowest and whose peripheral viral loads were highest. Although IRIS, properly handled, is rarely fatal, a high index of suspicion should be exercised in patients who present with deteriorating clinical pictures within 6 months after ART is initiated.

HIV-1 Persists and Continues to Deplete T Cells Despite ART

HIV-positive cells remain in the body, so that eradication of the virus from the body is not a realistic expectation with therapies currently available. Among therapy-adherent patients, about 1/3 do not reestablish normal $CD4^+$ T-cell numbers in the blood, despite complete or almost complete suppression of virus in the circulation.

Further, even if $CD4^+$ T-cell levels reach normal and even if HIV-1 replication is not detectable in circulating cells, HIV-1 persists and replicates. Viral replication continues in gut-associated lymphoid tissue and elsewhere. Gastrointestinal epithelial dysfunction leads to ongoing leakage of gut microbes and their antigens into the lymphoid tissues and beyond. This generates a state of continued antigenic stimulation, adding to that caused by persistent HIV-1 replication and release of antigens. High-level, persistent immune responses so generated have several important consequences: (1) exhaustion of $CD4^+$ T-cell reserves, whether by telomere depletion or other mechanisms; (2) ongoing high levels of oxidative stress with depletion of antioxidant reserves; (3) increased susceptibility to infections, such as CMV and EBV, that occur and tend to recur in settings of poor defenses; and (4) accelerated degenerative changes in other organ systems—like the cardiovascular system and the lung—that may not be directly attributable to HIV-1 infection but that may reflect the state of chronic excessive antigenic stimulation (Fig. 4-28). Finally, although ART may eliminate HIV-positive cells from the blood, even temporary interruption of therapy invariably leads to viral rebound (i.e., reactivation of HIV from reservoirs outside the circulation to produce a high circulating viral load).

Therefore, we have achieved tremendous success in controlling blood HIV-1 levels in most patients and consequent improvement in longevity and reduction in morbidity for HIV-1–positive patients. These people still suffer the consequences of their ongoing—if suppressed—HIV-1 infection, continued long-term antigenic stimulation and immune depletion that result, chronic excessive oxidative stress with its harmful consequences for various organs and the still intractable problem of HIV-1–associated neurodegenerative disease.

The Pathology of Neoplasia

A **neoplasm** (Greek, *neo,* "new," + *plasma,* "thing formed") is the autonomous growth of tissues that have escaped normal restraints on cell proliferation and accumulation and exhibit varying degrees of fidelity to their precursors. As well, some tumors (e.g., promyelocytic leukemia) involve impaired maturation, even if the tumor cells are committed to a specific line of differentiation. Neoplastic cells' resemblance to their cells of origin usually enables conclusions about tumors' sources and potential behavior. As most neoplasms occupy space, they are often called **tumors** (Gr., *swelling*). Tumors that remain localized are considered **benign,** while those that spread to distant sites are called **malignant,** or **cancer**. The neoplastic process entails not only cell proliferation but also variable modification of the differentiation of the involved cell types. Thus, in a sense, cancer may be viewed as a burlesque of normal development.

Cancer is an ancient disease. Evidence of bone tumors has been found in prehistoric remains, and the disease is mentioned in early writings from India, Egypt, Babylonia

and Greece. Hippocrates is reported to have distinguished benign from malignant growths. He also introduced the term *karkinos,* from which our term **carcinoma** is derived. In particular, Hippocrates described cancer of the breast, and in the 2nd century AD, Paul of Aegina commented on its frequency.

The incidence of neoplastic disease increases with age, and longer life spans in modern times enlarge the population at risk. In previous centuries, humans did not live long enough to develop many cancers that are particularly common in middle and old age, such as those of the prostate, colon, pancreas and kidney. If all cancer deaths caused by tobacco smoke are removed from the statistics, the overall age-adjusted cancer death rate has been decreasing. In part, this stability and decline in cancer death rates reflects improved early detection techniques (e.g., Pap smears, colonoscopy).

Neoplasms are derived from cells that normally can multiply. Thus, mature neurons and cardiac myocytes do not give rise to tumors. A tumor may mimic its tissue of origin to a variable degree. Some closely resemble their parent structures (e.g., hepatic adenomas), while others seem to be collections of cells that are so primitive that the tumor's origin cannot be identified.

BENIGN VERSUS MALIGNANT TUMORS

Although exceptions are known, benign tumors basically do not penetrate (invade) adjacent tissue borders, nor do they spread (metastasize) to distant sites. They remain as localized overgrowths in the area in which they arise. Benign tumors tend to be more differentiated than malignant ones—that is, they more closely resemble their tissue of origin. *By contrast, malignant tumors or cancers, invade contiguous tissues and metastasize to distant sites, where subpopulations of malignant cells take up residence, grow a new and again grow into surrounding areas.*

In common usage, **the terms "benign" and "malignant" refer to a tumor's overall biological behavior rather than its morphologic characteristics**. In most circumstances, malignant tumors have the capacity to kill, while benign ones spare the host. However, so-called benign tumors in critical locations can be deadly. For example, a benign intracranial tumor of the meninges (meningioma) can kill by exerting pressure on the brain. A minute benign tumor of the ependymal cells of the third ventricle (ependymoma) can block the circulation of cerebrospinal fluid, resulting in lethal hydrocephalus. A benign mesenchymal tumor of the left atrium (myxoma) may cause sudden death by blocking the mitral valve orifice. In certain locations, erosion of a benign tumor of smooth muscle can lead to serious hemorrhage—witness the peptic ulceration of a stromal tumor in the gastric wall. On rare occasions, a functioning, benign endocrine adenoma can be life-threatening, as in the case of the sudden hypoglycemia associated with an insulinoma of the pancreas or the hypertensive crisis produced by a pheochromocytoma of the adrenal medulla. Conversely, certain types of malignant tumors are so indolent that they pose no threat to life. In this category there are many cancers of the breast and prostate.

Tumors can usually be identified as benign or malignant by virtue of their microscopic morphologic characteristics. However, the biological behavior of some types of tumors may not necessarily reflect, or correlate with, pathologic appearance. Some tumors that look histologically malignant may not metastasize or be able to kill a patient. Thus, basal cell carcinomas of the skin may invade subjacent structures locally but rarely metastasize and are not life-threatening. On the other hand, some tumors showing benign histologic characteristics may be lethal. Aggressive meningiomas do not metastasize, but their local invasiveness may cause death by compromising vital structures. For many endocrine tumors (e.g., islet cell tumors of the pancreas) metastatic potential is not predictable from histology, and a tumor's benign or malignant nature can only be determined retrospectively, based on the presence or absence of metastases.

CLASSIFICATION OF NEOPLASMS

In any language, the classification of objects and concepts is pragmatic and useful only insofar as its general acceptance permits effective prognostication. Similarly, the nosology of tumors reflects historical concepts, technical jargon, location, origin, descriptive modifiers and predictors of biological behavior. Although the language of tumor classification is neither rigidly logical nor consistent, it still serves as a reasonable mode of communication.

HISTOLOGIC DIAGNOSIS OF MALIGNANCY

Essentially, labeling a tumor as benign or malignant is a prediction of its eventual biological behavior and clinical outcome. In effect, the criteria used to assess the true biological nature of any tumor are based not on scientific principles but rather on accumulated experience and historical correlations between histologic and cytologic patterns and clinical courses. In most cases, the differentiation between benign and malignant tumors poses few problems; in a few, additional study is required before an accurate diagnosis is secure. However, there will always be tumors that defy the diagnostic skills and experience of any pathologist; in these cases, the correct diagnosis must await the clinical outcome. *Remember that the definition of a benign tumor resides above all in its inability to invade adjacent tissue and to metastasize.*

The Primary Descriptors of All Tumors Are Their Cells of Origin

Although historically the suffix "oma" referred to benign tumors, current terminology is so varied that tumor names do not specify biological behavior with any precision. For example, tumors called melanomas, mesotheliomas and seminomas are all highly malignant even though they carry the suffix "oma." Growths called hamartomas are not even true neoplasms but disorganized developmental medleys of multiple structures. Nevertheless, by definition, the term "carcinoma" describes a malignant proliferation of epithelial cells and "sarcoma" refers to malignancies of mesenchymal origin. These terms are not necessarily all-inclusive, as most malignant proliferations of the blood-forming organs are called leukemias and those of the lymphoid system are lymphomas. Finally, tumors in which historically the histogenesis was poorly understood are often given an eponym—for example, Hodgkin disease or Ewing sarcoma.

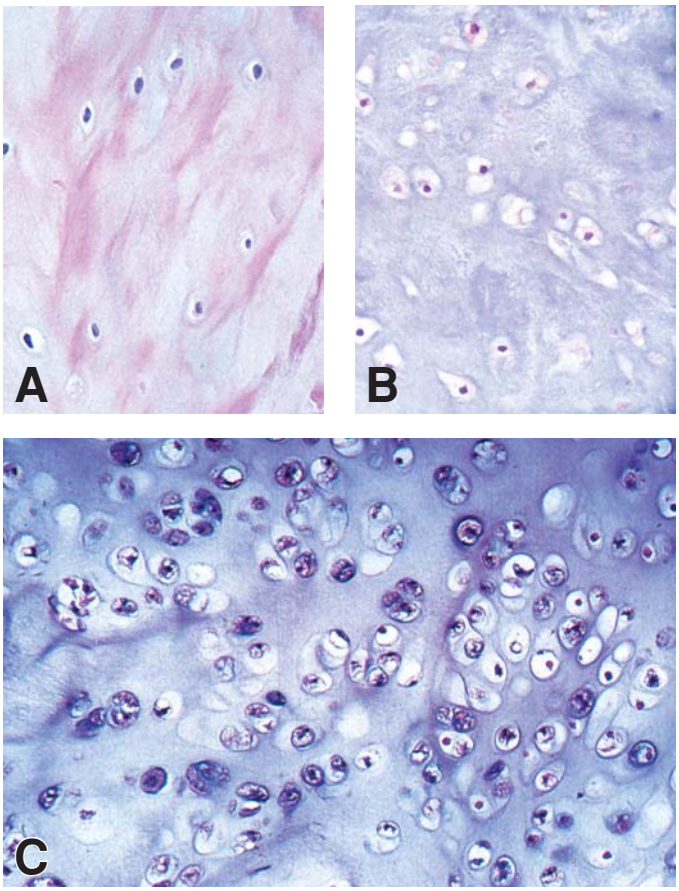

FIGURE 5-1. Cartilaginous lesions. A. Normal cartilage. **B.** A benign chondroma closely resembles normal cartilage. **C.** Chondrosarcoma of bone. The tumor is composed of malignant chondrocytes, which have bizarre shapes and irregular hyperchromatic nuclei, embedded in a cartilaginous matrix. Compare with **A** and **B**.

Some of the histologic features that are considered in distinguishing benign from malignant tumors include the following:

- **Degree of cellular atypia:** This term refers to the extent to which the tumor departs from the appearance of its normal tissue or cellular counterparts (Fig. 5-1). An example is the difference between normal cartilage, a benign chondroma and a malignant chondrosarcoma. In general, the magnitude of cellular atypia (also called **anaplasia**) correlates with the aggressiveness of the tumor. Cytologic evidence of anaplasia includes (1) variation in size and shape of cells and cell nuclei **(pleomorphism),** (2) enlarged and hyperchromatic nuclei with coarsely clumped chromatin and prominent nucleoli, (3) atypical mitoses and (4) bizarre cells, including tumor giant cells (Fig. 5-2).
- **Mitotic activity:** Many malignant tumors show high mitotic rates. For some tumors (e.g., leiomyosarcomas), a diagnosis of malignancy is based on finding even a few mitoses. Nonetheless, such obvious proliferative activity is not obligatory to consider a tumor malignant in all situations.
- **Growth pattern:** In common with many benign tumors, malignant neoplasms often exhibit disorganized growth, which may be expressed as sheets of cells, arrangements around blood vessels, papillary structures, whorls, rosettes and so forth. Malignant tumors often suffer from compromised blood supply and show ischemic necrosis.
- **Invasion:** Malignancy is proved by the demonstration of invasion, particularly of blood vessels and lymphatics. In some circumstances (e.g., squamous carcinoma of the cervix or carcinoma arising in an adenomatous polyp), the diagnosis of malignant transformation is made mainly on the basis of local invasion.
- **Metastases:** The presence of metastases identifies a tumor as malignant. If a metastatic tumor was not preceded by a diagnosed primary cancer, the site of origin may not be readily apparent from histologic characteristics alone. In such cases, electron microscopy and demonstration of specific tumor markers may establish the correct origin.

General criteria for malignancy are recognized but must be used cautiously in specific cases. For example, **nodular fasciitis,** a reactive proliferation of connective tissue cells (Fig. 5-3), appears more alarming histologically than many fibrosarcomas, and misdiagnosis can lead to unnecessary surgery. Conversely, well-differentiated endocrine adenocarcinomas may be pathologically identical to benign adenomas.

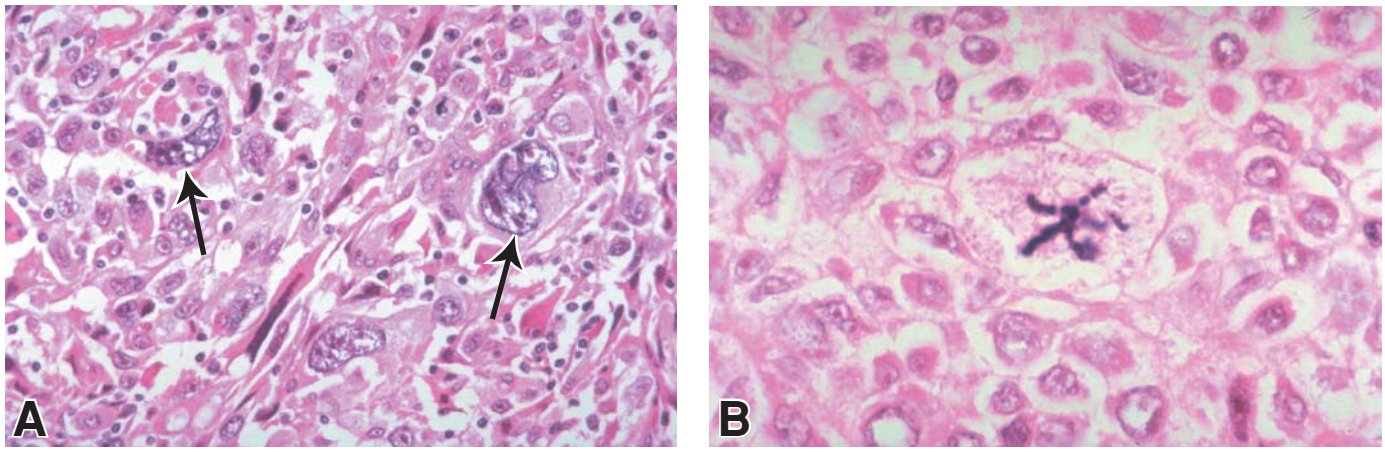

FIGURE 5-2. Anaplastic features of malignant tumors. A. The cells of this anaplastic carcinoma are highly pleomorphic (i.e., they vary in size and shape). The nuclei are hyperchromatic and are large relative to the cytoplasm. Multinucleated tumor giant cells are present (*arrows*). **B.** A malignant cell in metaphase exhibits an abnormal mitotic figure.

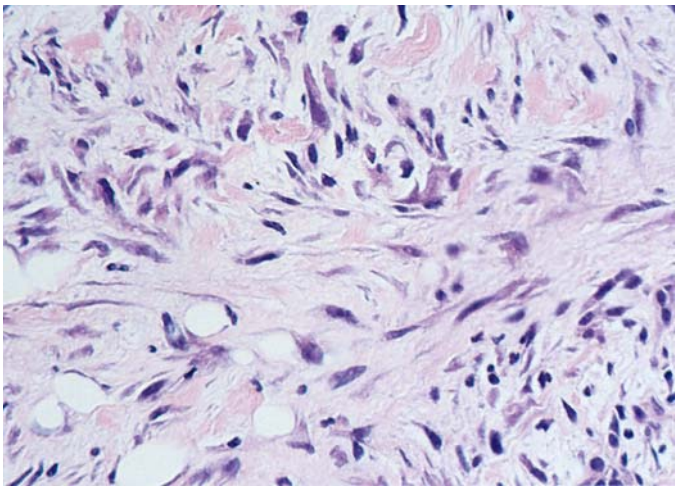

FIGURE 5-3. Nodular fasciitis. This cellular reactive lesion contains a typical and bizarre fibroblasts, which may be mistaken for a fibrosarcoma.

Marker Studies Are Used to Identify Tumor Origin

Electron Microscopy

There are no specific determinants of malignancy or even of neoplasia itself that can be detected by electron microscopy. Although this technique may aid in identifying poorly differentiated cancers whose classification is problematic by routine light microscopy, electron microscopy has largely been supplanted in tumor diagnosis by immunohistochemical staining. Nonetheless, carcinomas often contain desmosomes and specialized junctional complexes, structures that are not typical of sarcomas or lymphomas. The presence of melanosomes or premelanosomes signifies a melanoma, and small, membrane-bound granules with dense cores are features of endocrine neoplasms (Fig. 5-4). Another diagnostically useful granule is the characteristic crystal-containing granule of an insulinoma derived from the pancreatic islets.

Tumor Markers

Tumor markers are products of neoplasms that can be detected in the cells themselves or in body fluids. Some metastatic tumors may be so undifferentiated microscopically as to preclude even the distinction between epithelial and mesenchymal origin. Tumor markers rely on the preservation of characteristics of the progenitor cell or the synthesis of specialized substances by neoplastic cells to make this distinction. Determination of cell lineage of undifferentiated tumors is more than an academic exercise, because therapeutic decisions may be based on their appropriate identification. Among these diagnostically useful markers are such diverse products as immunoglobulins, fetal proteins, enzymes, hormones and cytoskeletal and junctional proteins. The ultimate tumor marker would be one that allows unequivocal distinction between benign and malignant cells. Unfortunately, no such marker exists.

Tumor markers can be detected in tissue sections by immunologic (immunohistochemistry, immunofluorescence) techniques (Fig. 5-5) and by molecular studies (in situ hybridization). Table 5-1 contains examples of marker studies that are used to identify the tissue of origin of tumors.

In addition to their use in identifying the lineages of malignancies, tumor-associated antigens are also used in

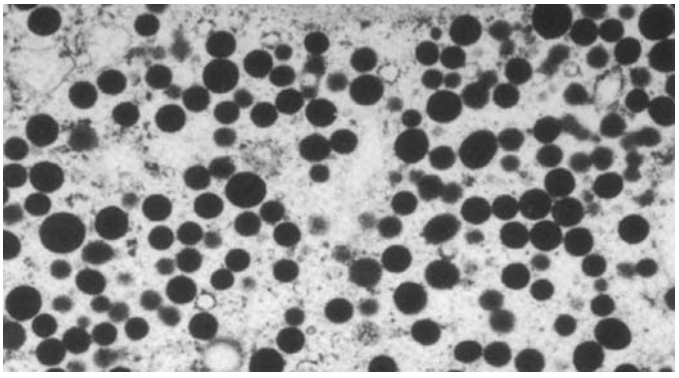

FIGURE 5-4. Electron micrograph of a metastatic cancer of the adrenal medulla (pheochromocytoma). The neuroendocrine origin of this poorly differentiated tumor was identified by the presence of characteristic cytoplasmic secretory granules.

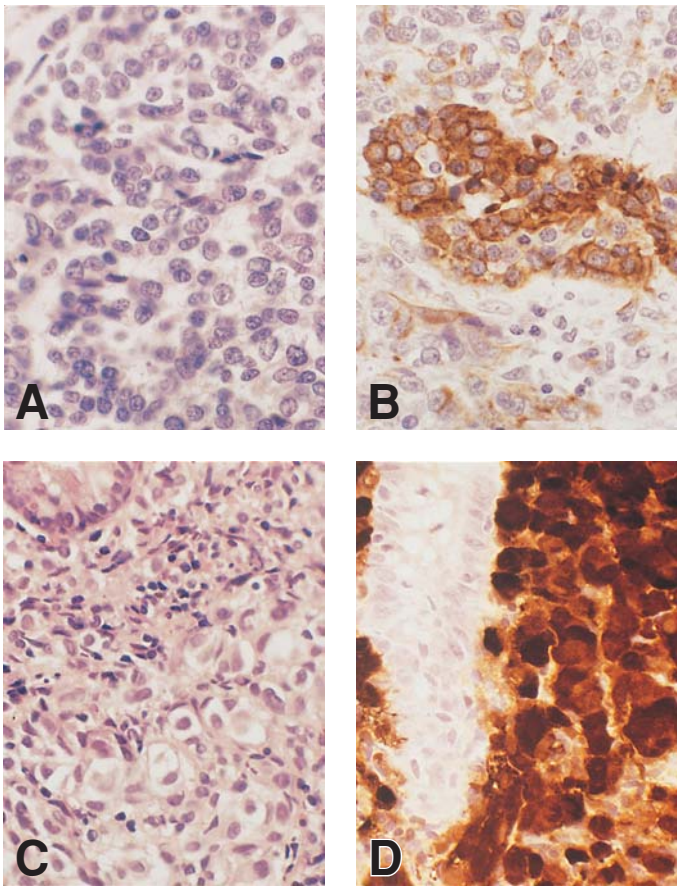

FIGURE 5-5. Tumor markers in the identification of undifferentiated neoplasms. A. A poorly differentiated metastatic bladder cancer is difficult to identify as a carcinoma with the hematoxylin and eosin stain. **B.** A section of the tumor depicted in **A** is positive for cytokeratin with an immunoperoxidase stain and is identified as carcinoma. **C.** A metastasis to the colon of an undifferentiated malignant melanoma is not pigmented, and its origin is unclear. **D.** An immunoperoxidase stain of the tumor shown in **C** reveals numerous cells positive for S-100 protein, a commonly used marker for cells of melanocytic origin.

TABLE 5-1
FREQUENTLY USED MARKERS TO IDENTIFY TUMORS

Marker	Target Cells
Epithelial Cells	
Cytokeratins (CKs)	Carcinomas, mesothelioma
CK7	Many nongastrointestinal adenocarcinomas
CK20	Gastrointestinal and ovarian carcinomas, urothelial carcinomas, Merkel cell tumor
Epithelial membrane antigen (EMA)	Carcinomas, mesothelioma, some large cell lymphomas
Ber-Ep4	Most carcinomas, but not in mesothelioma
B72.3 (tumor associated)	Many adenocarcinomas, but not in mesothelioma
Carcinoembryonic antigen (CEA)	Many adenocarcinomas of endodermal origin but not in others (e.g., renal, mesothelioma)
Mesothelial Cells	
Cytokeratins CK5/6	Mesothelioma
Vimentin	Mesothelioma
HBME	Mesothelioma, thyroid tumors
Calretinin	Mesothelioma
Melanocytes	
HMB-45	Malignant melanoma
S-100 protein	Malignant melanoma, glial cells
Mel A	Malignant melanoma
Neuroendocrine and Neural Cells	
Chromogranins, particularly chromogranin A	Neuroendocrine tumors
Synaptophysin	Neuroendocrine tumors
CD57	Neuroendocrine tumors, T and NK cells, Schwann cells
Glial Cells	
Glial fibrillary acidic protein (GFAP)	Astrocytoma and other glial tumors
Mesenchymal Cells	
Vimentin	Most sarcomas
Desmin	All types of muscle tumors
Muscle-specific actin	Muscle tumors, myofibroblast tumors
CD99	Ewing sarcoma, peripheral neuroectodermal tumors (PNETs), acute lymphoid and myeloid leukemias

Marker	Target Cells
Specific Organs	
Prostate-specific antigen (PSA)	Prostatic cancer
Prostate-specific alkaline phosphatase (PSAP)	Prostate cancer
Thyroglobulin	Thyroid cancer
α-Fetoprotein (AFP)	Hepatocellular carcinoma, yolk sac tumor
HepPar1	Hepatocellular carcinoma
WT1	Wilms tumor, some mesotheliomas
Placental alkaline phosphatase (PLAP)	Seminoma, embryonal carcinoma
Human chorionic gonadotropin (hCG)	Trophoblastic tumors
CA19-9	Pancreatic and gastrointestinal carcinomas
CA125	Ovarian carcinoma, endometrial carcinoma, some other nongynecologic tumors (pancreas, mesothelioma)
Calcitonin	Medullary carcinoma of the thyroid
CD Markers	
CD1	Some T-cell leukemias, Langerhans cell proliferations
CD2	T cells, T-cell malignancies
CD3	T cells, T-cell malignancies
CD4	T cells, T-cell malignancies, monocytes, monocytic malignancies
CD5	T cells, some B-cell malignancies
CD8	Suppressor T cells, some T-cell malignancies
CD10 (common ALL antigen, CALLA)	Acute lymphoblastic leukemia, some B-cell lymphomas, renal cell carcinomas
CD15	Reed-Sternberg cells, some T cells, some myeloid leukemias, many adenocarcinomas, but not in mesothelioma
CD19	B cells, B-cell malignancies
CD20	B cells, B-cell malignancies
CD30	Hodgkin disease, anaplastic large cell lymphoma
CD33	Myeloid leukemias

(*continued*)

TABLE 5-1
FREQUENTLY USED MARKERS TO IDENTIFY TUMORS (*Continued*)

Marker	Target Cells
CD34	Acute myeloid or lymphoblastic leukemias, some spindle cell tumors
CD117 (c-Kit)	Chronic myeloid leukemia, gastrointestinal stromal tumors, seminomas, also tumors of lung, breast, endometrium, urinary bladder
Non-CD Leukemia/Lymphoma Markers	
κ Light chain	B-cell malignancies
λ Light chain	B-cell malignancies
TdT	Acute lymphoblastic leukemia
Bcl-1 and cyclin D1	Mantle cell lymphoma
von Willebrand factor (vWF)	Vascular neoplasms
CD31	Vascular neoplasms, endothelial cells
CD34	Bone marrow stem cells, vascular neoplasms (endothelial cells)
Lectins	Vascular neoplasms
CD43	Almost all leukocytes
CD56	NK cells

CA = cancer antigen; CD = cluster designation; NK = natural killer; TdT = terminal deoxynucleotidyl transferase.

other ways. Blood levels of tumor antigens are helpful in following the development of metastases and progression of the tumor after the primary neoplasm has been treated. Representative examples include carcinoembryonic antigen (CEA) for gastrointestinal tumors, cancer antigen (CA) 125 for ovarian carcinoma and prostate-specific antigen (PSA) for prostate cancer. Tumor markers can be detected in blood using immunoassays (e.g., enzyme-linked immunosorbent assay [ELISA]) on serum, immunologic analyses of circulating blood cells (flow cytometry), electrophoretic separation of blood proteins and other methodologies. As effective as analysis of blood levels for tumor-produced substances may be in following a tumor's course, application of such analyses to screening for tumors has generally met with little success.

Some tumor antigens may also be used to make important therapeutic decisions (e.g., estrogen/progesterone receptors and HER2/neu in breast cancer, epidermal growth factor receptor [EGFR] for lung cancer and c-kit for gastrointestinal stromal tumors). Tumor antigens may also be useful therapeutic targets, as illustrated by HER2/neu for breast cancer and CD20 for B-cell lymphoma.

INVASION AND METASTASIS

Two properties that are unique to cancer cells are the ability to invade locally and the capacity to metastasize to distant sites. These characteristics are responsible for the vast majority of deaths from cancer; the primary tumor itself (e.g., breast or colon cancer) is generally amenable to surgical resection.

Direct Extension Damages Involved Organs and Adjacent Tissues

Most carcinomas begin as localized growths confined to the epithelium where they arise. As long as these early cancers do not penetrate the basement membrane on which the epithelium rests, such tumors are called ***carcinoma in situ*** (Fig. 5-6). In this stage, it is unfortunate that in situ tumors are asymptomatic, because they are invariably curable. When in situ tumors acquire invasive potential and extend through the underlying basement membrane, they can compromise neighboring tissues and metastasize. In situations in which cancer arises from cells that are not confined by a basement membrane—such as connective tissue cells, lymphoid elements and hepatocytes—an in situ stage is not defined.

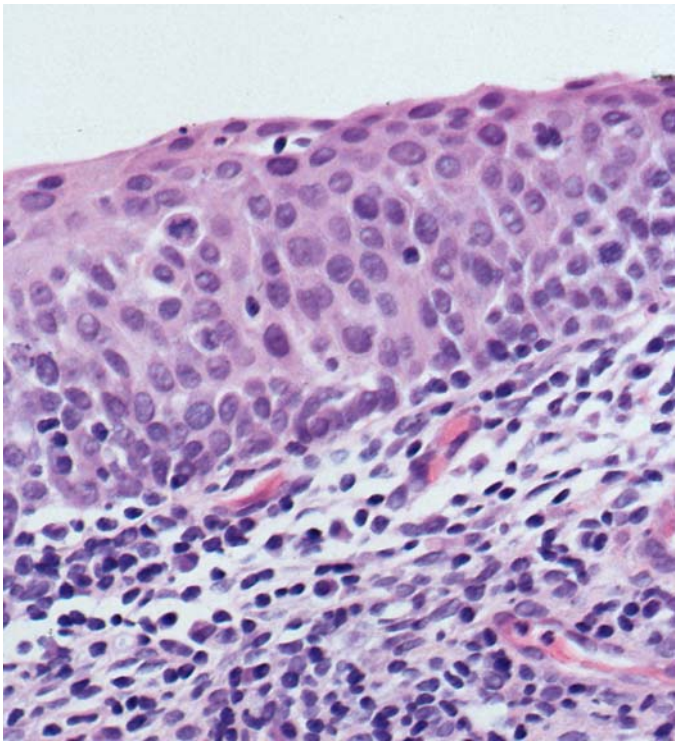

FIGURE 5-6. Carcinoma in situ. A section of the uterine cervix shows neoplastic squamous cells occupying the full thickness of the epithelium and confined to the mucosa by the underlying basement membrane.

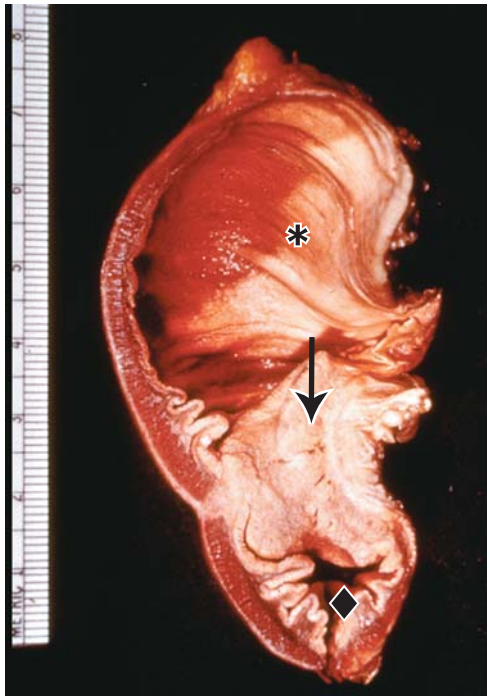

FIGURE 5-7. Adenocarcinoma of the colon with intestinal obstruction. The lumen of the colon at the site of the cancer is narrow (*arrow*). The colon above the obstruction is dilated (*). The colon distal to the stricture is normal caliber (♦).

Malignant tumors growing within the tissue of origin may also extend beyond the confines of that organ to involve adjacent tissues. The growth of the cancer is occasionally so extensive that replacement of the normal tissue results in functional insufficiency of the organ. Such a situation is not uncommon in primary liver cancer. Brain tumors, such as astrocytomas, infiltrate the brain until they compromise vital regions. The direct extension of malignant tumors within an organ may also be life-threatening because of their location. A common example is intestinal obstruction produced by colon cancer (Fig. 5-7).

The invasive growth pattern of cancers may secondarily impair the function of an adjacent organ. Squamous carcinoma of the cervix frequently grows beyond the genital tract to obstruct the ureters or produce vesicovaginal fistulas. Neglected cases of breast cancer are often complicated by extensive skin ulceration. Even small tumors can produce severe consequences when they invade vital structures. A small lung cancer can cause a bronchopleural fistula when it penetrates the bronchus or exsanguinating hemorrhage when it erodes a blood vessel. The agonizing pain of pancreatic carcinoma results from direct extension of the tumor to the celiac nerve plexus. Tumor cells that reach serous cavities (e.g., those of the peritoneum or pleura) spread easily by direct extension or can be carried by the fluid to new locations on the serous membranes. The most common example is the seeding of the peritoneal cavity by certain types of ovarian cancer (Fig. 5-8).

Metastatic Spread Is the Most Common Cause of Cancer Deaths

Metastasis (Greek, "displacement") is the migration of malignant cells from one site to another noncontiguous site. The invasive properties of malignant tumors bring them into contact with blood and lymphatic vessels, which they can also penetrate, and through which they disseminate to distant sites. They may also reach body cavities (e.g., pleural space), and so spread via those routes as well.

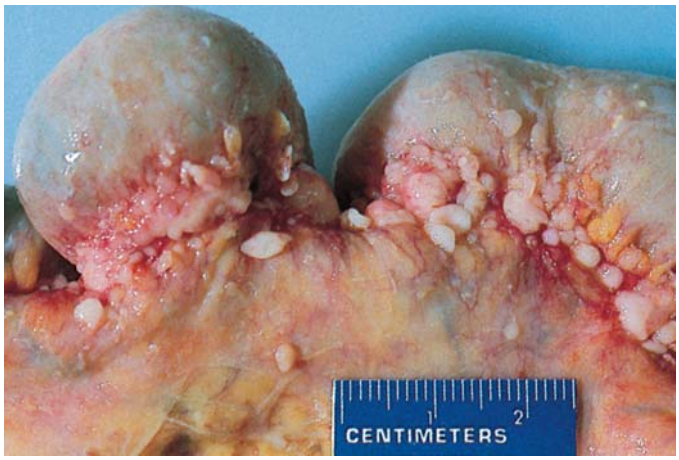

FIGURE 5-8. Peritoneal carcinomatosis. The mesentery attached to a loop of small bowel is studded with small nodules of metastatic ovarian carcinoma.

Hematogenous Metastases

Cancer cells often invade capillaries and venules, but thicker-walled arterioles and arteries are relatively resistant to their attack. Before they can form viable metastases, circulating tumor cells must lodge in the vascular bed of the metastatic site (Fig. 5-9). Here they attach to, and then traverse, blood vessel and lymphatic walls. Often, the location of a primary tumor with regard to blood or lymph flow determines the distribution of the initial metastases from that tumor. Thus, abdominal tumors that seed the hepatic portal system may cause liver metastases; other tumors penetrate systemic veins that eventually drain into the vena cava and hence to the lungs. Breast cancers first metastasize to regional lymph

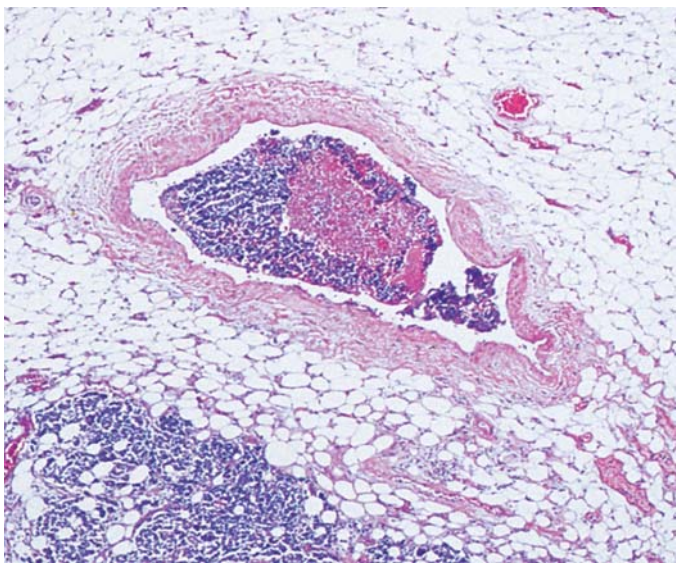

FIGURE 5-9. Hematogenous spread of cancer. A malignant tumor (*bottom*) has invaded adipose tissue and penetrated into a small vein.

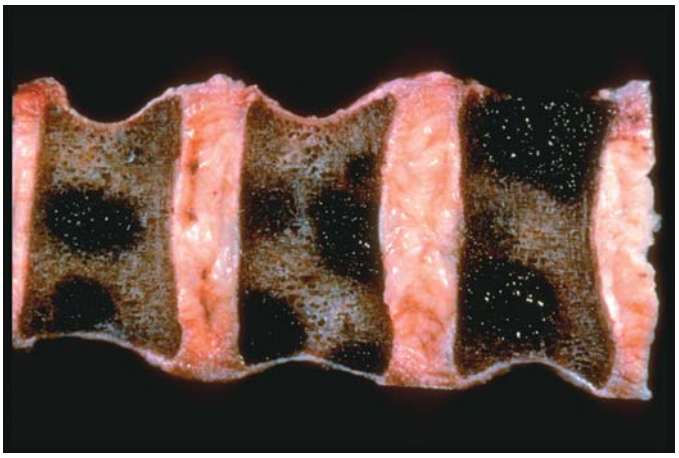

FIGURE 5-10. Multiple pigmented metastases in the vertebral bodies in a patient who died of malignant melanoma.

nodes because of the direction of lymphatic flow. More widespread metastatic disease may result from extensive early dissemination of tumor cells or from secondary spread from early metastatic foci (Fig. 5-10).

Lymphatic Metastases

Basement membranes envelop only large lymphatic channels; lymphatic capillaries lack them. Once in lymphatic vessels, itinerant tumor cells are carried to regional draining lymph nodes. There, they first lodge in the marginal sinus and then extend throughout the node. Lymph nodes bearing metastatic deposits may be enlarged to many times their normal size, often exceeding the diameter of the primary lesion (Fig. 5-11).

The regional lymphatic pattern of metastasis is most prominently exemplified by breast cancer. The initial metastases are almost always lymphatic, and these regional lymphatic metastases have considerable prognostic significance. Cancers that arise in the lateral aspect of the breast characteristically spread to axillary lymph nodes; those arising in the medial portion drain to the internal mammary thoracic lymph nodes.

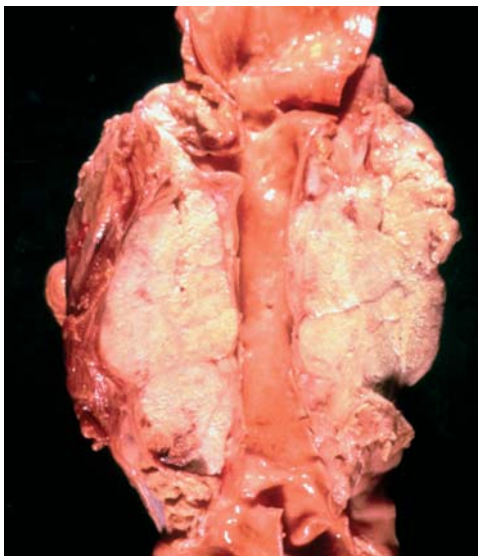

FIGURE 5-11. Metastatic carcinoma in periaortic lymph nodes. The aorta has been opened and the nodes bisected.

Lymphatic metastases are occasionally found in lymph nodes far from the primary tumor site. For example, the first sign of some abdominal cancers may be an enlarged supraclavicular node. A graphic example of the relationship of lymphatic anatomy to the spread of malignant tumors is afforded by cancers of the testis. Rather than metastasizing to inguinal nodes, as do other tumors of the male external genitalia, testicular cancers typically involve the draining abdominal periaortic nodes. The explanation lies in the descent of the testis from an intra-abdominal site to the scrotum, during which it is accompanied by its own lymphatic supply.

Seeding of Body Cavities

Malignant tumors that arise in organs adjacent to body cavities (e.g., ovaries, gastrointestinal tract and lung) may shed malignant cells into these spaces. Such body cavities principally include the peritoneal and pleural cavities, although occasional seeding of the pericardial cavity, joint space and subarachnoid space is observed. Similar to tissue culture, tumors in these sites grow in masses and often produce fluid (e.g., ascites, pleural fluid), sometimes in very large quantities. Mucinous adenocarcinoma may also secrete copious amounts of mucin in these locations.

Organ Tropisms of Metastases

It was recognized more than a century ago that the distribution of metastases in breast cancer is not random. In 1889, Paget proposed that the spread of tumor cells to specific secondary sites depends on compatibility between the tumor cells (the seed) and favorable microenvironmental factors in the secondary site (the soil). For example, cancers of the breast, prostate and thyroid metastasize to bone, a tropism that suggests a favored "soil." Conversely, despite their size and abundant blood flow, neither the spleen nor skeletal muscle is a common site of metastases. There is evidence that tumor-associated stromal cells in fact "plow the road" for tumor spread to particular sites that are suitable to the metastatic survival of implants from that tumor (see below).

STAGING AND GRADING OF CANCERS

Cancer Staging Describes the Extent of Spread

In an attempt to predict the clinical behavior of a malignant tumor and to establish criteria for therapy, many cancers are staged: they are assessed using specific protocols that help determine the detectable extent of their spread.

The choice of surgical approach, or the selection of treatment modalities, is influenced by the stage of a cancer. Moreover, most statistical data related to cancer survival are also based on this criterion. The significant criteria used for staging vary with different organs. Commonly used criteria include:

- Tumor size
- Extent of local growth, whether within or out of the organ
- Presence of lymph node metastases
- Presence of distant metastases

These patterns have been codified in the international **TNM cancer staging system,** in which "T" refers to the size and local extent of the primary tumor, "N" to the level of regional node metastases and "M" to the presence of distant metastases. Thus, for example, a breast cancer that is staged at T3N2M0 is a large primary tumor (T3) that has involved axillary lymph nodes moderately (N2) but has not detectably spread to distant sites (M0). The specific definitions of each T, N or M number vary among different tumors. As well, some tumor types, like central nervous system (CNS) tumors and hematologic malignancies, are staged according to different systems.

Cancer Grading Reflects the Architecture and Cytology of Tumors

Well-differentiated tumors are referred to as low grade, and poorly differentiated neoplasms are regarded as high grade. Cytologic and histologic grading, which are necessarily subjective and at best semiquantitative, are based on the degree of anaplasia and on the number of proliferating cells. The degree of anaplasia is determined from the shape and regularity of the cells and from the presence of distinct differentiated features, such as functioning gland-like structures in adenocarcinomas or epithelial pearls in squamous carcinomas. The presence of such characteristics identifies a tumor as well differentiated. By contrast, the cells of poorly differentiated malignancies bear little resemblance to their normal counterparts. Evidence of rapid growth is provided by (1) large numbers of mitoses, (2) atypical mitoses, (3) nuclear pleomorphism and (4) tumor giant cells. Most grading schemes classify tumors into three or four grades of increasing malignancy (Fig. 5-12). The general correlation between the cytologic grade and the biological behavior of a neoplasm is not invariable: there are many examples of tumors of low cytologic grades that exhibit substantial malignant properties. Thus, in most cases, staging is a more important criterion in predicting a tumor's course and influencing therapeutic decisions than is grading.

The Biology and Molecular Pathogenesis of Cancer

Normal cells, even those that divide the most rapidly (e.g., myelocytes, intestinal mucosal cells), are exquisitely controlled in the rate and location of their proliferation and accumulation. Cancer arises with accumulated DNA mutations within a single cell. When enough mutations have occurred, the cell escapes growth control and eventually acquires additional mutations that permit local invasion and subsequent spread through vascular and lymphatic channels.

For most of recorded history, cancer was considered to be simply due to a mysterious act of God. That is, the causation of cancer was not inherently comprehensible. However, in the late 18th century, specific causes of cancer were first identified. At that time, John Hill of London proposed that exposure to tobacco caused cancer. Shortly thereafter, in 1775, Sir Percival Pott described scrotal cancer caused by soot among chimney sweeps in London. More than a century later, bladder cancer was reported in aniline dye workers in Germany.

In modern times, major events in our understanding of oncogenesis include:

- 1911: F. Peyton Rous first described an avian cancer as being caused by a filterable agent (virus).
- 1920s: Human exposure to x-rays via fluoroscopy led to cancer.
- 1941: Berenblum first proposed the two-step (initiation/promotion) theory of chemical carcinogenesis.
- 1953: Watson and Crick identified DNA as the genetic material of cells and elucidated the structure of DNA.
- 1971: A. G. Knudson reported the involvement of two mutated alleles of the retinoblastoma (Rb) gene in the development of retinoblastomas and named these genes tumor suppressors.
- 1974: The gene responsible for defective DNA repair in the skin disease xeroderma pigmentosum was linked to visceral cancers.

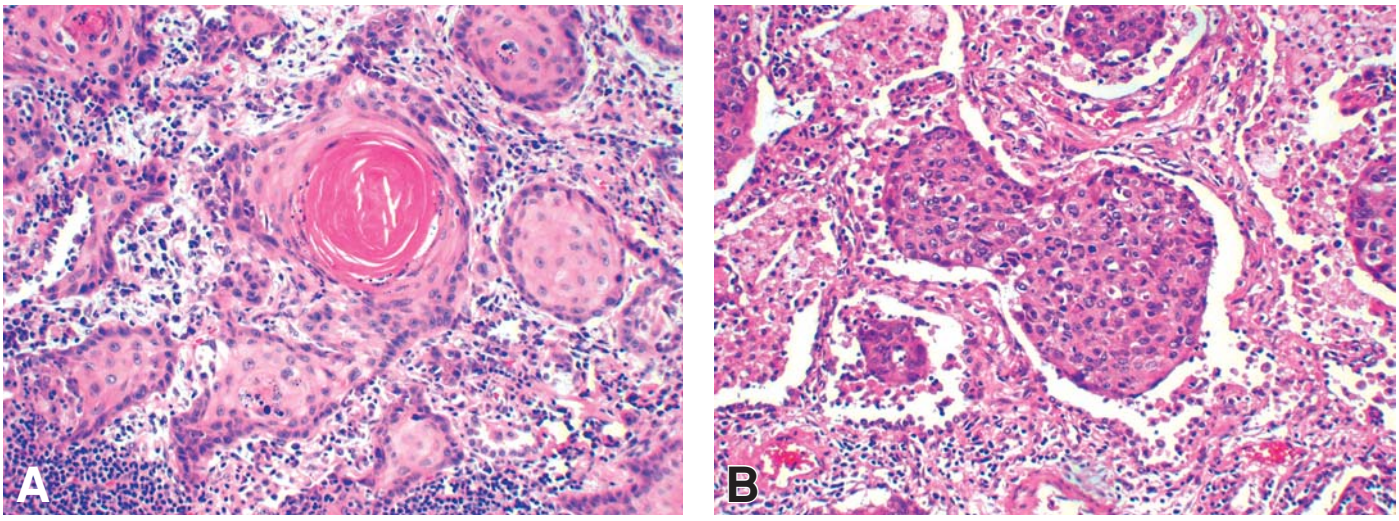

FIGURE 5-12. Cytologic grading of squamous cell carcinoma of the lung. A. Well-differentiated (grade 1) squamous cell carcinoma. The tumor cells bear a strong resemblance to normal squamous cells and synthesize keratin, as evidenced by epithelial pearls. **B.** Poorly differentiated (grade 3) squamous cell carcinoma. The malignant cells are difficult to identify as being of squamous origin.

- 1976: Bishop and Varmus demonstrated mammalian genetic homologs, called **proto-oncogenes,** of viral transforming genes **(oncogenes)**. When mutated, these cellular genes may become growth-promoting genes that can lead to cancer.

Substantial progress has been made in understanding neoplasia by the study of human tumors. Nonetheless, much of our appreciation of the processes involved in cancer development and spread has been derived from experiments in cells in culture, laboratory animals and genetically modified species. The applicability of those studies to oncogenesis in people should not always be assumed.

NORMAL PROCESSES THAT REGULATE CELLS AND INHIBIT ONCOGENESIS

As we will see shortly, cancer develops as a consequence of genetic changes in cells, leading to development, and often spread, of a tumor that is potentially fatal. Several critical cellular processes protect the organism and prevent tumor development. These processes are closely related, and intertwined: cell cycle regulation, DNA repair and telomerase activity. The next several pages describe how these cellular defenses operate and open the door to an understanding as to how they can be, and are, subverted during oncogenesis. As we will see, these defense mechanisms offer clues as to approaches to attacking tumors.

What is a gene? A century before the discovery of the structure of DNA, Gregor Mendel described discrete units of heredity that were later called genes. With the elucidation of the genetic code, the term "gene" came to signify a DNA string that defined the amino acid sequence of a protein. However, the idea of a gene is now being reexamined because regions of the genome previously thought to be "noncoding" are now known to produce new classes of RNAs that influence gene expression. Moreover, regulatory DNA sequences may be located adjacent to, at a large distance from and even within the protein-coding sequences. The contemporary notion of a gene entails interdependent structures and layers and webs of control involving DNA sequences, RNA species, regulatory proteins and a complex signaling apparatus. Thus, the precise definition of a gene remains unsettled.

Mutations and polymorphism: DNA replication is not perfect, and with each cell division about 1 nucleotide in 10^9 differs from the original. Thus, although the vast majority (99.6%) of base pairs in somatic cells are identical within the human race, two humans differ on average by about 2.4×10^7 base pairs out of 6×10^9 base pairs.

Variations in DNA sequences may result from germline changes or acquired alterations in somatic DNA as a result of single nucleotide substitutions or insertion or deletion of one or more nucleotides. **Polymorphisms** are defined as variations in DNA sequence that are not associated with known diseases. **Mutations** are comparable genetic changes that contribute to disease. (Mechanisms and types of DNA sequence variations are described in Chapter 6.)

The Normal Cell Cycle Drives Cellular Proliferation

Since most cancers are characterized by uncontrolled cellular proliferation, an understanding of the normal cell cycle is important. We focus here only on those aspects of the cell cycle that are commonly aberrant in the pathogenesis of cancers.

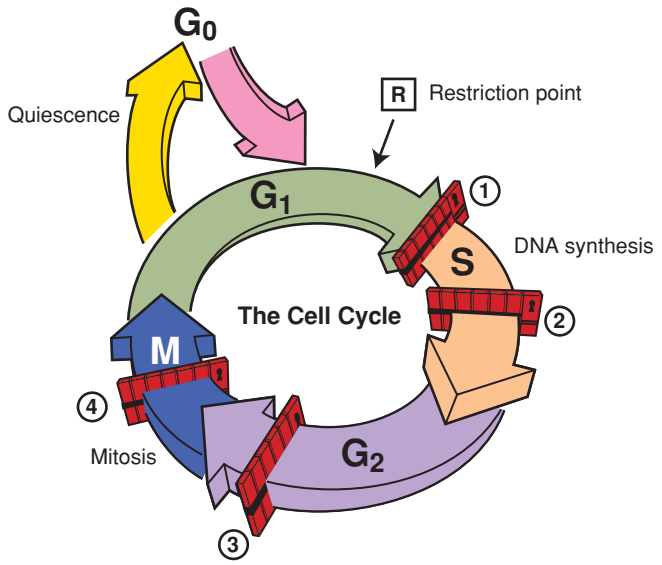

FIGURE 5-13. Normal cell cycle. The phases of the cell cycle, with key checkpoints indicated. *R* = restriction point.

Phases of the Cell Cycle

Cells may be cycling or quiescent. Those that replicate continuously (e.g., intestinal mucosa, hematopoietic progenitor cells) always transition from mitosis (M phase) to G_1, which is the antechamber to further cell division. By contrast, cells that replicate infrequently (e.g., hepatocytes) are in a quiescent phase, G_0. Cells in G_0 may be propelled to enter G_1 by various stimuli. They then replicate their DNA in S phase and proceed to G_2 and ultimately M (Fig. 5-13). When they are in an actively dividing mode, cells progress directly from M phase into G_1 by diverse stimuli. Thereafter, they initiate DNA replication, which occurs in S phase. G_2 follows S, and ultimately cells undergo mitosis (M phase). Following mitosis, cells again enter G_1 if they are in an actively dividing mode.

Cyclins and Cyclin-Dependent Kinases Driving Cell Cycle Progression

A cell's progress through the proliferative cycle is dependent on two important classes of regulatory molecules, **cyclins** and **cyclin-dependent kinases (CDKs)** (Fig. 5-14). These form a series of dimeric complexes that propel cell proliferation. Once a cell is stimulated to divide (e.g., by growth factors), D-type cyclins are activated first and form complexes of two CDKs (4 and 6). These cyclin D–CDK complexes play key roles in inactivating the retinoblastoma protein (pRb; see below). Together with cyclin E–CDK2 complexes they drive the cell into S phase. Other cyclins, A and then B, bind to CDKs (1 and 2), then push the cycle to completion.

Regulation of Cyclins and CDKs Provides Critical Protection against Tumor Development

Considering their importance in driving cell proliferation, it is not surprising that the activities of cyclins and CDKs

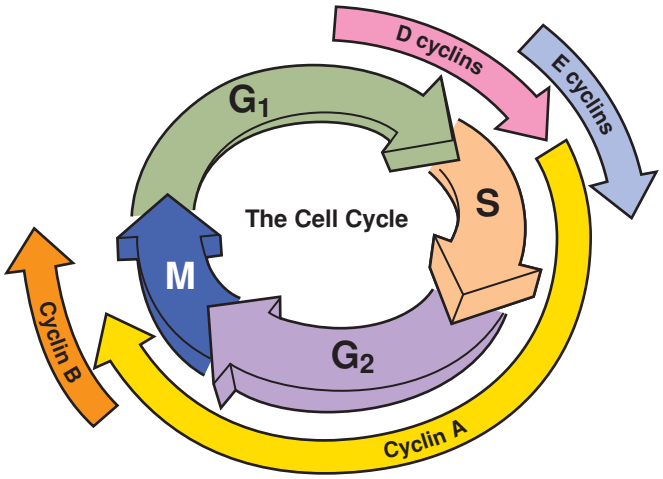

FIGURE 5-14. Activities of the cyclins and cyclin-dependent kinases (CDKs) in the cell cycle. The D cyclins mediate passage through G_1 and into early S phase. The E cyclins overlap D cyclins early in S phase. Cyclin A shepherds the cell through S and G_2 phases, into M phase. Finally, cyclin B overlaps cyclin A in late G_2 phase and directs the cell through mitosis (M phase).

are carefully controlled. Restraint of the cyclin–CDK system occurs in several ways (Fig. 5-15).

Decreasing Cyclin Availability

CDKs require activation by cyclins. Thus, the availability of cyclins limits the activity of CDKs. Levels of most cyclins fluctuate with the cell cycle: most are synthesized only when needed, and then, when the cell has traversed that part of the cycle for which a particular cyclin is required, that cyclin is ubiquitinated and degraded by the ubiquitin–proteasome system (UPS; see Chapter 1).

CDK Inhibitors

Several families of CDK inhibitors (CKIs) strongly inhibit cell proliferation and so collectively represent an important protective mechanism against oncogenesis. Not surprisingly, then, CKIs are commonly mutated in human cancers. CKIs mostly act by either binding the binary cyclin–CDK complexes or themselves binding with CDKs and preventing CDK activation by cyclins. The three major families of CKIs are:

- **INK4** proteins bind and inhibit CDKs 4 and 6 (*in*hibit cd*k4*), and prevent them from forming complexes with cyclin D. INK4 CKIs thus block cell cycle progression in G_1. There are several INK4 proteins: p15, p16, p18 and p19. As well, $p14^{ARF}$ is encoded by the same gene as $p16^{INK4a}$ but is an alternate reading frame (i.e., ARF). These proteins play important roles in regulating both CDKs and MDM2 (see Chapter 1 and below).
- **Cip/Kip** proteins bind and strongly block CDK2 and, to a lesser extent, CDK1. Thus, they take up where the INK4 family leaves off and inhibit the rest of the cell cycle. The best understood of the Cip/Kip proteins is $p21^{CIP}$ (also called $p21^{WAF1}$).
- **Rb** family members (see below) also target CDK2.

Expression of CKIs can be induced by senescence, contact inhibition, extracellular antimitogenic factors (e.g., transforming growth factor-β [TGF-β]) and the tumor suppressor protein p53 (see below).

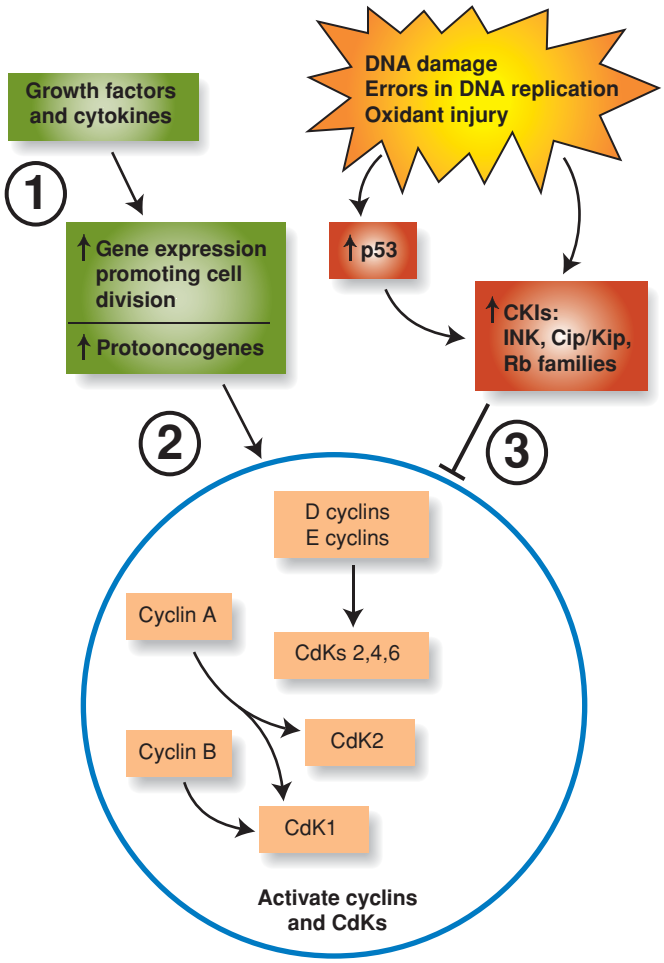

FIGURE 5-15. Activation and inhibition of the cyclins. 1. Activation. Cells receive signals via growth factors, cytokines and so forth that trigger the process of cell division. This leads to increased expression of genes that promote cell cycle progression, including a number of proto-oncogenes. **2. Actions of the early-phase cyclins.** D and E cyclins increase activity of cyclin-dependent kinases (CDKs) 2, 4 and 6. In addition, cyclin A activates CDKs 2 and 1, while cyclin B activates the latter. These CDKs drive cell cycle progression. **3. Inhibition.** Diverse stimuli, including errors in DNA replication, DNA damage and inhibitory signals of many kinds, may counteract the activating signals in **1.** These may do so by activating p53. Whether via p53 action or directly, these inhibitor stimuli increase production and activity of cyclin kinase inhibitors (CKIs), such as the INK family of proteins, CIP and KIP, as well as Rb. These families of CKIs block all the steps listed in **2.**

Other Forms of Inhibition of Cyclin–CDK Activities

In addition to mechanisms mentioned above, cells limit the ability of cyclin–CDK complexes to drive proliferation by selective posttranslational modification, largely phosphorylation, to inactivate some CDKs. Specific nuclear export systems also prevent cyclin–CDK dimers from accumulating in the nucleus, which is their site of activity. Both of these mechanisms support regulation supplied by other modalities mentioned above.

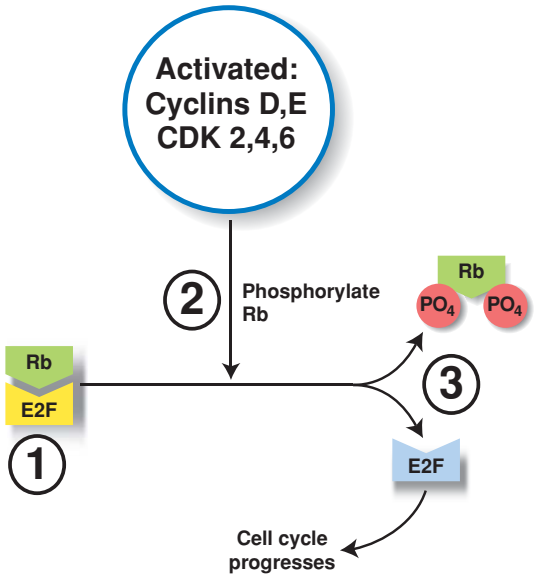

FIGURE 5-16. Role of cyclins and cyclin-dependent kinases (CDKs) in removing Rb-mediated blockade of cell cycle progression. 1. Normally Rb protein is complexed with E2F transcription factor. In this complex, E2F is inactive, yet it must be freed in order for cell division to proceed. **2.** Activated cyclins D and E, together with activated CDKs 2, 4 and 6, phosphorylate and then hyperphosphorylate Rb. **3.** This induces a conformational change that makes Rb release E2F, which is now free to direct transcription of proteins that help cell division to proceed.

Retinoblastoma Protein and Its Family

One of the most important mechanisms regulating the cell's commitment to division involves the family of retinoblastoma proteins, which principally act near the $G_1 \rightarrow S$ boundary. The prototype of these related proteins is $p105^{Rb}$ (pRb). Other members are related structurally and functionally, and for simplicity, we refer here only to pRb. pRb inhibits progression of the cell cycle by binding members of the **E2F** family of transcription factors. These E2F factors mediate cell entry into, and transit through, S phase by increasing transcription of downstream cyclins (A and E), as well as other proteins that promote DNA replication.

Binding of E2F by pRb blocks E2F activity. Phosphorylation of pRb by the complex of cyclin D–CDK4/6 (see above) alters pRb conformation, releasing E2F. E2F-mediated upregulation of other cyclins (A and E; see above), which, complexed to CDK2, again phosphorylate pRb, allows the cell cycle to progress (Fig. 5-16). The Rb system thus integrates many signals that control cell cycle progression.

Interestingly, Rb resumes its cell cycle inhibitory activity as cell division culminates. In anaphase, a protein phosphatase (PP1) dephosphorylates pRb, allowing it to bind E2F again, thus preventing further division.

Landmark Transitions in the Cell Cycle

The major cell cycle transitions are $G_1 \rightarrow S$ and $G_2 \rightarrow M$. Passage from $G_1 \rightarrow S$ occurs when the activity of complexes involving cyclins A and E overwhelm inhibition by the Cip/Kip family of inhibitors. Cells progress from $G_2 \rightarrow M$ when cyclin B–CDK1 complexes are activated by removing inhibitory phosphorylation of CDK1.

Cell Cycle Checkpoints

Transit from one phase to another of the cell cycle is regulated at **checkpoints,** namely, times when progression in the cell cycle can be arrested, should the need arise. There are checkpoints in G_1, before entry into S, during S and in G_2 before entry into M. These are activated by DNA damage. Others, during S phase and during M phase, are activated differently (see below).

Checkpoints Activated by DNA Damage

Safeguarding the integrity of the cell's DNA requires ceaseless vigilance, of which specific mechanistic details are discussed below. However, once DNA damage is sensed (by ATM and ATR proteins; see below), p53 is activated (Fig. 5-17). If the cell is in G_1, p53 increases production of Cip/Kip CKIs, blocking further progress in cell division. If the cell is in G_2, there are two means by which cycling is stopped. One involves p53-mediated downregulation of cyclin B and CDK1. The other involves two related enzymes called checkpoint kinases (**chk1, chk2;** see below), which block cell cycle progression immediately. These kinases are also responsible for blocking the cycle at the S phase DNA damage checkpoint as well.

Restriction Point

During G_1, the cell commits itself to enter S phase at the **restriction point (R)**. Here, the cell crosses the Rubicon and decides whether to proceed with mitosis or not. Past the R point, external forces driving or inhibiting mitosis no longer come into play (i.e., cell proliferation is determined only by intracellular mechanisms). The R point is activated by cyclin D–CDK4/6 phosphorylation of pRb, with consequent release of E2F (see above) to facilitate mitosis. *Loss of R-point control occurs in many cancers and deregulates progression through the cell cycle.*

Other Checkpoints

The duration of the proliferative cycle is finite. On occasion, the cell dawdles (usually because of exposure to a

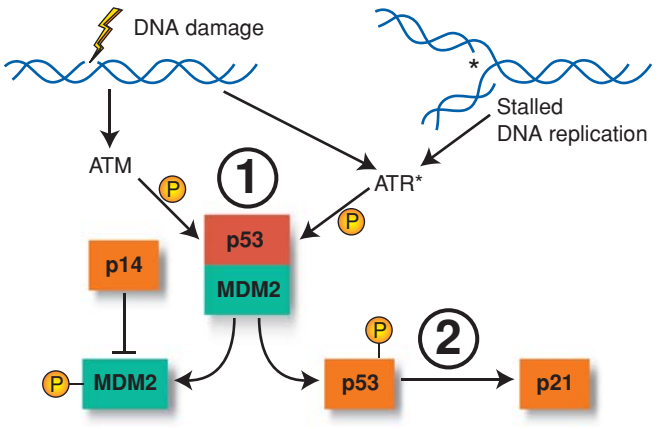

FIGURE 5-17. Linkage of DNA damage and replication stress to cell cycle arrest, via p53. 1. Both DNA damage and other interference with DNA replication activate the kinases ATM (ataxia telangiectasia mutated) and ATR (ATM and Rad3 related). These kinases phosphorylate p53, releasing it from binding to its inhibitor, MDM2. **2.** Activated p53 stimulates p21 (also called $p21^{CIIP1/WAF1}$).

toxic agent) in S phase. Should that happen, nature loses its patience and activates chk1 to block mitotic separation of incompletely duplicated chromosomes. This is called the **replication checkpoint**.

During M phase, there are elaborate controls to ensure that daughter cells each receive the correct complement of chromosomes. Thus, sensors at the points (kinetochores) where chromosomes attach to the mitotic spindle may activate a **spindle integrity checkpoint** if they sense that the segregation process is unbalanced or inaccurate. An additional mechanism involves an important enzyme, **Aurora B kinase,** which ensures that the kinetochore binds effectively and the mitotic spindle is effective, and so prevents improper segregation of chromosomes.

p53 in the Cell Cycle

As mentioned in Chapter 1, p53 has been called "the guardian of the genome." It coordinates cellular responses to DNA damage, mediates activation of G_1/S and G_2/M checkpoints and initiates apoptosis. Mechanisms underlying p53 activities include:

1. Normally, p53 is maintained at low levels by MDM2 (murine double minute), an E3 ubiquitin (Ub) ligase that conjugates p53 to Ub and triggers its proteasomal degradation (Fig. 5-18A; see Chapter 1).
2. The protein kinases **ATM** (ataxia telangiectasia mutated) and **ATR** (ATM and Rad3 related) recognize DNA damage and, in combination with chk1 and chk2 kinases, phosphorylate, and therefore activate, p53. Activation of p53 through these kinases or via telomere dysfunction (see Chapter 1 and below) contributes to cell cycle arrest (Fig. 5-17).
3. Activation of a cell cycle checkpoint requires a period of arrest to permit DNA repair. When p53 is phosphorylated, it dissociates from MDM2 and translocates to the nucleus.
4. In this location, p53 further promotes cell cycle arrest by stimulating production of $p21^{Cip1}$, one of the Cip/Kip family of CKIs (Fig. 5-18B).
5. If DNA is repaired, the block is removed and the cell cycle proceeds (Fig. 5-18B).
6. If DNA cannot be repaired, p53 triggers apoptosis (Fig. 5-18C).

It is important to appreciate that tumor cells often have mutations in genes that control cell cycle transit and that, whether these genes are mutated or not, many antineoplastic agents target cell cycle–related genes to try to limit the ability of cancer cells to divide. Mutations in cyclins or CDKs, for example, may render them impervious to the regulatory activities described above. Other alterations, in regulatory proteins like Cip/Kip CKIs or pRb, may eliminate one or another aspect of their ability to limit cell cycle progression.

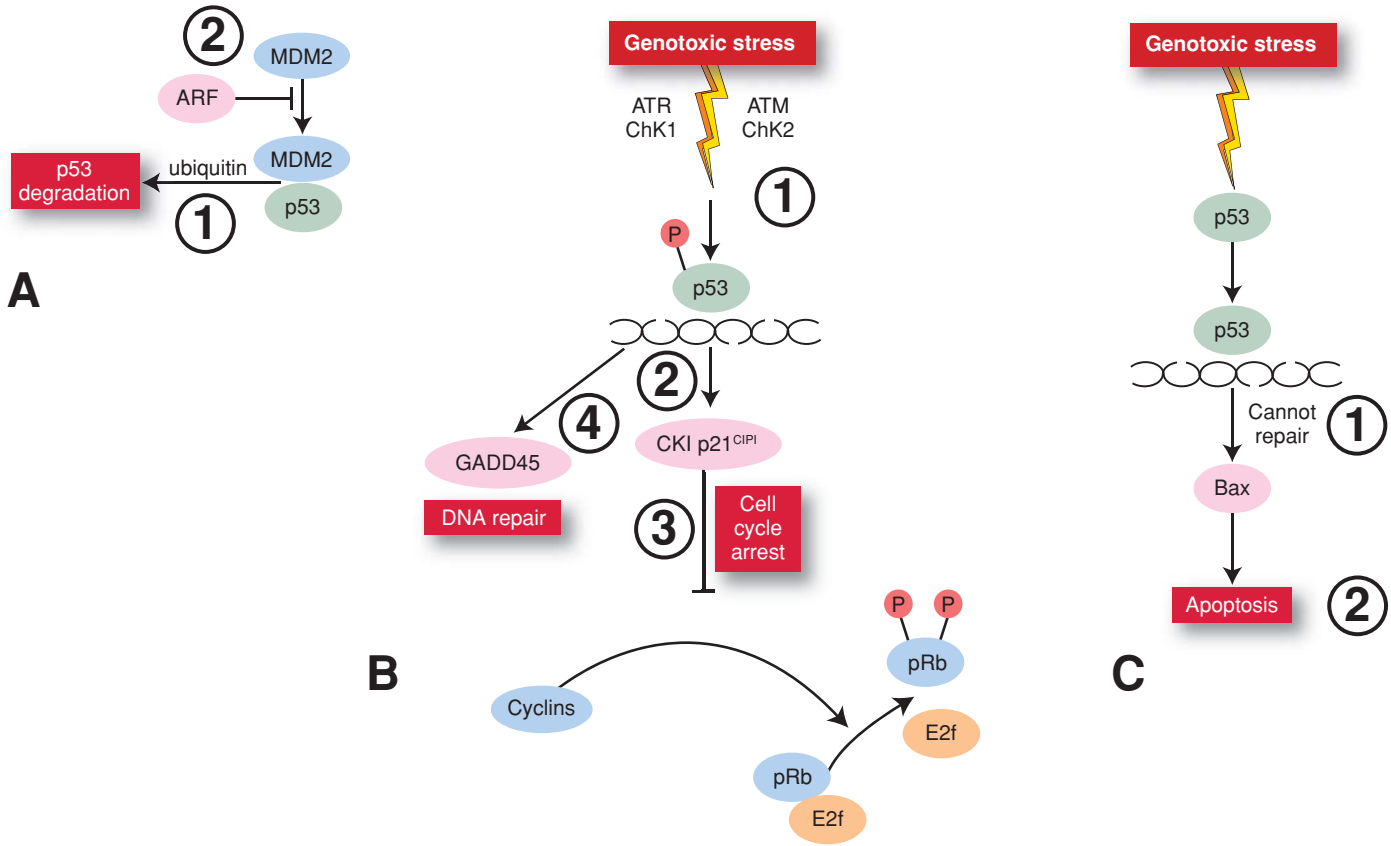

FIGURE 5-18. A. Regulation of p53 and MDM2 (murine double minute). 1. MDM2 is an E3 ubiquitin ligase that binds to and directs the inactivation of p53. **2.** MDM2 activity is inhibited by the tumor suppress $p14^{ARF}$. **B. 1.** In response to genotoxic stress (e.g., ionizing radiation, carcinogens, mutagens), ATR (ATM and Rad3 related) and ATM (ataxia telangiectasia mutated) increase p53, which does two things. **2.** It binds to DNA and upregulates transcription of several genes, including cyclin kinase inhibitor (CKI) $p21^{CIP1/WAF1}$. **3.** It also induces cell cycle arrest by preventing release of E2F from retinoblastoma protein (pRB). **4.** GADD45 promotes DNA repair. **C. 1.** Should DNA repair not be possible, p53 directs increased transcription of the proapoptotic protein Bax. **2.** Increased Bax triggers apoptosis.

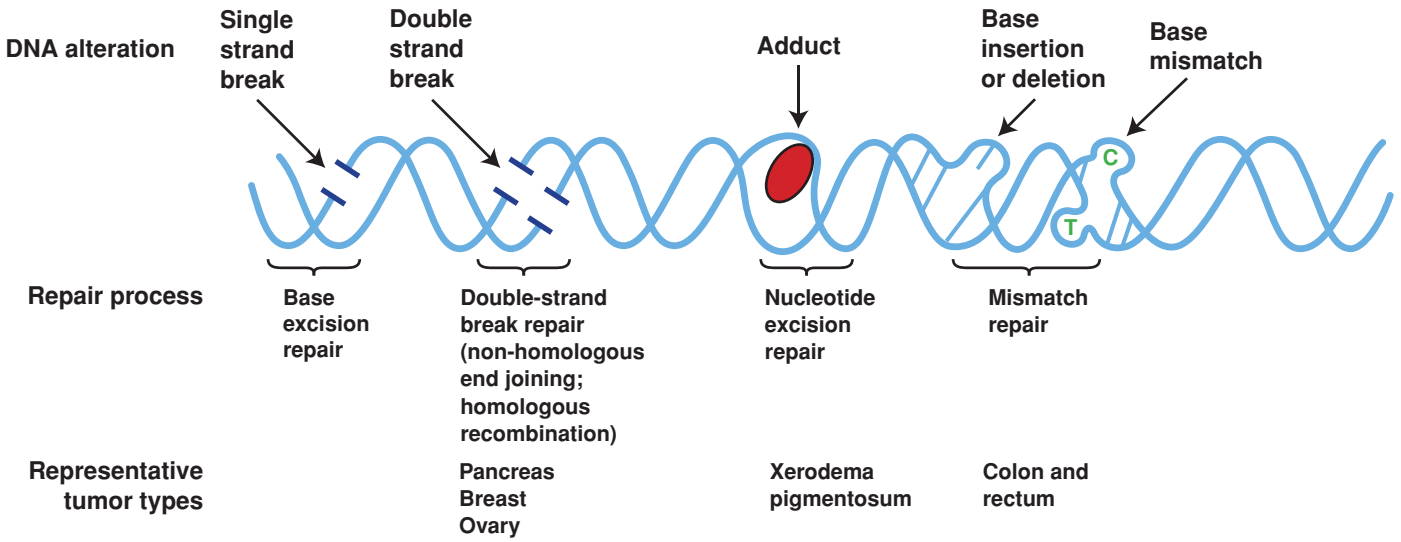

FIGURE 5-19. DNA damage and the mechanisms that repair DNA damage. Most forms of localized DNA damage are either (1) single-strand breaks, (2) double-strand breaks, (3) DNA adducts, (4) base insertions or deletions or (5) base mismatches. The mechanisms that repair these insults are, respectively, (1) base excision repair, (2) double-strand break repair, (3) nucleotide excision repair, and (4) and (5) mismatch repair. Some tumor types that arise from dysfunctional DNA repair mechanisms are indicated in conjunction with the mechanisms that tend to malfunction in those tumors.

DNA Repair Protects Cellular Genomes from Genotoxic Stresses

The DNA of the one hundred trillion (10^{14}) cells that constitute the human body is under relentless assault by both internal and exogenous stresses, including environmental chemicals, ultraviolet and ionizing radiation, reactive oxygen species (ROS) and an intracellular milieu that may break down the chemical bonds that hold DNA together. Cellular DNA is further at risk from the infidelity of DNA polymerases. Cells maintain genomic stability via diverse mechanisms that are ceaselessly vigilant in detecting and repairing such damage. In addition, these systems also communicate with cell cycle checkpoint regulators (see above) and apoptosis triggers, so that mutations are not transmitted to daughter cells. Collaborations among diverse proteins restore genomic integrity after such DNA modifications as single- and double-strand breaks, single nucleotide substitutions, base insertions and deletions of variable lengths and other perturbations of orderly and correct double-stranded DNA structure.

The importance of understanding these mechanisms extends beyond their roles in homeostasis and, if impaired, tumorigenesis. DNA repair systems may also protect tumors from genotoxic therapies. In this sense, they represent a key facet of tumor resistance to treatment and, therefore, important targets for current drug development.

DNA Repair Pathways

DNA damage may occur at different times in the cell cycle, be caused by diverse insults and reflect different types of alterations in DNA structure. Maintaining the integrity of a cell's genome thus requires multiple DNA repair processes, illustrated in Fig. 5-19.

Mismatch Repair

This pathway is mainly involved in repairing errors in DNA replication. From one somatic cell division to the next, the error rate in duplicating the genome is 1 miscopied base per 10^9 bases. In germ cells, it is even lower, 1 miscopied base in 10^{11}. The two polymerases that replicate human DNA (called Pol δ and ε) possess editing functions that have error rates of 1 base/10^{4-5}. The difference between the error rates of polymerase editing and the final product, 4–5 orders of magnitude, largely reflects the effectiveness of mismatch repair (MMR) processes (Fig. 5-20). MMR includes two overlapping systems, one that mainly corrects single base mismatches and another that fixes insertions and deletions caused by slippage during DNA replication.

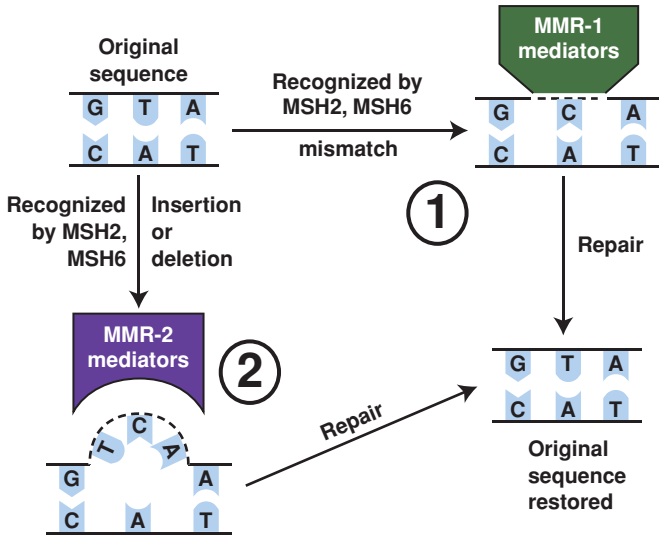

FIGURE 5-20. Mediators of mismatch repair (MMR). 1. A DNA single base mismatch (here, a C is present where a T should be) is recognized by two proteins, MSH2 and MSH6. These recruit a group of MMR repair enzymes, which correct the defect. **2.** If the mispairing is the result of a small insertion or deletion, a second group of MMR enzymes, MSH2 and MSH3, recognize the mistake and recruit another group of MMR mediators to correct the defect and restore the correct sequence.

Errors are recognized and repaired by a family of enzymes (e.g., MSH6, MSH2, MLH1; Fig. 5-20) that stop DNA replication at the G_2/M checkpoint, correct the mistake and then allow replication to continue. If the damage is irreparable, MMR enzymes activate apoptosis.

Defective MMR may be inherited or acquired. Acquired defects in MMR may reflect either mutations that develop over time in somatic cells or epigenetic silencing (see below) of a component of the MMR system. An important indicator of defective MMR is **microsatellite instability**. Microsatellites are short sequences of up to 6 base pairs that may be repeated as many as 100 times. They are common in the human genome and are inordinately prone to mutation, including changes in numbers of repeats. Microsatellite mutations are usually detected and repaired by MMR enzymes. If, however, they escape repair in germline or somatic cells, microsatellite mutations may indicate the likelihood of cancer developing (see below).

Nucleotide Excision and Repair

This process corrects distortions of DNA helical structure, such as are caused by bulky DNA adducts, by base oxidation by ROS derived from mitochondria or other sources or by ultraviolet (UV) and ionizing radiation (Table 5-2). Nucleotide excision and repair (NER) searches for DNA damage in two ways. One constantly scans the genome and the other identifies alterations that interfere with RNA transcription. Inherited defects in these NER detection systems are associated with human cancer syndromes. The first (scanning) pathway is deficient in **xeroderma pigmentosum,** and the second (transcription coupled) in **Cockayne syndrome**.

Once either NER system recognizes a defect, both pathways repair it similarly, via an enzyme called ERCC1. This enzyme is of considerable practical therapeutic importance. As mentioned above, effective DNA repair by tumor cells helps to protect them from chemotherapies that target DNA. For certain types of tumor, the activity (or lack thereof) of ERCC1 helps to predict the sensitivity of cancer cells to chemotherapy with such DNA-damaging agents as *cis*-platinum.

Base Excision Repair

Base excision repair (BER) is related to NER, and the two overlap somewhat in the types of DNA damage for which they are responsible (Table 5-2). BER mostly repairs chemical injury to DNA bases, such as hydrolysis of base–sugar bonds, single-strand breaks and small chemical changes in base structure. Such alterations occur 10^4 times/cell/day. Insults leading to BER are mostly caused by environmental and other chemicals, ROS and UV and ionizing radiation. Inherited defects in BER have not been described.

Double-Strand Break Repair

Double-strand breaks (DSBs) may be caused by ROS or ionizing radiation, or during DNA replication if replication is stalled at a single-strand break (Table 5-2). Such DNA lesions commonly lead to chromosome rearrangements, particularly when they occur, as they often do, in clusters.

Two related enzymes, ATM and ATR (see above, Fig. 5-17), are the sensors for DSBs, and each recognizes different types of DSBs. ATM identifies those that result from DNA damage (e.g., ionizing radiation). Once activated, ATM recruits chk2. ATR detects single-stranded DNA at stalled replication forks, whereupon it in turn activates chk1 (see above).

TABLE 5-2
TYPES OF DNA DAMAGE, THEIR COMMON CAUSES AND THE RESPECTIVE REPAIR PATHWAYS

Type of Damage	Causes	Repair Pathway
Base oxidation	Mitochondrial ROS Phagocyte-generated oxidants UV and ionizing radiation Smoking	NER, BER
Other base modifications	Chemotherapeutic drugs Neutrophil bactericidal enzymes Cigarette smoke Other environmental chemicals	BER
Alterations Perturbing DNA Architecture		
Additions	Errors in transcription, ROS UV light	NER
Interstrand DNA cross-links	Ionizing radiation Arrested DNA replication Environmental chemicals	Other[a]
Single-strand nicks	ROS Ionizing radiation Spontaneous loss of sugar–phosphate bonding	BER, NER
Double-strand breaks	Arrested DNA replication Ionizing radiation Chemical damage	HR, NHEJ

[a]Other mechanisms include Fanconi-related repair pathways.
BER = base excision repair; HR = homologous recombination; NER = nucleotide excision repair; NHEJ = nonhomologous end-joining; ROS = reactive oxygen species; UV = ultraviolet.

Both resulting complexes, ATM/chk2 and ATR/chk1, phosphorylate p53 and so activate cell cycle checkpoints, halting cell division until the break is fixed. DSBs are repaired either by **nonhomologous end-joining (NHEJ)** or by **homologous recombination (HR)**.

In HR, which is mostly active in S and G_2, the sister chromatid or the homologous chromosome is used as a template, to reproduce the original sequence. However, in so doing, two major types of genome alterations may result. If HR uses the homologous chromosome as a template for DNA repair, allelic differences between the two chromosomes may be lost (**loss of heterozygosity [LOH];** see below). As well, because repetitive sequences are abundant throughout the human genome, HR repair of a break that happens to occur in repetitive sequences in one chromosome may lead to use of an identical repetitive sequence on a nonhomologous chromosome as a template for recombination, thus generating a translocation. Several genes (e.g., BRCA1, BRCA2, PALB2) whose protein products are important for HR are often mutated or inactivated in many human tumors. This

may occur (see below) either as part of inherited cancer susceptibility syndromes or epigenetically during oncogenesis.

By contrast, NHEJ repairs DSBs by rejoining the broken ends. NHEJ thus restores DNA integrity but may not reproduce the original sequence (depending on the nature of the break). Furthermore, there is no guarantee that the ends that are so joined are in fact the broken ends of the same chromatid, in which case, translocations may result.

Unlike HR, NHEJ operates throughout the cell cycle. It is more efficient than HR and uses the Ku proteins (Ku70, Ku80), which are among the most abundant protein species within cells. NHEJ is the mechanism behind V(D)J recombination to generate diversity in B lymphocytes.

NHEJ generally functions well, and without many errors. However, it does not easily account for the original base order of the DNA sequences it joins. In settings in which there are multiple, clustered DSBs, NHEJ may link non-contiguous DNAs. It should be noted that defective NHEJ is not associated with any known inherited predispositions to developing cancer, nor is it commonly associated with oncogenesis.

HALLMARKS OF CANCER

Tumor development generally requires accumulation of changes in cellular behavior, many of which occur via mutation. Extensive and ongoing analyses of human tumors have uncovered a great many mutations. Not all changes so identified are equally important for tumor development and spread: some are more equal than others.

A relatively small number of genetic changes are fundamental to oncogenesis. These are called **"drivers."** It should be stressed that **driver mutations** may affect both DNA sequences that encode proteins and so-called noncoding sequences, since altered sequences and levels of untranslated RNAs (see below) and of regulatory regions may drive oncogenesis. Thus, the idea of driver mutations should be inclusive and should accommodate the complexities of regulation of gene expression and action.

Other mutations—"passengers" or "hitchhikers"—seem to be along for the ride. How they affect tumor development and progression, if at all, is unknown.

What is clear is that there are several basic activities that distinguish cells of solid malignancies from their normal counterparts. (Hematologic cancers develop and spread differently, and so share some, though not all, of these characteristics.) To understand oncogenesis and how cancer-related processes are being targeted therapeutically, the following hallmarks or attributes of malignant tumors should be appreciated:

- **Unregulated cellular proliferation:** In normal tissues, progression through the cell cycle (see above) is carefully regulated. However, cancer cells have acquired the ability to determine their own destinies, independently of normal restraints to multiplication.
- **Cellular immortalization:** While normal cells in culture have a limited potential for replication, cancer cells can multiply indefinitely. Thus, malignant cells circumvent the process of senescence and retain youthful vigor and ability to reproduce.
- **Evasion of programmed cell death (PCD):** Programmed cell death (see Chapter 1) can be activated by such factors as genomic instability and inhospitable cellular microenvironments. Cancer cells often develop strategies that circumvent destruction via such suicide programs.
- **Stimulation of vascular proliferation:** Expansion of solid tumors requires increased supplies of nutrients and oxygen. This, in turn, necessitates proliferation of blood vessels. Thus, tumor cells secrete signaling molecules that stimulate **angiogenesis** (i.e., formation of new blood vessels).
- **Invasion and metastasis:** Death from cancers is usually caused by tumor dissemination (metastasis). To accomplish such spread, tumor cells must be able to surmount anatomic barriers such as basement membrane, traverse intervening connective tissues, enter blood vessels and lymphatics, identify fertile sites for implantation, exit the vasculature and then establish colonies far from their origin.
- **Inactivation of tumor suppressors:** Many strong influences normally limit cell cycle transit, maintain genomic stability and regulate other key functions. These restraints affect most of the key attributes mentioned above, as well as associated facilitating processes described below. If a tumor is to be successful, these endogenous tumor suppressors must be evaded or inactivated.

Additional Processes Facilitate Tumor Cell Growth and Spread

Some mechanisms play supporting roles in developing and maintaining many cancers but are not yet generally accepted as being obligatory to tumor development.

- **Genomic instability:** Most human cancer cells show increased susceptibility to random mutation. This allows tumor cells to evolve quickly and to achieve genotypes that favor cancer maintenance and progression.
- **Altered epigenetic regulation:** Epigenetics refers to management of gene function by mechanisms independent of the DNA base sequences whose activities are being controlled. Among the modalities involved are covalent modifications of DNA and DNA-associated proteins (such as histones), noncoding RNAs, altered messenger RNA (mRNA) translation and posttranslational modifications of gene products.
- **Altered bioenergenetics:** Generally, cancer cells favor glycolysis over oxidative phosphorylation for adenosine triphosphate (ATP) generation. This metabolic change requires increased glucose utilization, which has many consequences for the cell's metabolic needs and products.
- **Immune avoidance:** A body of clinical and experimental evidence suggests that the immune system may protect from tumor production and progression. However, the nature of the interactions between tumors and host immunity remains uncertain.
- **Inflammation:** Inflammatory cells infiltrate most developing solid tumors and secrete diverse factors that facilitate tumor development and progression.

Most cancers develop because multiple mutations accumulate in dividing cells. Incipient tumors become malignant by undergoing serial genetic changes that lead to their acquiring hallmarks of cancers, as listed above. The order in which these changes arise may vary from tumor to tumor, but eventually a tumor amasses all of them.

These basic tumor attributes and contributing factors are interdependent mechanistically, and a single altered protein or gene may contribute to more than one characteristic, and no one trait operates in isolation. Interrelated though they are, cancer hallmarks are conceptually distinct. Further, every tumor evolves differently. Thus, certain attributes and genes may contribute to one tumor but not to others, or may suppress oncogenesis in one context but encourage it in another. The discussion of neoplasia that ensues follows the sequence of essential tumor characteristics and contributing factors listed above.

Tumor Cells Elude Processes That Normally Regulate Proliferation

Tumor cell escape from controlled proliferation occurs as a result of mutations that have the effects of both activating and inactivating certain genes. Generally, activating mutations stimulate passage through the cell cycle. The genes affected by such mutations have traditionally been called oncogenes. Inactivating mutations, by contrast, usually prevent the inhibitory influences of tumor suppressor genes (see below).

The Concept of Oncogenes

Early research on transforming retroviruses showed that some viral genes could impart a neoplastic phenotype to normal cells. It was later found that transfer of specific genes from human cancer cells **(oncogenes)** in vitro could also impart a transformed phenotype to normal recipient cells. Some such transforming human tumor genes were found to be mutant versions of normal genes **(proto-oncogenes)** that stimulated cellular proliferation. Transforming retroviral genes were designated with a *v-* (e.g., *v-myb*), and their cellular counterparts with a *c-* (e.g., *c-myb*).

Mechanisms by Which Cell Proliferation Is Driven

Among the key genes often altered during oncogenesis are those that stimulate cell multiplication. They are in the biochemical pathways that guide entry into the cell cycle. These include the following (Fig. 5-21):

- Growth factors
- Cell surface receptors
- Intracellular signal transduction pathways
- DNA-binding nuclear proteins (transcription factors)

Growth Factor–Related Signaling and Oncogenesis

Cell proliferation normally reflects a balance between forces driving cells to divide and, on the other hand, the cell cycle regulators discussed above. In acquiring the

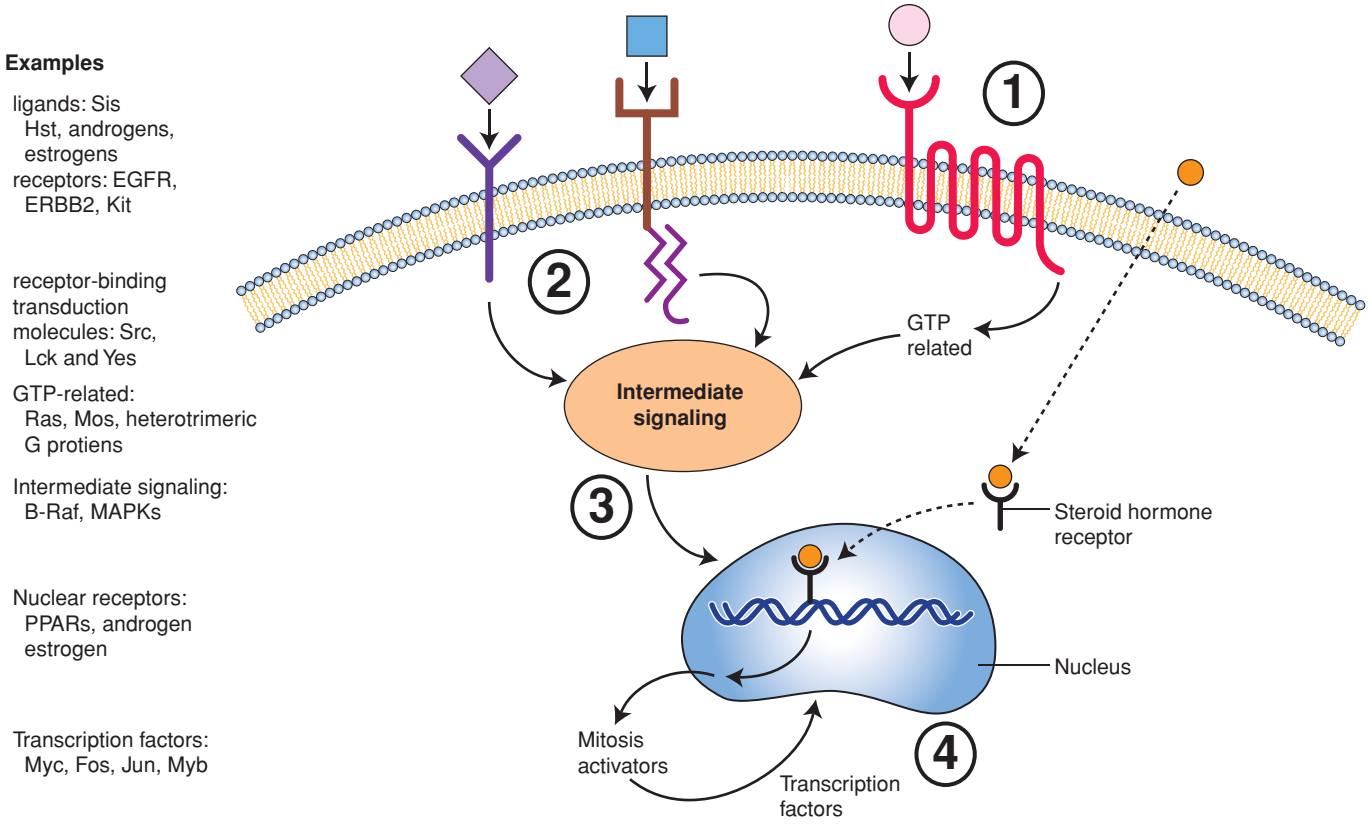

FIGURE 5-21. Signaling paradigms in cellular transformation. 1. Extracellular ligands bind to cell membrane receptors. **2.** One of several pathways of signaling is then activated. The receptor itself can activate intracellular signaling (*left*). A protein that binds to the activated receptor may trigger intracellular signaling (*center*). The receptor may be a G-protein–coupled receptor, which stimulates guanine nucleotide–related signaling. Or, the ligand may traverse the cell membrane to activate receptors within the cytosol directly, without a cell membrane intermediate (*far right*). **3.** In the first three cases, cellular intermediates of many types are activated. **4.** The end result for all pathways is activation of transcription, particularly of proteins that help take the cell through the cell cycle. Shown at the *left* are examples of proto-oncogenes and other cellular products that act in each capacity.

TABLE 5-3
COMMON PROTEINS THAT DRIVE CELL PROLIFERATION, THEIR ACTIVITIES AND ACTIVATION

Activity	Name of Protein	Nature of Mutation	Explanation
Ligand	Hst	Amplification	Growth factor in FGF family
	Sis	Derepression (autocrine stimulation)	PDGF, β subunit
	FGF3	Amplification	
RTK	Kit	Activating point mutation	Receptor for stem cell factor
	Her2/neu (ErbB2)	Amplification	Constitutively activated
	EGFR	Mutations, amplification	Constitutively activated
	Met	Translocation	HGF receptor
	Ret	Point mutation, translocation	Constitutively activated
Intracellular signaling intermediate	Ras (K-Ras, N-Ras, H-Ras)	Point mutation	GTP binding protein, three different *RAS* genes, activated in different settings
	B-Raf	Point mutation	Tyrosine kinase
	Src	Point mutation	Tyrosine kinase
	Abl	Translocation	Mutant protein, Bcr-Abl
Transcription factor	Myc (c-Myc, N-Myc, L-Myc)	Amplification, translocation	Directs transcription of up to 15% of human genes
	Fos	Amplification	Part of AP-1, with Jun
	Myb	Point mutations	Promotes hematopoietic stem cell proliferation
	Rel	Amplification, point mutations	Member of NFκB family, expressed mainly in lymphocytes
	Ets	Translocation	Large family; fusion products may drive tumorigenesis

AP-1 = activation protein-1; EGFR = epidermal growth factor receptor; FGF = fibroblast growth factor; GTP = guanosine triphosphate; HGF = human growth factor; NF = nuclear factor; PDGF = platelet-derived growth factor; RTK = receptor tyrosine kinase.

ability to multiply without restraint, cancer cells must be able to circumvent dependence on outside stimulatory influences. They usually do this by mimicking those influences. To understand how this occurs, one must first review how receptor–ligand interactions drive cells into mitosis. A general schematic relating the roles of ligand–receptor interactions in tumor development is shown in Fig. 5-21.

Tumor-driving mutations may occur at any step of this process. The consequence of such mutations is that proteins are produced that drive cellular proliferation without the normal restraints that match cell numbers to the body's needs.

Ligands, Their Receptors and Cell Proliferation

Ligands. In general, the role of external ligands reflects an ongoing need of normal cells and, often, developing tumors for exogenous stimulation that activates and maintains proliferation. Some ligands may drive cell multiplication in early stages of oncogenesis, with tumor cells eventually becoming independent of those ligands, owing to changes in, for example, receptors or other molecules. Sometimes, the developing (or developed) tumor cell itself undertakes production of these ligands, which amounts to an autocrine trigger to cell division. Some such stimulatory molecules occasionally act as oncoproteins being overexpressed, mostly by virtue of gene amplification (Table 5-3).

Receptors. There are several basic classes of receptors that may stimulate or inhibit cell proliferation. These are listed in Table 5-4. Except for the steroid hormone receptors, these are cell membrane molecules that respond to ligands produced by other cells. Usually, receptor–ligand interactions cause changes in the receptors, leading to their serving as docking sites for one or more intracellular signaling networks.

TABLE 5-4
TYPES OF SIGNAL-TRANSDUCING RECEPTORS IMPORTANT IN TUMORIGENESIS

Receptor Category	Prototypical Ligands
Tyrosine kinase (RTK)	EGF, IGF-I, insulin
G-protein–coupled receptor (GPCR)	Prostaglandins, RANTES, SDF-1
Nuclear receptors	Androgens, estrogens, other steroid hormones
Serine/threonine kinases	TGF-β
Kinase-associated receptors	GH, TCR, IL-2
Extracellular matrix receptors	Fibronectin, collagen, laminin

EGF = epidermal growth factor; GH = growth hormone; IGF-I = insulin-like growth factor-1; IL-2 = interleukin-2; RANTES = CCL5, a ligand for CCR5; SDF-1 = CXCL12, stromal-derived factor-1 (CXCR4 ligand); TCR = T-cell receptor; TGF-β = transforming growth factor-β.

The changes that ligands elicit in receptors reflect the specifics of the receptor:

- **Receptor tyrosine kinases (RTKs)** possess intrinsic tyrosine kinase activity that causes the receptor to phosphorylate itself, and perhaps other molecules as well, after recognizing its ligand.
- **Nonkinase receptors** include many that undergo structural rearrangements, making them receptive to initiating downstream signaling (see below). These types of receptors often associate with nonreceptor tyrosine kinases (**NRTKs;** see below), which mediate further signaling.
- **G-protein–coupled receptors (GPCRs)** are the most common type of membrane receptors. Upon binding their ligands—which include very diverse types of molecules—GPCRs change conformation. In so doing, they activate guanosine triphosphate (GTP)-related nucleotide exchange factors (GEFs; see below). Some GPCRs transduce mitogenic signals triggered by such ligands as prostaglandins, endothelin and thrombin. GPCRs may be amplified in cancers or they may mediate stimulatory autocrine or paracrine signals.

The nature of signaling elicited by receptor–ligand interaction varies. Many activated RTKs and nonkinase receptors serve as platforms for other proteins, including NRTKs. The latter often phosphorylate the nonkinase receptor, as well as the NRTKs themselves. In these settings, a cell membrane complex is formed, which recruits signaling intermediates and activates diverse downstream signaling pathways.

Receptor proteins are among the most important transforming proteins. They are widely implicated in oncogenesis (Table 5-3), *often driving tumor formation via mutations that render them constitutively active, independently of their ligands.*

Signaling after Receptor Activation

Once a receptor binds to its ligand, downstream signaling pathways are stimulated. If an RTK or NRTK is involved, the phosphorylated tyrosine is recognized by the next cadre of signaling intermediates via specialized structures, called SH2 (for Src-homology-2) domains, on these intermediates. These domains bind phosphotyrosines. They also are specific for individual proteins bearing the phosphotyrosines.

What follows depends on many factors, including the type of receptor activated, if its activation entails tyrosine kinase activity and the molecular species that immediately follow. Pathways that may be set in motion include:

- **Ras:** The three members of the Ras family (K-Ras, N-Ras, H-Ras) are small guanine nucleotide-binding proteins that may be activated by tyrosine kinases via a linker protein, usually Grb2. To understand activated Ras and Ras-related oncogenesis, the Ras cycle should be appreciated (Fig. 5-22). Ras binds guanosine diphosphate (GDP) and GTP. In the GTP-bound state, Ras is active. GTP binding is catalyzed by a GEF (see above), which is in turn activated when Grb2 recognizes phosphorylated tyrosines (see above). A GTPase activating protein (GAP) directs the GTPase activity of Ras, thus activating downstream signaling, converting Ras–GTP to Ras–GDP and returning Ras to its quiescent resting state.

  Many malignant tumors possess a mutated form of Ras. Such mutated Ras does not undergo the deactivation step and is constitutively turned on.

  Activation of many GPCRs stimulates a similar type of response, but by a different group of proteins, called heterotrimeric G proteins. Unlike Ras, these G proteins tend not to be mutated in cancers. Rather, they may be overexpressed, achieving a comparable effect (i.e., constitutive activation of downstream signaling).
- **Phosphatidylinositol-3 (PI3) kinase:** This family of enzymes is generally activated by RTKs and GPCRs. Family members add a phosphate group to a phosphatidylinositol lipid to create the small molecule phasphatidylinositol-3-phosphate [PI(3)P], as well as more heavily phosphorylated derivatives such as PI(3,4,5)P_3. These

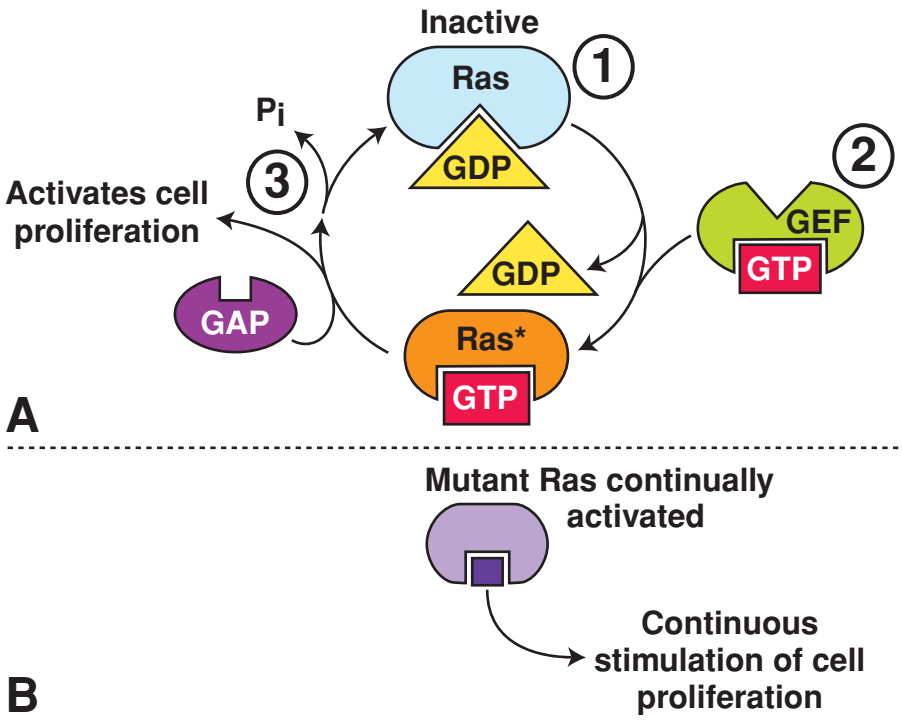

FIGURE 5-22. Mechanism of action of Ras. A (upper). Normal. The Ras protein, $p21^{Ras}$, exists in two conformational states, determined by the binding of either guanosine diphosphate (GDP) or guanosine triphosphate (GTP). **1.** Normally, most of the $p21^{Ras}$ is in the inactive GDP-bound state. **2.** An external stimulus, or signal, triggers the exchange of GTP for GDP, an event that converts Ras to the active state. **3.** Activated $p21^{Ras}$, which is associated with the plasma membrane, binds GTPase-activating protein (GAP) from the cytosol. The binding of GAP has two consequences. In association with other plasma membrane constituents, it initiates the effector response. At the same time, the binding of GAP to Ras GTP stimulates by about 100-fold the intrinsic GTPase activity of Ras, promoting hydrolysis of GTP to GDP and the return of Ras to its inactive state. **B (lower).** Mutated Ras protein is locked into the active GTP-bound state because of an insensitivity of its intrinsic GTPase to GAP or because of a lack of the GTPase activity itself. As a result, the effector response is exaggerated, and the cell is transformed.

mediate many proliferation-related (see below) and cell survival reactions.

- **Phospholipase C:** This family of enzymes is commonly activated by diverse types of receptors, especially GPCRs, but also others. They cleave certain phospholipids and so participate in generation of inositol phosphate signaling intermediates and diacylglycerol. These both may drive cellular multiplication via (respectively) calcium signaling pathways and protein kinase C.
- **Mitogen-activated protein kinases (MAPKs):** These enzymes mediate many different types of signaling reactions, leading to cell proliferation. MAPKs may be triggered by upstream proteins such as Ras (after RTK activation), GPCRs or other mechanisms. Some very important driver mutations for malignancy (e.g., b-Raf) occur among these proteins, frequently leading to constitutive activation. Typically, MAPK cascades involve three sequential species, one activating the next. The consequences of MAPK stimulation are diverse, and there is extensive cross-talk between these and other signaling intermediates.

Transforming Growth Factor-β and Other Cytokines

TGF-β, an extracellular cytokine in the microenvironment of cancer cells that triggers important regulatory pathways, is an example of a cell communication mediator that strongly influences the pathogenesis of tumors. Its role in the genesis of cancer appears to be important, although cell and tissue responses to this cytokine are highly contextual. Normally, TGF-β tends mainly to suppress tumor development by modulating cell proliferation, survival, adhesion and differentiation. It also inhibits mitogenesis induced by constituents of the extracellular matrix (see above).

However, frankly malignant cells often acquire the capacity to evade or even to manipulate TGF-β pathways for their own wicked ends. Abnormal signaling in the TGF-β pathway can actually stimulate proliferation of tumor cells, facilitate their evasion of host defense mechanisms (see below) and foster invasion and metastasis.

Cancer cells may develop the ability to circumvent TGF-β–related suppressive activity via mutations in genes for TGF-β receptors or by interfering with downstream signaling by mutation or by promoter methylation of key proteins. Under these circumstances, cancer cells can hijack the regulatory activities of TGF-β to further their needs, such as tumor growth, invasion and metastasis. The loss of the tumor suppressor function of TGF-β through inactivating mutations of genes in its core pathway has been described in cancers of the colon, prostate, stomach, breast, pancreas and ovary and many others. A summary of the effects of TGF-β in cancer is presented in Table 5-5.

Other cytokines (e.g., granulocyte/monocyte colony-stimulating factor [GM-CSF] and interleukin-3 [IL-3]) may contribute to tumor development simply by overexpression, especially for hematopoietic malignancies.

TABLE 5-5
TRANSFORMING GROWTH FACTOR-β (TGF-β) AND CANCER

Promotes	Inhibits
Normal Tumor-Suppressive Effects	
Apoptosis	Inflammation
Differentiation	Mitogenesis induced by extracellular matrix
Maintenance of cell number	
Failure of Tumor Suppression	
Autocrine mitogens	Immune surveillance
Motility	
Invasion and Metastasis	
Recruitment of myofibroblasts	
Malignant cell extravasation	
Modification of microenvironment	
Mobilization of osteoclasts	

Normally, TGF-β compels homeostasis and exerts tumor-suppressive activity through effects on the target cells themselves or the extracellular matrix.

Failure of this activity by TGF-β permits production of growth factors, evasion of immune surveillance and establishment of factors that facilitate tumor cell invasion and metastasis.

Steroid Hormones

Some three centuries ago, the Italian physician Ramazzini observed that nuns had a particularly high incidence of breast cancer. This curiosity is now recognized to reflect the unopposed estrogen stimulation of breast epithelium, uninterrupted by pregnancy and lactation. Both estrogens and progesterone bind to specific cytoplasmic receptors. The resulting hormone–receptor complexes are then translocated to the nucleus, where they act as transcription factors that foster proliferation of responsive cells. Antiestrogen therapy for hormone receptor–positive tumors reduces the risk of recurrence after surgery. Other nuclear receptors have been identified in breast cancer, including those that bind androgens, corticosteroids, vitamins A and D, fatty acids and some dietary lipids. The interactions of these signaling pathways with each other and with other signaling pathways are highly complicated and not well understood.

The influence of androgens is most conspicuous in the case of prostate cancer, in which they stimulate growth by binding to the androgen receptor. This receptor pathway engages in cross-talk with other important pathways that affect the cell cycle, apoptosis and differentiation. Such interactions involve EGF, insulin-like growth factor-I (IGF-I), fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), TGF-β and other important signaling species. Removing androgen stimulation, whether by surgical or pharmacologic means, inhibits the growth of prostate cancer, although in most cases the tumors eventually become androgen insensitive.

Membrane-Bound Mucins

Traditionally, mucins have been thought to be exclusively extracellular molecules charged with establishing an interface between many epithelial surfaces and the exterior. It is now recognized that membrane-bound mucins comprise a large family of glycoproteins that are frequently

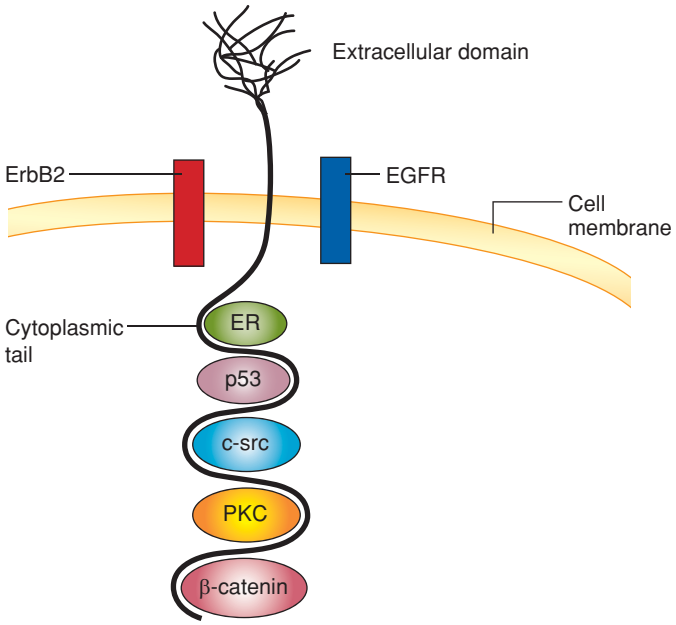

FIGURE 5-23. Membrane-bound mucins with important signaling molecules. *ER* = estrogen receptor; *PKC* = protein kinase C.

overproduced in a variety of cancers. Extracellular domains of these membrane-bound mucins (MUCs) lubricate and protect the cell surface. The cytoplasmic domains of these transmembrane glycoproteins function as scaffolds for interaction with signaling molecules that influence cell proliferation and survival (Fig. 5-23). In this context, MUC1 is overexpressed in the large majority of breast cancers, and often in malignancies of the colon, ovary, pancreas and lungs.

Interaction among Intermediate Signaling Pathways

Whether elicited by receptor–ligand interactions or by constitutively activating driver mutation, the signaling avenues discussed above, and many others, interconnect extensively. This fact endows them with baffling complexity and challenges both those seeking to understand how cells sustain proliferation and those seeking specific targets for therapy. In this context, it should be emphasized that the results of unrestrained activation of a given gene are not always predictable. A mutant protein may drive proliferation in one cell type, apoptosis in another and differentiation in a third.

Transcriptional Activation

In the end, a key element of the ability of cancer cells to proliferate without restraint is the array of genes whose transcriptional activities are turned on or off. Thus, whatever upstream driver mutations there are, transcription factors sit at the end of the afferent limb of the processes that push cancer cells to undergo uncontrolled mitosis. When transcription factors drive oncogenesis, the genetic changes responsible usually entail increased production of wild-type proteins. Thus, driver mutations of transcription factors generally entail, for example, translocations that place them under the control of more vigorous promoters. Many transcription factors are implicated in oncogenesis. Among the best known and most often inculpated are:

- **Myc:** A ubiquitous transcription factor that may control transcription of as many as 10%–15% of all human genes, c-Myc and its cousins, N-Myc and L-Myc, are key to development of many tumors. Among its functions, Myc pushes cellular proliferation, favors stemness (see Cancer Stem Cells, below), increases energy production and facilitates tumor cell invasiveness. It is of interest that Myc may also activate cell death programs in cells with intact p53 and other cell death effectors.
- **Fos and Jun:** Together, these proteins form the **AP-1** (activation protein-1) transcription factor. Increased AP-1 activity promotes cellular proliferation and survival (Fig. 5-24) and is generally a result of increased signaling via several pathways, including MAPK and the protein kinase C family (PKC; see above). AP-1 also represses expression of such tumor proteins as p53 (see below).
- **Androgen and estrogen receptors:** These cytoplasmic receptor proteins act both as receptors and as transcription factors. They translocate to the nucleus upon binding their cognate ligands. Once in the nucleus, they act as transcription factors. Depending on the cell type, these steroid sex hormone receptors may stimulate cell proliferation. Thus, estrogen receptors stimulate mammary epithelial cell proliferation and are important in the progression of many breast cancers. In many prostate cancers, similarly, androgens cause prostatic tumor cells to proliferate.

As noted above, however, cell proliferation mediated by these and similar receptors need not necessarily require exogenous hormones. Autocrine stimulation may occur when the tumor cells themselves produce the requisite androgen or estrogen. The ability of the tumor to progress thus becomes independent of exogenous sources of the stimulatory hormone and the tumor is resistant to hormone antagonist therapies.

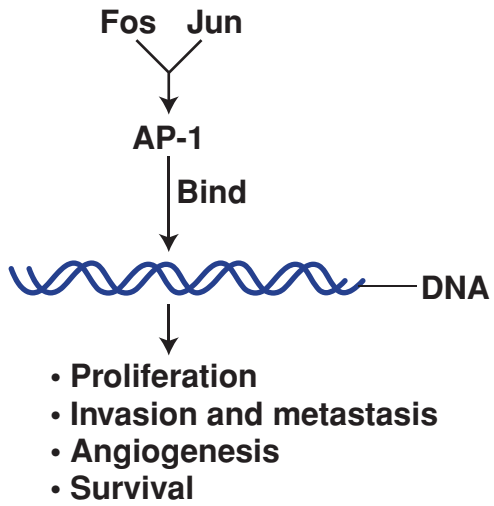

FIGURE 5-24. Activating protein-1 (AP-1) complex. The AP-1 transcription factor complex is formed by the protein products of two proto-oncogenes, Fos and Jun. When these factors form a heterodimer, they bind DNA and direct transcription of genes whose products are involved in cell proliferation, tumor cell invasion and metastasis, angiogenesis and inhibiting apoptosis.

Thus, whether by gene amplification, point mutation, translocation or other mechanisms (see genomic instability, below), tumors are characterized by cellular proliferation that is unshackled by the regulatory chains that limit normal cells. They must still, however, escape other restraints.

Cellular Senescence Helps Prevent Cancer

Senescence is a process that maintains cell viability when a cell can no longer contribute by cell division to continued homeostasis. Senescent cells are growth arrested and viable but remain unable to proliferate.

This state was reported initially in cultured normal human fibroblasts. After a certain number of mitoses (usually 40–45), they stopped dividing but remained alive. The upper limit of the number of mitoses is called the Hayflick limit, after its original discoverer. It largely reflects the effects of telomere depletion in preventing cell cycling when a cell's telomeres become very short (see below).

Mediators of Cellular Senescence

Clearly, a mechanism that limits the number of mitoses a cell may undergo must be neutralized for malignant cells to indulge in endless proliferation. The senescent phenotype entails increased formation of heterochromatin (senescence-associated heterochromatin formation [SAHF]), in which certain proteins are modified, leading them to bind chromosomal DNA and impede transcription of E2F-activated genes such as mediate cell multiplication (see above). Several effectors of senescence are involved:

- **The DNA damage response (DDR):** As noted above, once telomeres have shortened to a certain point, they elicit DDR. DNA damage-sensing proteins activate p53 and cdc25, and the cell stops dividing until either the offending DNA damage is fixed or the cell is directed into senescence or apoptosis pathways. This mechanism is critical to oncogene-induced senescence (OIS; see below).
- **Tumor suppressors:** The intimacy between several critical proteins and cell cycle blockage is important in forcing cells into a senescent phenotype. Key among these proteins are $p16^{INK4a}$ and Rb, which induce certain proteins to associate with the cell's DNA. This results in SAHF and gene silencing.
- **Oxidative stress:** In cultured cells, senescence can be delayed by decreasing ambient oxygen. Conversely, it can be hastened by adding oxidants like H_2O_2 to the culture. Activation of some oncogenes, like RAS, increases oxidative stress. Resulting increases in ROS may trigger p38 MAPK signaling and activate ATM.
- **Cytokines:** Cells secrete factors, including IL-6 and IL-8, that help trigger the senescent phenotype. Together with their receptors, they help to establish and maintain the senescence. Their participation led to the descriptive designation, secretion-associated senescent phenotype (SASP). Transcriptional regulation that these cytokines elicit inhibits cellular proliferation and promotes senescence.

Telomere Stability and Tumorigenesis

Telomeres are tandem repeats of the sequence TTAGGG, at the 3′ ends of each DNA strand. They serve as docks for protein caps that bind the ends of DNA sequences and prevent them from being used in NHEJ (see above) reactions. Because DNA polymerases "fall off" as they approach the ends of chromosomes, telomere lengths decrease with each cell division. When telomeres are reduced beyond a critical size, they become uncapped and are subject to NHEJ. Resulting NHEJ may fuse the ends of either two sister chromatids or nonhomologous chromosomes. As the cell cycle progresses, this fusion generates a chromosome "bridge" as the fused DNA strands are pulled apart during anaphase. The force of chromosome separation may then lead to chromosomal breakage, which can lead to further recombination (Fig. 5-25).

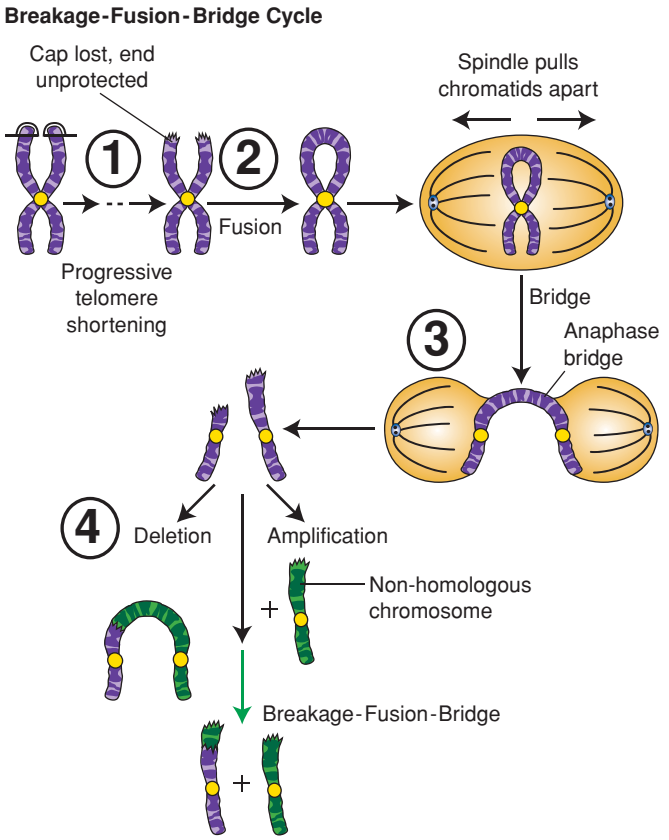

FIGURE 5-25. The genesis of telomere-related chromosome breakage. **1.** In the absence of telomerase, extensive cell proliferation leads to unprotected telomere ends. **2.** These are "repaired" by fusion of telomeres between sister chromatids, creating a bridged structure like a tongs. **3.** During anaphase, the spindles attached to the two centromeres pull the now-attached chromatids apart, resulting in abnormal chromosomes. **4.** Further production of chromosome ends without telomeres may cause the cycle to repeat itself.

This process can be prevented in several ways. In normal cells, where p53 and pRb pathways are intact, shortened telomeres activate cell cycle checkpoints and cell division ceases. This is called replicative senescence (Fig. 5-26). The cell then remains in G_0 or dies. Alternatively, many cells that replicate frequently (e.g., colon crypt epithelium) express **telomerase,** a ribonucleoprotein enzyme that lengthens telomeres and so maintains genomic stability in the face of continuing cell proliferation.

Oncogene-Induced Cellular Senescence

The vast majority of cells sustaining oncogenic mutations never become cancers. In the human body, such mutations occur several times per minute, which contrasts with

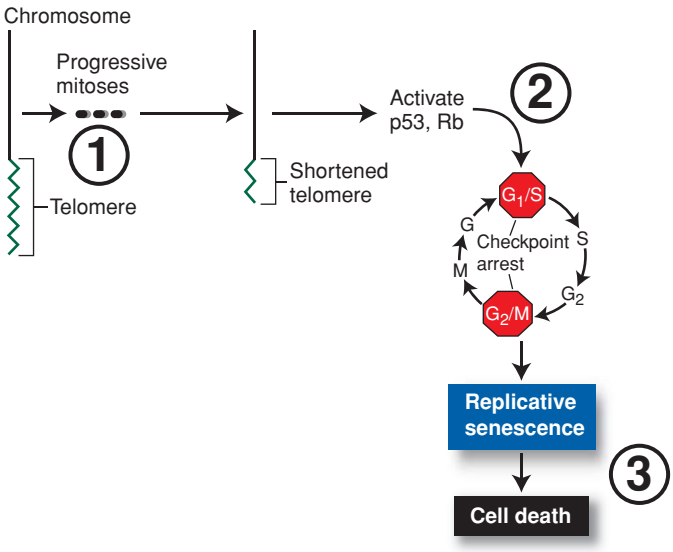

FIGURE 5-26. The sequence of events resulting from DNA instability as a result of telomere shortening and leading to cell death. This sequence occurs when the tumor suppressors p53 and Rb are intact. **1.** Progressive telomere shortening activates p53 and Rb. **2.** This leads to cell cycle arrest at the G_1/S and G_2/M checkpoints. **3.** Consequent replicative senescence triggers cell death programs.

the relative infrequency of cancer in a human life span. A major barrier to the development of cancer appears to be OIS (Fig. 5-27). OIS has been shown to constrain tumor development for many types of cancer. Consistent with this role for OIS, oncogene activation stimulates tumor suppressors such as p53 and Rb.

Earlier studies showed that after activated Ras enhanced proliferation of affected cells, an irreversible growth arrest (i.e., senescence) occurred. This senescence could be avoided by crippling p53 and Rb pathways, suggesting that such OIS actually evolved as a means to prevent tumors (Fig. 5-27). Activating alterations in other oncogenes also induce OIS in vivo. The ability to undergo OIS is a major distinction between many benign and malignant tumors, as well as between "premalignant" cell proliferations and frankly malignant ones. That is, benign tumors can senesce, but advanced malignant tumors do not. For example, benign tumors may show heightened responsiveness to IL-8 (see above), which is lost in malignancy. Thus, OIS prevents benign cell proliferations from progressing to cancers.

Evading Senescence

If critical shortening and uncapping of telomeres occur in the context of acquired loss of cell cycle checkpoint regulation (e.g., mutations in $p16^{INK4a}$ or p53), chromosomes become susceptible to instability resulting from the types of rearrangements mentioned above (breakpoint–fusion–bridge cycles). Such instability promotes carcinogenesis by facilitating chromosomal rearrangements, which in turn can lead to aneuploidy, translocations, amplifications and deletions. Thus, telomere attrition leads to sufficient genomic instability to set the stage for the development of mutations in sufficient numbers for cells to cross the borderline from benign to malignant.

Cancer cells may solve this problem, as indicated above, via telomerase. In normal human cells, levels of this enzyme are insufficient to maintain telomere length, and each cell division therefore leads to progressive telomere attrition. However, in normal cells that divide frequently, telomerase makes a DNA copy of an RNA telomere template and affixes it to the 3′ end of the replicating DNA strand. In this way, the

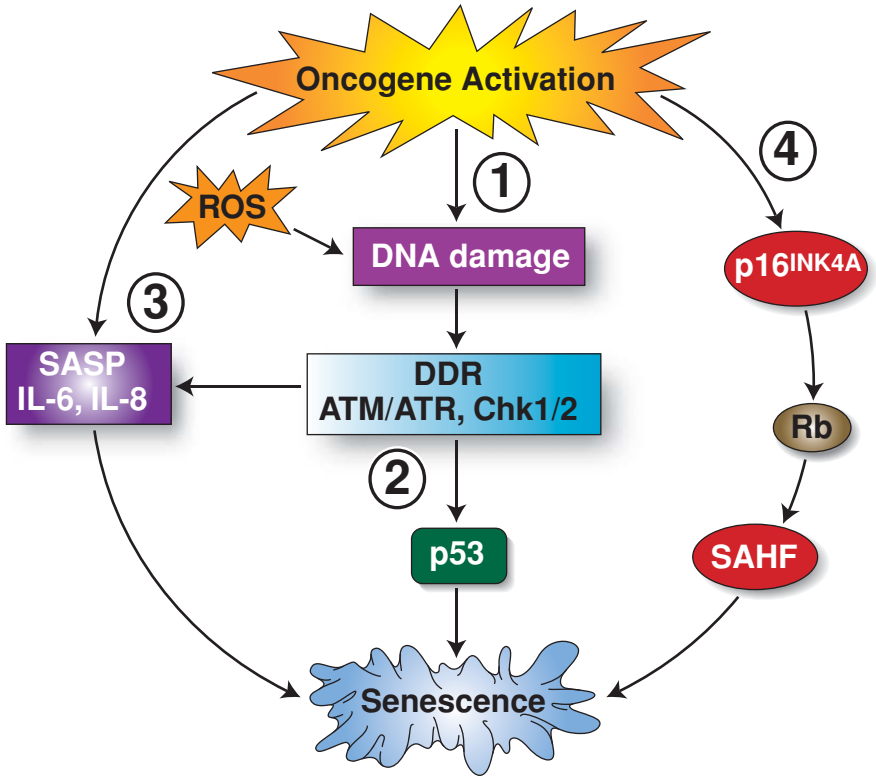

FIGURE 5-27. Oncogene-induced senescence (OIS). Oncogenic stress can elicit cellular responses that eventuate in cellular senescence. **1.** Excessive cell division, a result of oncogene activation, for example, causes oxidative stress and DNA damage to accumulate. **2.** As a consequence, the DNA damage response (DDR) is activated, with p53 expression blocking cell cycle progression. **3.** The same DDR may also activate the senescence-associated secretory phenotype (SASP), which leads affected cells to secrete cytokines that maintain the senescent state (interleukin-6 [IL-6], IL-8). SASP can also be activated directly by the excessive oncogene activity. **4.** Oncogene activation may directly activate the tumor suppressor $p16^{INK4A}$, which in turn activates Rb. This leads to the formation of senescence-associated heterochromatin (SAHF), which restricts expression of cell cycle drivers.

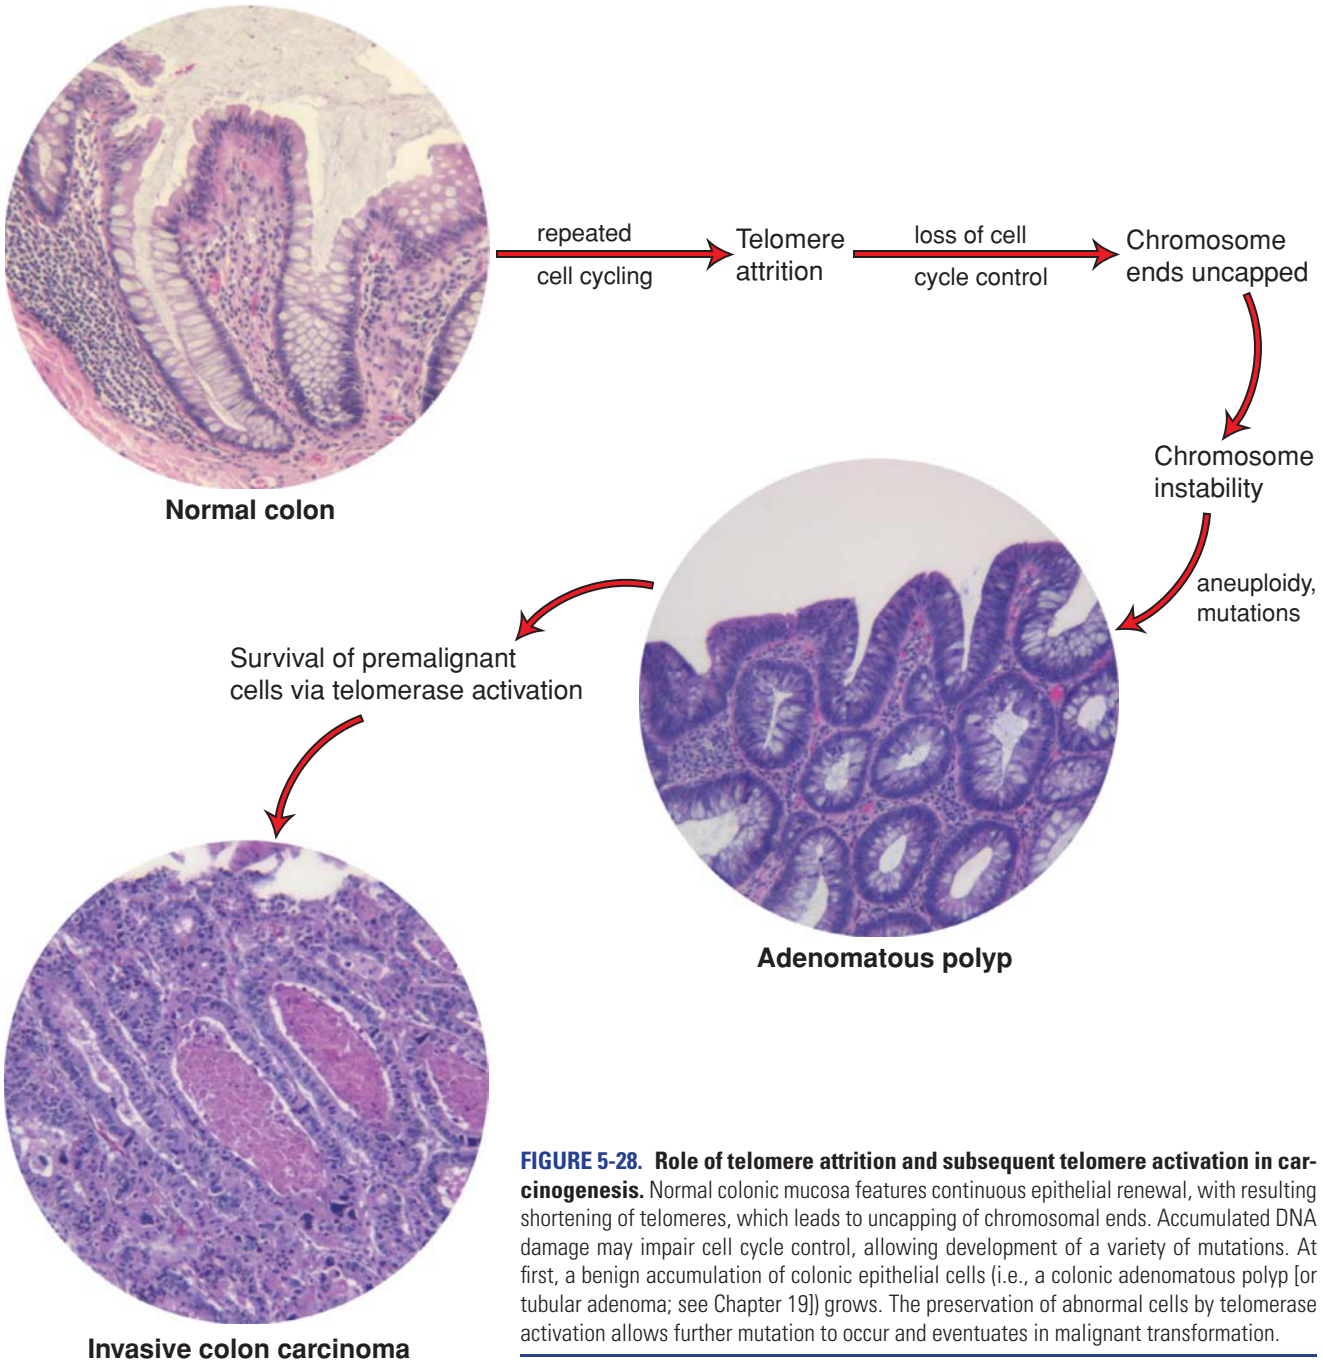

FIGURE 5-28. Role of telomere attrition and subsequent telomere activation in carcinogenesis. Normal colonic mucosa features continuous epithelial renewal, with resulting shortening of telomeres, which leads to uncapping of chromosomal ends. Accumulated DNA damage may impair cell cycle control, allowing development of a variety of mutations. At first, a benign accumulation of colonic epithelial cells (i.e., a colonic adenomatous polyp [or tubular adenoma; see Chapter 19]) grows. The preservation of abnormal cells by telomerase activation allows further mutation to occur and eventuates in malignant transformation.

enzyme preserves telomere length and chromosomal integrity despite continuing cell division. Not surprisingly, then, normal cells that express telomerase include those that need to continue to divide for the lifetime of the individual (e.g., hematopoietic progenitor cells, gastrointestinal epithelium and germ cells).

The cancer cell takes a page from that book. Presumably as a protective adaptation to genomic instability, tumor cells reactivate telomerase: 80% of human tumors show increased telomerase activity. A high level of this activity actually protects the cancer cell by suppressing the development of further, potentially lethal, chromosomal instability. *Thus, telomerase activation permits—but does not directly cause—the emergence of cancer* (Fig. 5-28).

If a cell manages to avoid senescence after oncogene activation, however it does that, the cell can continue to proliferate and may be said to have been immortalized. It has been shown in some cases that benign human tumors may retain the ability to senesce, while their malignant counterparts have lost that capacity. Thus, loss of tumor suppressor activities that promote senescence is important for the emerging cancer cell.

Programmed Cell Death Prevents Oncogenesis

The total number of cells in any organ reflects a balance between cell division and cell death. Interference with this intricate equilibrium can lead to tumor development. Cell

death programs encompass several different pathways (see Chapter 1), dysfunction of which is often a fundamental requirement for tumor development. The best understood of these is apoptosis and its cousin, anoikis.

Apoptosis as an Inhibitor of Cancer

As mentioned above and in Chapter 1, apoptosis eliminates damaged or abnormal cells. Apoptotic pathways are activated by errors in DNA replication or repair, detected genetic or metabolic instability, loss of anchoring connections to the extracellular matrix (ECM) **(anoikis)** and other stimuli. Since many triggers for apoptosis are among the attributes of tumor cells, it is not surprising that those cells often evolve mechanisms to disable it. There are many known pro- and antiapoptotic proteins that interact in a head-spinning number of ways. To make this topic understandable, we present illustrative examples. Thus, cancers may avoid PCD by impairing proapoptotic activities and/or by augmenting prosurvival functions.

Fighting for Survival Against the Forces of Death

There are many participants in the programs of cell death. The best known is p53, and it is no surprise that the gene for this protein, *TP53*, is mutated in over half of human cancers (see below). As the key angel of cell death, p53 is activated when oncogenic danger is sensed, for example, if damage to cellular DNA cannot be repaired (see Chapter 1). Wearing several of its many hats, activated p53 upregulates transcription of proapoptotic Bcl-2–like proteins and downregulates their prosurvival cousins. In addition, it is a BH3-only protein (see Chapter 1) and so may meddle directly in Bcl-2 family affairs by binding, for example, prosurvival Bcl-2 or Bcl-X_L to force them to release proapoptotic Bad and Bax. The latter activate effector caspases and cause the cell to die. It is worth recalling that apoptosis does not elicit florid, cytokine-rich inflammatory responses, but rather that apoptotic cells pass from the world not with a bang but with a whimper—they are quietly removed by macrophages.

Along similar lines, anoikis is form of apoptosis that is activated with epithelial cell membrane integrins that no longer bind their appropriate ECM partners. Integrins mediate prosurvival signals. Their detachment from their extracellular ligands leaves cells excessively susceptible to all manners of proapoptotic stimuli. Also, unligated integrins may activate caspase-8 directly. However, in some cancer cells, unbound integrins can maintain survival signaling and so protect from PCD.

The prototypical example of the effectiveness of inhibiting apoptosis in human cancer is follicular lymphoma (see Chapter 26). There, the prosurvival protein, Bcl-2, is constitutively activated by a translocation [t(14:8)] that places its expression under the control of the immunoglobulin heavy-chain promoter. As a result, the normal equilibrium between the life and death of B lymphocytes is altered in favor of the former, thus allowing accumulation—or, perhaps, more to the point, insufficient elimination—of excess neoplastic B cells.

Some other tumor types, including lung cancer and non-Hodgkin lymphoma, also express excess Bcl-2. Chromosomal translocation is not the only mechanism by which tumor cells increase Bcl-2 expression. They may show methylation and suppression of microRNAs (miRNAs) that repress Bcl-2 expression. Similarly, any impairment of p53 function can increase Bcl-2 production and decrease expression of proapoptotic Bcl-2 binding partners (see Chapter 1) and, in so doing, promote tumor formation.

The issue of PCD and cancer is further complicated by **oncogene-mediated apoptosis**. For example, although the transcription factor Myc is generally considered to be oncogenic, if PCD pathways are intact, Myc overproduction induces a default apoptosis pathway. Thus, promotion of cell proliferation by deregulated production of Myc is usually balanced by increased apoptosis. Induction of apoptosis by Myc acts as a molecular safety valve to block cancer development. If Myc-stimulated tumors are to develop, some cells overproducing Myc must also inactivate PCD, whether by overexpressing antiapoptotic proteins or by inactivating apoptosis mediators like p53.

This example illustrates the complexity inherent in the control of the on/off switch of apoptosis in cancer development.

Tumors Stimulate New Blood Vessel Formation (Angiogenesis)

Angiogenesis is the formation of new blood vessels from preexisting small blood vessels. In order to grow beyond about 2 mm in diameter, tumors need more nutrient and oxygen supply than preexisting blood vessels can provide. Most tumors experience hypoxia, which induces expression of **hypoxia-induced factors (HIFs),** especially **HIF-1α**. In turn, HIF-1α elicits production of angiogenic growth factors, which stimulate formation of new tumor-associated blood vessels. This process is obligatory for a primary tumor to grow and metastasize.

Under homeostatic conditions, there is a fine equilibrium between factors favoring new blood vessel formation and those impeding it. Consequently, endothelial cells turn over slowly, renewing themselves over the course of months or years. Solid tumors often disrupt this equilibrium in favor of new blood vessel formation.

Steps in the Formation of New Blood Vessels

Tumor angiogenesis begins when existing cells (e.g., tumor cells or attendant stromal cells) secrete substances (see below) that stimulate new blood vessel formation. The process triggered by these chemicals resembles vasculogenesis in embryonic development and follows several steps:

1. Proteolytic enzymes perforate postcapillary venule basement membranes.
2. Endothelial cells in the area of the interrupted basement membrane proliferate and migrate toward the source of the angiogenic cytokines.
3. A lumen develops in the advancing cell mass.
4. These immature capillaries are invested with a basement membrane.
5. The cells in the vanguard of the developing structure ("tip cells") join to other similar tip cells to produce a capillary network.

Under some circumstances, and for some tumor types, tumor vessels may form differently—directly from the tumor cells themselves. The end result, however the blood vessels are generated, is not always well-formed vasculature. Tumor-associated vessels may differ from their non-tumor-associated counterparts in several ways.

Tumor-associated capillaries may be variably invested by pericytes and basement membranes. They may vary in size and shape, leak blood components excessively, display excessive tortuosity and be distributed inhomogeneously. Excessive leakiness of tumor blood vessels may increase tissue hydrostatic pressure and so retard diffusion of soluble materials into tissues. Consequently, some areas of tumors may be richly supplied with oxygen and nutrients while other areas may go begging.

Mediators of Tumor Angiogenesis

Three main groups of factors may mediate tumor angiogenesis: (1) the family of VEGFs, (2) angiopoietins and (3) other agents that stimulate tumor-associated blood vessels to proliferate. These are assisted by a bevy of associated helpers including TGF-β (see below), several interleukins (IL-6, IL-8) and steroid sex hormones. The multiplicity—some might suggest redundancy—of stimulating and interacting factors has important implications for the efficacy of tumor therapies that preferentially target one or another.

VEGF

This term actually represents a family of related proteins, the best understood of which is VEGF-A, which has several isoforms. The family will be referred to collectively as VEGF, but the multiplicity of VEGFs should be borne in mind. VEGF is a major mediator of tumor angiogenesis and is made by the cells of most tumors. However, quantities of VEGF capable of stimulating tumor angiogenesis may also be produced by other cells, chiefly platelets and connective tissue cells. A related family of mediators, platelet-derived growth factors (PDGFs), has a similar spectrum of activities. In addition to stimulating new blood vessel formation, VEGF also enhances capillary permeability, promotes endothelial cell survival and mobilizes progenitor cells (e.g., from the bone marrow) to participate in angiogenesis.

VEGF Mechanisms of Action

As noted above, tumor cells produce HIF-1α when they sense insufficient oxygen. HIF-1α is a transcription factor that upregulates diverse genes, including the VEGFs. The family of VEGFs bind a family of receptors on endothelial cells, the most important of which is VEGFR2. VEGF–VEGFR2 interaction activates several signaling pathways (Fig. 5-29). Consequences of VEGFR2 activation include endothelial cell proliferation, protection from PCD, enhanced cell migration and increased vascular permeability. The latter function leads to leakage of such blood components as fibrinogen into the area. Once outside blood vessels, fibrinogen generates a fibrin matrix that facilitates endothelial cell migration and angiogenesis. VEGFR2-positive progenitors from the blood are also recruited to the site. Several members of the VEGF family also mediate proliferation of lymphatic vessels.

Angiopoietins

Of the several known angiopoietins, angiopoietin-2 contributes the most to tumor blood vessel formation. It acts principally to stabilize growing blood vessels and stimulate pericytes to surround the developing structures.

Other Angiogenic Factors

Other important stimuli include cytokines (e.g., IL-6), androgens and estrogens, as well as diverse growth factors. These

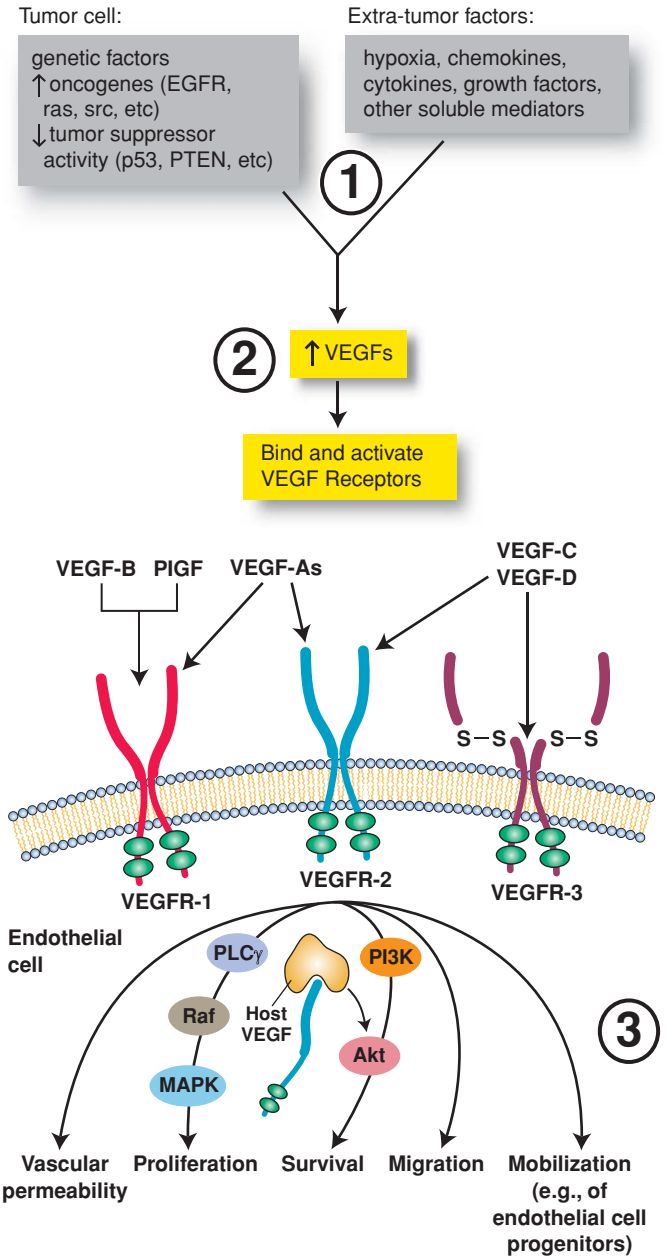

FIGURE 5-29. The vascular endothelial growth factor (VEGF) system and its effects. 1. Under the influence of factors generated by tumor cells (*left;* increased expression of certain oncogenes or decreased activity or tumor suppressors) or coming from other sources (tumor-related stroma, external environment, etc.), several VEGFs are produced. **2.** These bind the several VEGF receptors (VEGFRs), the principal of which is VEGFR-2. **3.** Downstream signaling from these receptors has diverse effects on vascular endothelium, including increasing vascular permeability, activating cell proliferation and survival mechanisms, inducing in-migration of endothelial cells and mobilizing progenitor cells to the area, to help form new blood vessels. PlGF = placental growth factor.

serve diverse functions, including eliciting VEGF production. Mutations in several important oncogenes, including *src, EGFR* and *ras,* may increase VEGF secretion by tumor cells, as may impairment of activities of certain tumor suppressor genes (see below).

The multiplicity of proangiogenic activities includes such factors as basic FGF (bFGF), PDGF, VEGF homologs and isoforms and others. These may augment blood vessel growth

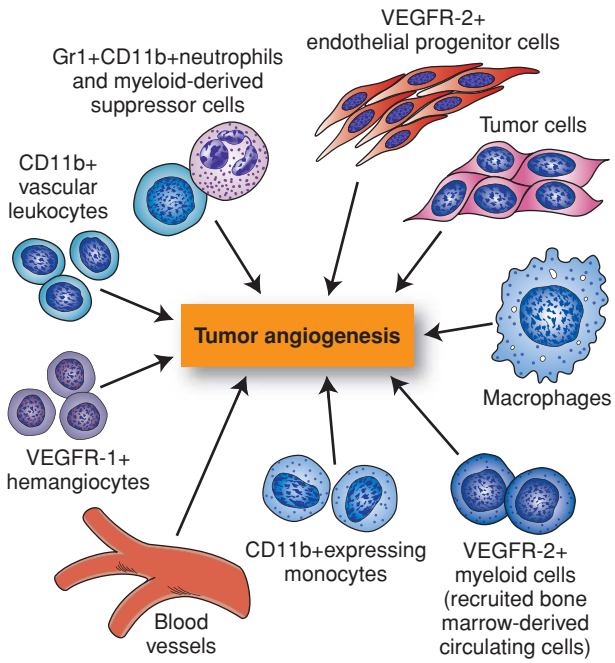

FIGURE 5-30. Diverse populations of bone marrow–derived cells that participate in angiogenesis. Circulating cells derived from bone marrow progenitors contribute to the development of tumor-related blood vessels. These include macrophages, early cells in the myeloid (neutrophil) series, neutrophils and myeloid-derived suppressor cells, endothelial progenitor cells and tumor cells themselves.

that is triggered by primary factors such as FGF2 or angiopoietin. This breadth of tumor angiogenic factors, combined with the likelihood that at least some tumor cells may differentiate into tumor blood vessels, frustrates attempts at effective tumor treatment by targeting individual VEGFs or VEGFRs.

Inflammatory Cytokines and Chemokines

Bone marrow–derived immune and inflammatory cells, including macrophages, neutrophils, natural killer cells, dendritic cells and myeloid precursor cells, all produce numerous soluble angiogenic factors and stimulators, and some may even differentiate into endothelial cells (Fig. 5-30). Equally important are tumor-associated stromal fibroblasts. The contributions of these cells to tumor blood vessel growth reflects the context of the tumor. In some settings, these cells assume a Dr. Jekyll–like antineoplastic phenotype and produce antitumor and antiangiogenic activities. In other settings, they become Mr. Hyde and generate proangiogenic and protumor microenvironments. As if this were not sufficiently complex, cells such as dendritic cells and myeloid-derived suppressor cells are capable of trans-differentiating into endothelial cells.

Invasion and Metastasis Are Multistep Events

The lethality of cancer resides in its ability to spread. Over 90% of patients who die of cancer succumb to metastatic disease. While we have accumulated considerable understanding of tumorigenesis, our appreciation of the basic principles of metastasis remains rudimentary. What is clear is that tumor spread is a multistep process, with each step potentially representing major genetic and epigenetic modifications in tumor cells and their behavior.

Malignant cells go through several steps to establish a metastasis (Fig. 5-31):

1. Invasion of the basement membrane underlying the tumor
2. Movement through extracellular matrix
3. Penetration of vascular or lymphatic channels
4. Survival within circulating blood or lymph
5. Homing to a new site and exiting from the circulation there
6. Establishment of a micrometastasis

A final step, growth of micrometastatic foci into sizeable tumor masses, culminates this progression and represents the ultimate lethality of almost all malignancies.

Cancer cells develop at a given location, comfortable in their native environments, owing in part to their interactions with tumor-associated matrix constituents and stromal and inflammatory cells (see below). The latter may either be present in the extracellular matrix or be recruited from the bone marrow. In order to metastasize, cancer cells must also establish a comparably commodious ecosystem at a distant site. This is no small undertaking.

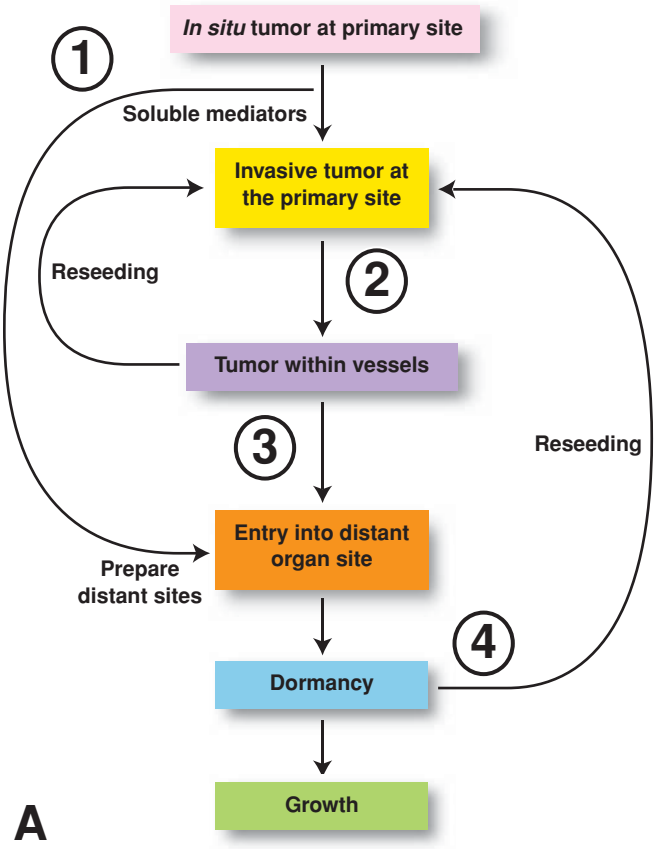
As the discussion below will demonstrate, some—perhaps most—of the traits necessary for tumors to metastasize are quite distinct from those needed for tumors to establish themselves at their sites of origin. It bears mention that it is not clear how the traits required for metastatic behavior are selected in primary tumors. While some traits needed for tumorigenesis may overlap the needs of metastases, other do not. Further, as one climbs the ladder of steps needed for metastasis, it is not known how cells that carry a phenotype that allows them to succeed at one rung are in a position to select for characteristics that facilitate success at the next rung.

The practical upshot of these philosophical ruminations is that *once a primary tumor has been removed, metastatic deposits are already in place.* The goal of subsequent therapy is to limit the growth of metastases that already exist.

Tumor cells start to disseminate early in oncogenesis. Many tumor cells enter the circulation daily (it is estimated to be 10^6 cells per gram of tumor per day). Taking out a gross primary tumor does not, therefore, "get it all out": micrometastases already exist.

Invasion and Tumor Cell Motility

For solid tumors, invasion requires that the previously stationary cell become motile. It must also become capable of disrupting and penetrating the underlying basement membrane, and then passing through the ECM. Orchestrating movement through the ECM requires proteases secreted by cancer cells and nonmalignant tumor-associated cells (see below). Cancer cells develop protrusions that contain an actin core and integrins. These projections, called **invadopodia,** express **matrix metalloproteinases (MMPs;** see below) and other proteases. Integrins in the ECM may not only act as mechanical anchors but also promote development of invadopodia. The invadopodia help to degrade the ECM and offer a guide to the perplexed cell in navigating its microenvironment via exploration of cell–cell and cell–matrix adhesions and by sensing chemoattractive molecules.



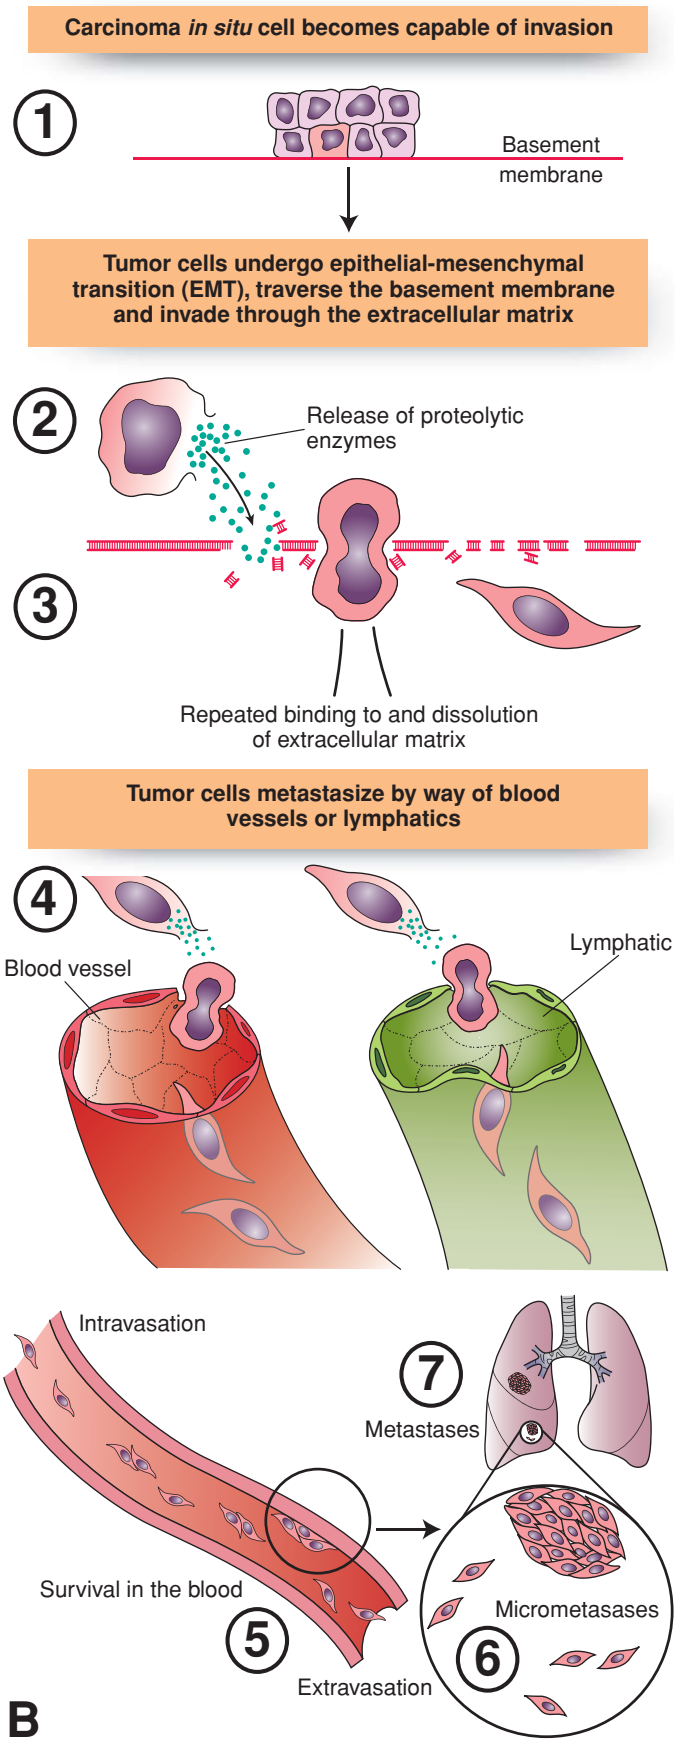


FIGURE 5-31. Mechanisms of tumor invasion and metastasis. The mechanism by which a malignant tumor initially penetrates a confining basement membrane and then invades the surrounding extracellular environment involves several steps. **1.** The tumor first acquires the ability to bind components of the extracellular matrix. These interactions are mediated by the expression of a number of adhesion molecules. **2.** The tumor undergoes epithelial–mesenchymal transition (EMT) and traverses the basement membrane. **3.** Proteolytic enzymes are then released from the tumor cells, and the extracellular matrix is degraded. **4.** After moving through the extracellular environment, the invading cancer penetrates blood vessels and lymphatics by the same mechanisms. **5.** After survival in blood vessels or lymphatics, the tumor exits the vascular system. **6.** It establishes micrometastases at the site where it leaves the vasculature. **7.** These micrometastases grow into gross masses of metastatic tumor.

Epithelial–Mesenchymal Transition

To escape the confines of the mucosa in which they originate, the epithelial cancer cells assume a phenotype that permits enhanced motility. The tumor cells, which are nonmotile and are encased in cell collectives via cell–cell tight junctions, disrupt these bonds and assume a new guise as single, nonpolarized mobile mesenchymal cells. This chameleon-like **epithelial–mesenchymal transition (EMT)** is reversible and temporary.

What Elicits EMT?

Many factors contribute to EMT (see below), but diverse stimuli probably can trigger this function. Among these, hypoxia is felt to be critical. Since the diffusion radii of glucose and oxygen are limited to 100–150 μ, tumors growing in situ (e.g., comedo-type breast intraductal carcinomas; see Chapter 25) may show central necrosis. Hypoxia induces HIF-1α (see above), which itself regulates many genes. Among these are the proteases, MMP1 and MMP2, and lysyl oxidase (LOX). (Other HIF-1α functions are discussed below.) MMP2 degrades basement membrane, and MMP1 and LOX help to digest ECM to clear a path for the tumor cell.

EMT also entails the activation of a series of transcription factors that promote a mesenchymal phenotype. These factors—colorfully named Slug, Snail, Twist and ZEB1—were once active in mediating cell mobility during embryogenesis. They are reactivated to make adult epithelial cells act like their mesenchymal embryonic forbearers. Snail and Twist downregulate expression of E-cadherin (see below), a glycoprotein that anchors epithelial cells to each other and suppresses motility. In addition, Twist and ZEB1 downregulate the antiproliferative proteins $p16^{INK4a}$ and $p21^{CIP1}$. Freed of their E-cadherin shackle, epithelial cells can then invade. Proteases clear the way.

Tumor-Associated Cells

Nonneoplastic cells associated with tumors constitute about half of all cells within tumor masses. They include macrophages, leukocytes, fibroblasts, vascular endothelial cells, neuronal cells and fat cells (Fig. 5-32). Many of these resided originally in the ECM, but others are of bone marrow origin and are recruited to the site of the expanding tumor. All of these nontumor cells can influence the behavior of the cancer, both at its site of origin and at locations of metastases.

The Contributions of Tumor Stroma

Stimulation of tumor cell invasiveness by nearby stromal elements plays an important role in the ability of cancer cells to breach the basement membrane and traverse underlying connective tissues. Tumors co-opt normal stromal cell functions, trigger inflammatory reactions and recruit additional cells to the area of the developing malignancy to further subvert anatomic and other barriers to invasion. Perversely, components of inflammatory and wound repair processes (see Chapters 2, 3 and 4) that protect against, for example, pathogens are then brought to bear to render the individual susceptible to cancer cell invasiveness. It is important to appreciate that *the players in inflammatory and wound healing that are observed in nearby tumors are orchestrated by the developing cancers themselves* (Fig. 5-33) *and should not be misconstrued as protecting the host:*

- **MMPs:** The MMPs are a family of endopeptidases that are normally regulated by tissue inhibitors of MMPs (TIMPs). MMPs are synthesized and secreted by normal cells during physiologic tissue remodeling, at which times the balance between MMPs and TIMPs is strictly regulated. By contrast, invasive and metastatic phenotypes of cancer cells are characterized by dysregulation of the MMP–TIMP balance.

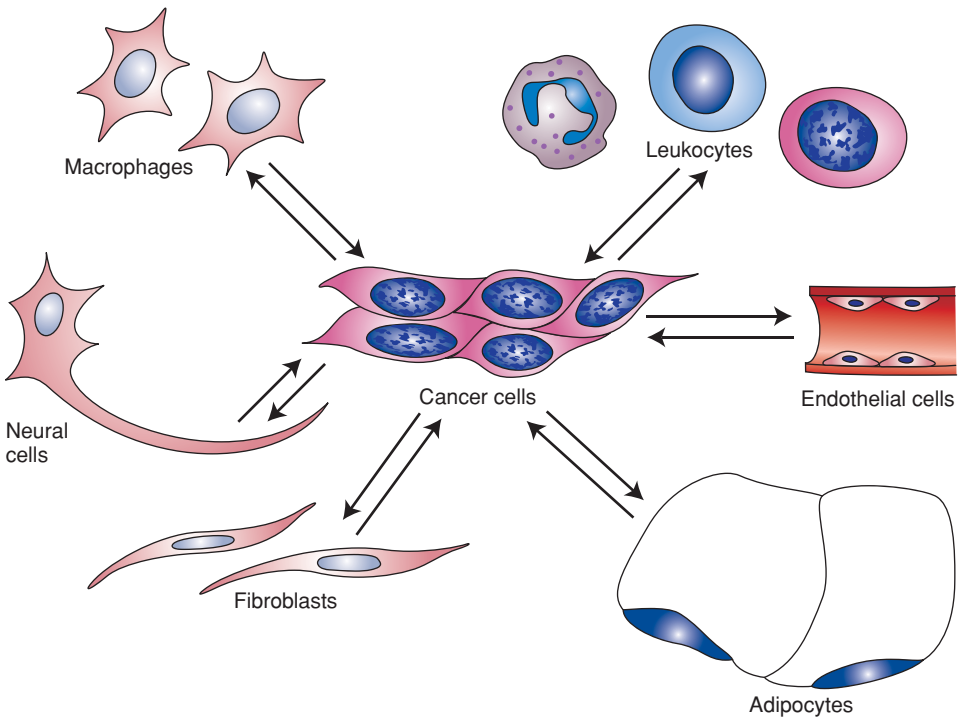

FIGURE 5-32. The cancer cell ecosystem. The developing tumor cells interact with the nonmalignant cells in their environment, via production of soluble and other mediators.

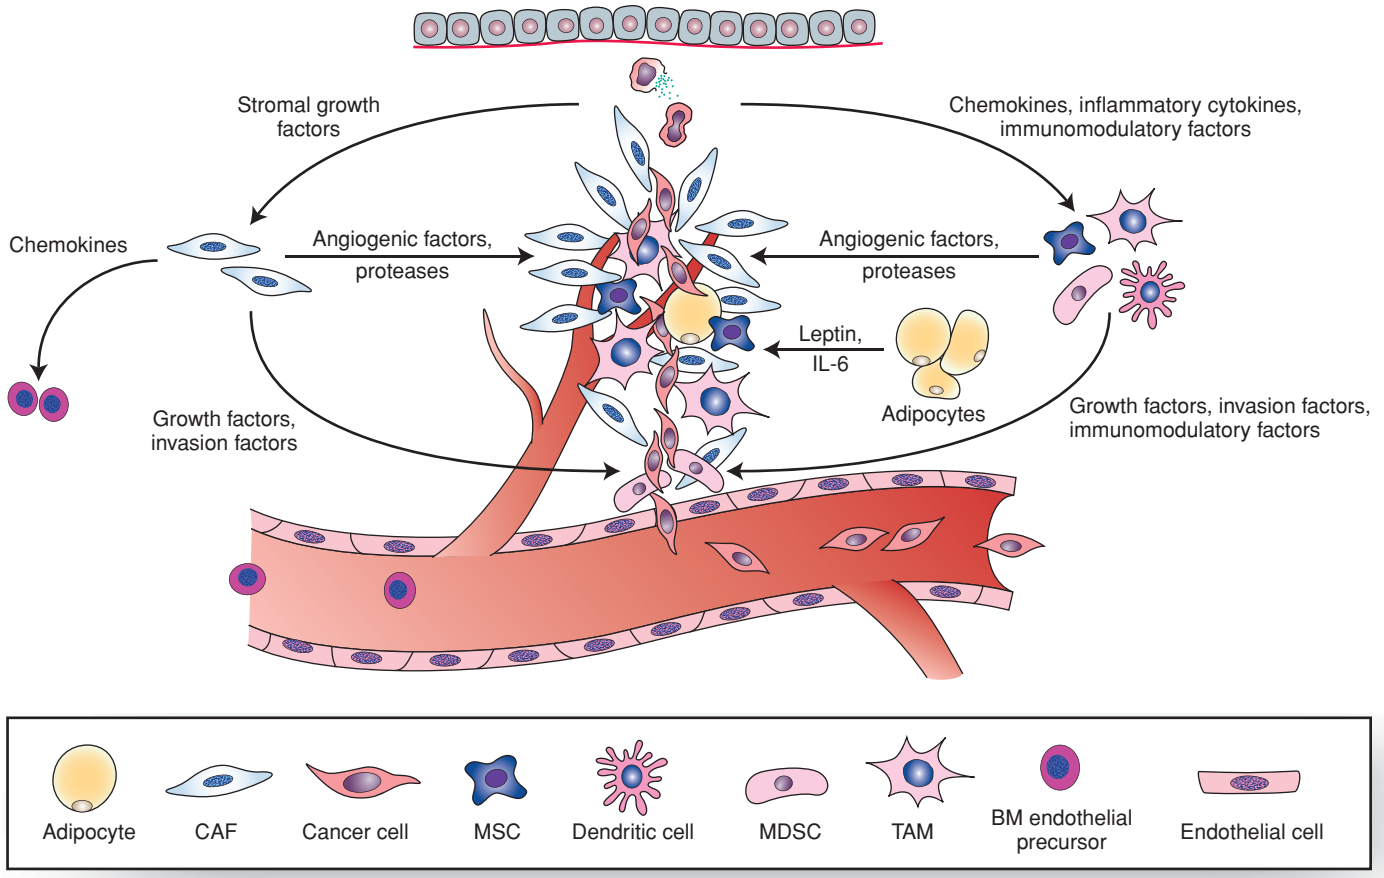

FIGURE 5-33. Tumor cell–stromal interactions involved in invasion and metastasis. Stroma adjacent to tumor is critical to the survival of tumor cells in place and to their dissemination. Such "cancerized stroma" contains bone marrow–derived elements (Fig. 5-30), including myeloid-derived suppressor cells (MDSCs), dendritic cells, tumor-associated macrophages (TAMs), fibroblasts, adipocytes and endothelial cells. Cytokines, chemokines and other mediators produced by tumor cells, as well as influences of tissue destruction and hypoxia, recruit TAMs, MDSCs, cancer-associated fibroblasts (CAFs) and mesenchymal stem cells (MSCs). MDSCs and TAMs are present at the invading tumor front—points where the basement membrane is being broken down and the tumor cells are infiltrating the stroma. These cells produce angiogenic factors, proteases and other factors that promote tumor invasion. CAFs produce similar facilitators and bring marrow–derived blood vessel precursor cells to generate new blood vessels.

In many tumors, invasiveness correlates directly with increased MMP expression. In many of these same tumors, TIMPs are decreased. MMPs in invading cancers may be produced by the tumor cells themselves, by surrounding stromal cells or both, depending on the particular neoplasm. MMPs secreted by stromal cells may be bound to integrins on the surface of the tumor cells, thus providing particularly high local concentrations of protease activity precisely where the tumor needs it in order to invade. Deregulated MMP activity permits cancer cells to enter and traverse the ECM.

Tumor cell motility is enhanced by upregulation of CXCR4 chemokine receptors in cancer cells at the invasion front. Interestingly, the invading cells induce nearby stromal cells to secrete SDF-1 (also called CXCL12), the ligand for this receptor.

- **Marrow-derived suppressor cells (MDSCs):** Tumors recruit these cells from the blood and bone marrow. They are at the edges of developing tumors and affect host responses to tumors (see below). MDSCs also secrete MMPs, which help to degrade basement membrane and ECM. They stimulate angiogenesis by secreting VEGF and PDGF.
- **Tumor-associated macrophages (TAMs):** These cells congregate at areas in which the basement membrane is breaking down. Like MDSCs, they secrete proteases, particularly urokinase plasminogen activator (uPA), which converts plasminogen to plasmin. The latter, in turn, helps digest type IV collagen in basement membranes. TAMs also produce cathepsin proteases in response to IL-4 made by tumor cells, further augmenting tumor invasiveness.
- **Carcinoma-associated fibroblasts (CAFs):** Like TAMs, CAFs produce proteases that facilitate tumor cell invasion. They also synthesize growth factors and angiogenic factors, and recruit precursor cells from the marrow, to become vascular endothelium.
- **Adipocytes:** The stroma in which many tumors arise contains adipocytes. Cross-talk between these cells and tumor cells facilitates early stromal invasion by the malignant cells. Fat cells near tumors often express a particular MMP that assists cancer cells in traversing surrounding connective tissues. Adipocyte-derived IL-6 stimulates tumor cell invasiveness. Leptin produced by adipocytes (see Chapter 13) induces macrophages to secrete proinflammatory cytokines, which, in turn, promote invasion and metastasis.

- **Lymphocytes:** T cells may facilitate tumor invasiveness via TAMs. $CD4^+$ lymphocyte-activated TAMs can elicit EGFR-related activation in some types of cancers.

The combination of these and other elements by developing tumors is sometimes called cancerized stroma. It should be noted that many interactions between invading cancer cells and their stromal accessories in crime constitute a positive feedback loop: tumors recruit and activate stromal cells, which repay the favor by magnifying the tumor's invasive tendencies.

Following their invasion of surrounding tissue, malignant cells may spread to distant sites by a process that includes a number of steps.

Invasion of the Circulation

Malignant cells penetrate lymphatic or vascular channels. Solitary cells that have already undergone EMT represent only a small component of the entire primary tumor. As lone travelers, however, these cells move more rapidly than do cell clusters and **intravasate** (penetrate) into blood vessels, which provide a route for migration to faraway body sites. Tumor-associated capillaries stimulated by tumor-produced VEGF and related angiogenic factors (see above) are not completely invested by pericytes. Tumor blood vessels are constantly being remodeled, and so are less well formed than their physiologic cousins. The angiogenesis initiator, VEGF, increases vascular permeability. In addition, TAMs produce EGF and tumor cells secrete colony stimulating factor-1 (CSF-1), both enhancing intravasation. MMP1 and MMP2, as well as other tumor and stromal cell products, increase the leakiness of tumor-induced blood vessels and facilitate their invasion by cancer cells.

By contrast, compact cell collections preferentially transfer to the lymph nodes, where they generally remain in place. Collective cell migration to lymph nodes appears to be independent of spread through blood vessels, and each may be the preferred mode of dissemination for specific tumors. However, metastases may in turn metastasize and single cells may exfiltrate and disseminate widely via the bloodstream. This phenomenon is the basis of currently used assays to quantitate single tumor cells in the peripheral blood, the results of which are used both as prognostic indicators and to guide choice of chemotherapy.

In lymph nodes, communications between lymphatics and venous tributaries allow the cells access to the systemic circulation. Most tumor cells do not survive their journey in the bloodstream, and a tiny percentage remain to establish a new colony.

Survival in the Vascular System

Once in the circulation, tumor cells have two main tasks: to survive and to find a new home. **Circulating tumor cells (CTCs)** are unlikely to spend long in the vascular system. Their size (20–30 μ on average) far exceeds the diameter of pulmonary capillaries (about 8 μ). A single passage through the pulmonary circulation should filter the vast majority from the blood.

To remain viable when detached from their native ECM, CTCs must be able to avoid anoikis (see Chapter 1), a form of apoptosis that is triggered by loss of the ECM anchors that constitute a cell's native environment. In some cases, this is achieved by activating TrkB, a suppressor of anoikis.

Preparing the Soil

It has been known for many years that metastasis is not random, that is, that certain types of tumors specifically tend to colonize particular organs. The molecular basis for some of these patterns of cancer spread is beginning to be understood.

There are certain general mechanisms that, even before a tumor begins to disseminate, help to prepare distant sites in ways that make the wandering tumor comfortable. Secretion of angiogenesis factors, VEGF and its cousin, placental growth factor (PlGF), with variable cocktails of other growth factors generated by tumor cells and their stroma causes hematopoietic progenitor myeloid cells (HPCs) to leave the bone marrow. These cells home to specific organs and set up a microenvironment there that accommodates the needs of the soon-to-arrive metastatic tumor cells. These so-called premetastatic niches undergo repeated remodeling by cytokines and enzymes produced by the marrow-derived cells. Inflammatory cells recruited from organ stroma and from the blood produce cytokines and enzymes (such as MMPs and LOX) that make the distant environment even more homey for metastatic colonization. The result is like a prefabricated house, just waiting for its future occupants.

Tumor Cell Arrest in the Circulation

While circulating, tumor cells associate with diverse formed constituents in the blood, including neutrophils, immune cells and platelets. These blood cells protect tumor cells from shear, immune and other stresses in the circulation. Such associations are mediated by adhesion molecules such as integrins, selectins (see Chapter 2) and a glycoprotein (CD44) at the surface of tumor cells. Tumor cells produce a factor that activates platelets via production of thrombin, and including fibrin and von Willebrand factor as bridging proteins. The binding of tumor cells to platelets requires P-selectin and platelet integrins, which recognize tumor cell CD44 via von Willebrand factor and fibrin. Similar interactions mediate tumor cell recognition and tethering to endothelial cells and to endothelial-bound leukocytes (Figs. 5-34A,B).

Leaving the Circulation

After arrest in the bloodstream, tumor cells and their fellow travelers mediate the process of extravasation. This is a bit more complex than its obverse—intravasation—earlier in the cancer cells' odyssey, because blood vessels at the tumor cells' destination are well constructed and anatomically complete, rather than new, poorly formed tumor-induced blood vessels. Extravasation appears to be relatively organ specific, so that the factors that are involved in extravasation of one tumor type into the lung, for example, differ from those that help the same or other tumor types exit the circulation elsewhere.

With that caveat in mind, the ability of tumor cells to enter the lung has been ascribed to a small number of proteins that increase vascular permeability, degrade tight junctions between endothelial cells and promote tumor cell escape from the circulation. These include several MMPs and VEGFs, cyclooxygenase-2 (COX-2), the EGFR ligand epiregulin and a protein called **angiopoietin-like 4 (Angptl4)**. This latter cytokine is particularly important for dissolving tight junctions between endothelial cells, thus facilitating tumor cell migration through vascular walls.

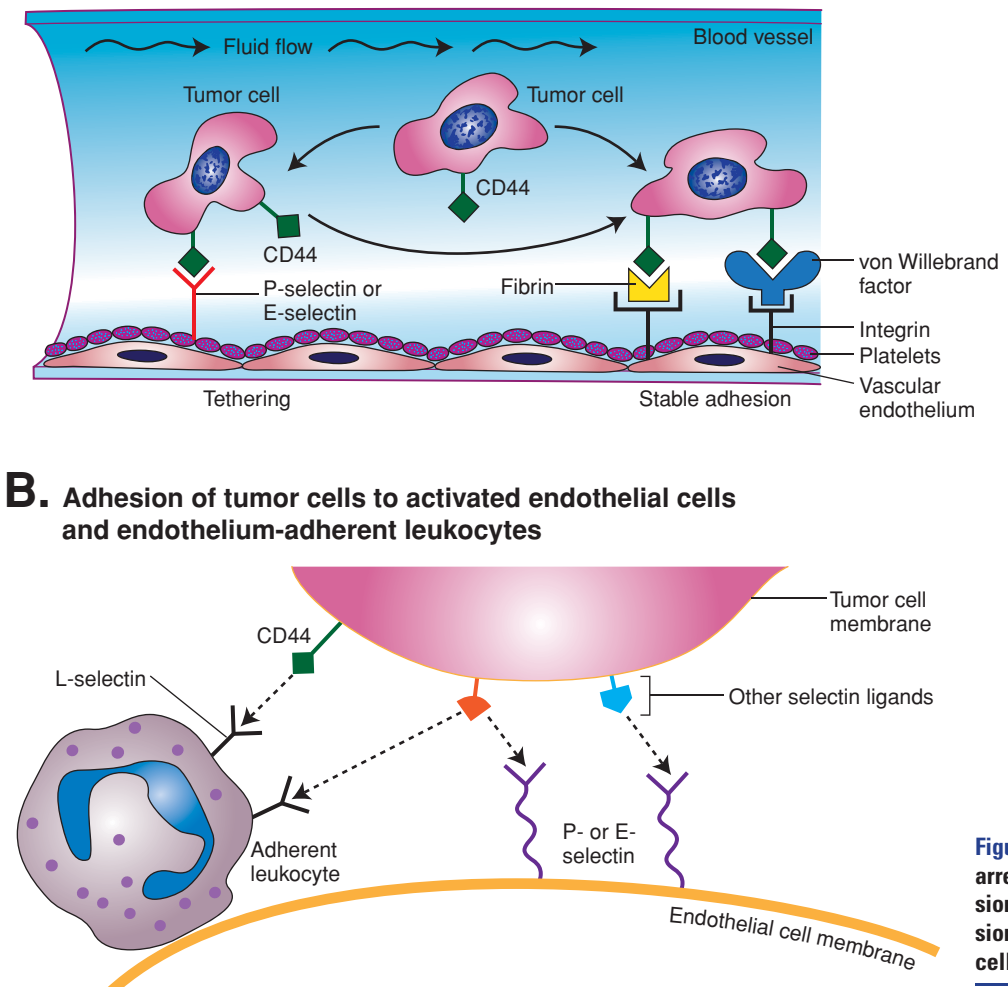

Figure 5-34. Mechanisms of tumor cell arrest in the circulation. A. Tumor cell adhesion to surface-anchored platelets. B. Adhesion of tumor cells to activated endothelial cells and endothelium-adherent leukocytes.

Establishing Micrometastases

The process of establishing colonies distant from primary tumors requires complex synchronization of the biochemistry, matrix and cellular composition of the soon-to-be metastatic site with the circulating tumor cells. Micrometastases may survive but never grow. Or they may not survive. Prospective micrometastatic foci must cope with issues relating to the suitability of the ECM, blood supply and stromal cells for tumor growth. More often than not, individual tumor cells or small clusters of tumor cells either become dormant in distant sites (see below) or die. For example, extravasated carcinoma cells may be unable to connect adequately with adhesion processes at foreign locations. Among the factors that enable micrometastatic foci to persist is the recruitment of bone marrow–derived HPCs to help guide tumor cells and stimulate their growth. SDF-1, derived from such cells, binds its receptor, CXCR4, on the tumor cells and stimulates proliferation. Active signaling through Src (see above) is important in ensuring continued survival of nascent micrometastases.

The Inefficiency of Metastasis

Tumor cells circulate in large numbers in cancer patients. It has been estimated that for every gram of tumor mass, 10^6 tumor cells are released into the circulation daily. CTCs can be detected even before the primary tumor becomes pathologically invasive. Furthermore, patients who inadvertently developed very high CTC levels because of a peritoneal-vascular shunt developed metastatic disease only infrequently.

What accounts for the inefficiency of metastasis is not clear. Mechanisms that suppress it (see below), both inherent to and outside tumor cells, undoubtedly contribute. Until we better understand these mechanisms and how tumors evade them, our effectiveness in treating metastatic solid tumors is likely to be limited.

Tumor Dormancy and Evolution of Micrometastases

What happens to all those CTCs that never become gross metastatic deposits? Some surely die, whether by apoptosis, anoikis, immune elimination or some other mechanism. Many, though, establish a dormant state. It is well known that metastases may become clinically apparent many years, even decades, after a primary tumor mass is removed. This is particularly the case in breast cancers and malignant melanomas. Such deposits were clearly derived from the original tumor yet remained below the clinical radar for long periods of time.

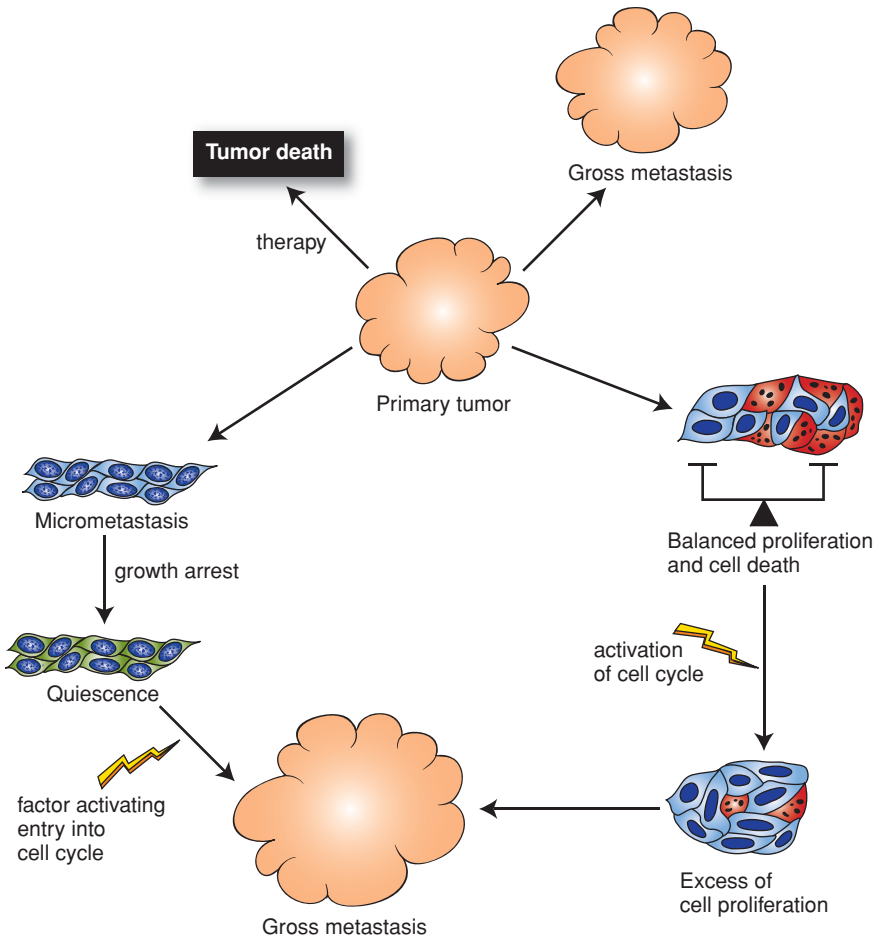

FIGURE 5-35. The fate of foci of cancer micrometastases. A primary cancer may be killed by therapies, such as radiation or chemotherapy, or it may be surgically removed. The tumor may produce a grossly evident metastasis. A number of factors may cause minute, clinically inapparent, metastatic foci of tumor cells to enter G_0 (*green*), but may be reactivated to enter the cell cycle (*blue*) and form a clinically detectable metastasis. Micrometastasis may also entail a balance between cell proliferation (*blue*) and cell death (*red*). If this equilibrium is disturbed in favor of tumor cell proliferation, the result may be a grossly evident mass of metastatic tumor.

It is also clear that some primary tumors may exist for many years before they are detected clinically. The presence of cancers, whether primary or metastatic, that do not enlarge to the point of being clinically detectable is **tumor dormancy**.

Growth of both the primary tumor and metastases is not necessarily exponential. Rather, it is often interrupted by quiescent intervals. As a result, the time needed for a tumor to grow into a clinically detectable mass is highly variable, likely reflecting fluctuations in stimulating or permissive signals on the one hand, the actions of inhibitory factors on the other or both.

Although tumor dormancy is a well-established observation, the mechanisms underlying this phenomenon are poorly understood. Factors that have been implicated in tumor dormancy and in escape from somnolence include angiogenesis, immune surveillance, apoptosis after oncogene inactivation (in cells that are oncogene addicted; see above), local processes such as inflammation, activation of cancer stem cells and adhesion molecules such as integrins. Sometimes, dormant tumor foci may represent a highly dynamic state—an equilibrium between cell proliferation and cell loss. At other times, the tumor cells are hypnotized into a somnolent state, in which they remain in the G_0 phase of the cell cycle (Fig. 5-35).

There are many **metastasis suppressor genes** that prevent various segments of the metastatic pathway. Thus, tumor dormancy has many faces, as reflected by the panoply of pathways by which tumor cells may be blocked from propagating and may be subsequently awakened by a still unrecognized Prince Charming (Fig. 5-35).

Currently, resection of many tumors in patients without evidence of distant metastases is often followed by adjuvant therapies that are directed against undetected micrometastases. Such treatments are usually of short duration and are often aimed at rapidly proliferating tumor cells. If metastases are dormant, these types of therapies may not affect somnolent tumor foci. Future cancer therapies may need to be able to exploit the characteristics of tumor dormancy (e.g., by altering the equilibrium that sustains dormancy in favor of cell death or by forcing dormant foci into more active cycling to facilitate their targeting by more conventional chemotherapy).

TUMOR SUPPRESSORS

Tumor suppressors are a very large and diverse group of cellular functions, carried out via many different pathways and mediators. Suppressors exist for all the cancer attributes mentioned above (immortalization, evading PCD, etc.) and those companion tumor characteristics (genomic instability, altered metabolism, etc.) described below. This section highlights how tumor suppression works and the nature of many different molecules, and the diverse types of molecules, that carry the burden of these functions. It is organized according to the tumor attributes listed above and illustrates how some processes counteract those attributes.

Tumor suppression is an amalgam of processes. Some of these processes are inherent in particular cellular molecules (e.g., cell cycle regulation and Rb, or the intrinsic pathway of apoptosis and Bax). It is tempting to confuse the function with the mediators of that function, a logical jump that is made all the time. But, just like that extra scoop of ice cream, this temptation should be resisted, and the student would do well to remember that tumor suppression is defined by function, not by structure. One tumor suppressor function may be executed by several different molecules, and any one molecule may have multiple functions.

There are almost infinite variations on the themes of tumor suppression. Many tumor suppressors only inhibit development and spread of some types of tumors. Still others (e.g., WT1) are tumor suppressors in some circumstances but act as oncogenes in others. Some molecules may execute their duties in some settings, but not always. Further, some mutated tumor suppressors (like p53) not only fail to inhibit tumor development but also may actively facilitate it and inactivate other tumor suppressors. This fluidity should be kept in mind. We present tumor suppressors as static structures (e.g., PTEN, VHL, etc.) as a means to aid in understanding how they work, the processes they antagonize and what goes awry when they are mutated or inactivated.

The student should be mindful of this complexity, as it may come in handy when dealing with one of nature's most vexing principles, the law of unintended consequences. That is, it may help in appreciating that, for example, therapeutic manipulations conceived with ironclad theoretical logic so as to produce a particular result may yield consequences quite different from expectations.

Tumor Suppressor Mechanisms Protect from Oncogenesis by Inhibiting Every Tumor Attribute

Cells possess complex mechanisms that guard against tumor development. The molecular guardians responsible for this protection are called tumor suppressors, and the genes that encode them, tumor suppressor genes (TSGs). Major activities of tumor suppressors are illustrated in Fig. 5-36. If an incipient tumor is to develop successfully, it must generally inactivate one or more TSGs or their products.

There are many TSGs, with diverse targets, functions and mechanisms of action. Some tumor suppressors have multiple functions and targets. Some are not proteins, but may be untranslated RNA species (see below). And some are part-time tumor suppressors and part-time oncogenes. In light of this considerable complexity, we focus here on key concepts

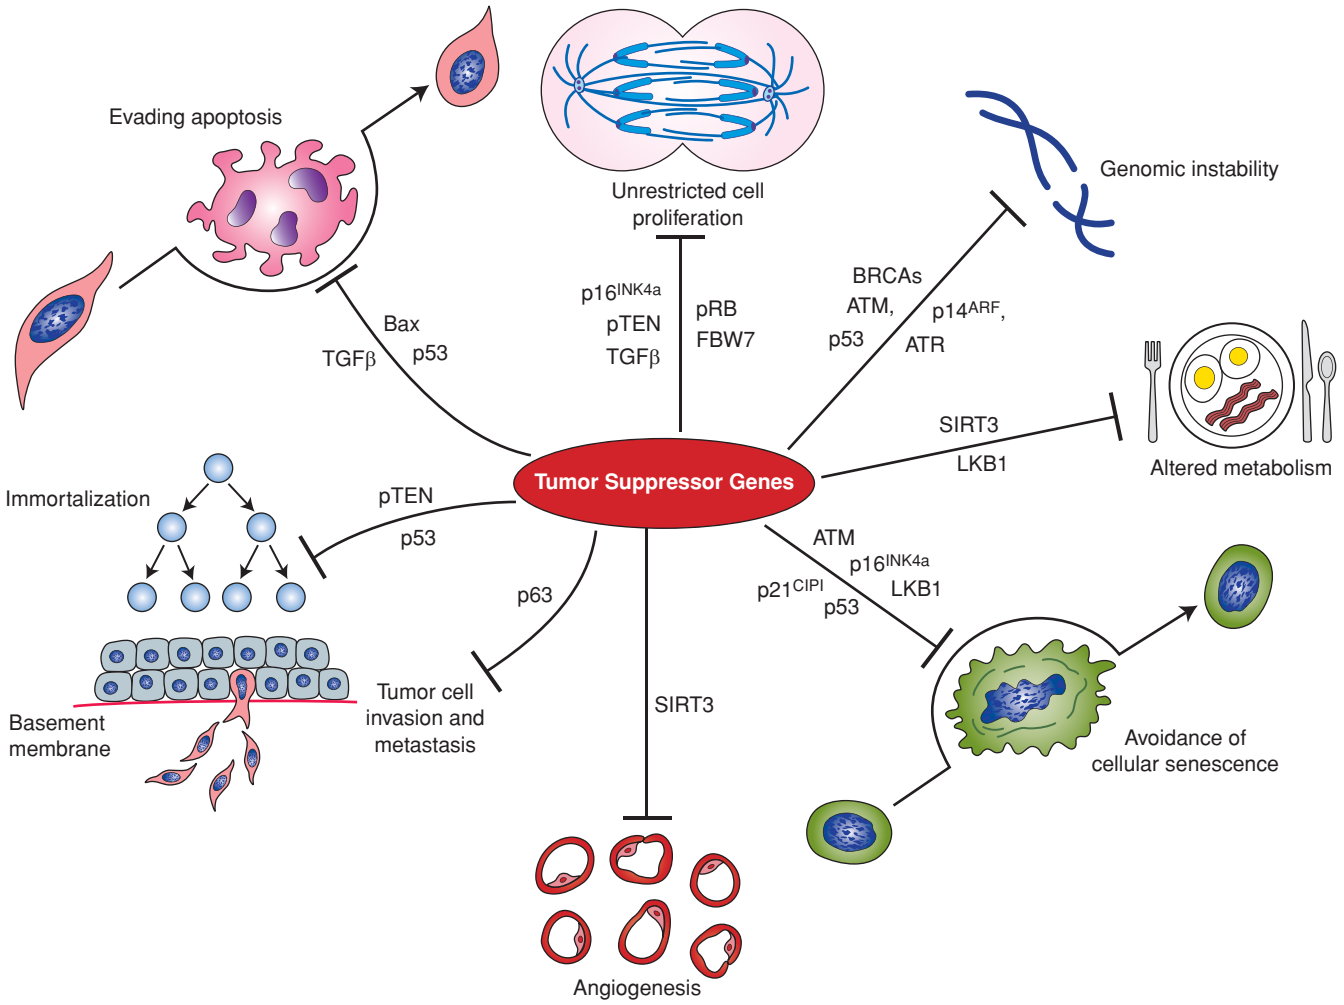

FIGURE 5-36. Tumor-related activities that are targeted by important tumor suppressor genes and representative tumor suppressors involved. The major hallmarks of malignant tumors each is antagonized by multiple tumor suppressor gene products. Those hallmarks, and the tumor suppressor activities that work against them, are illustrated here.

in understanding how important aspects of tumor suppression work, the ways in which tumor suppressors are circumvented and how tumors arise once TSG activities go awry. The protective activities of tumor suppressors are illustrated below for each of the major cancer attributes (see above).

Tumor Suppressors Regulate Cellular Proliferation

In normal settings, there are several important mechanisms that limit cell division. As noted previously, interactions between extracellular molecules and their cell membrane receptors trigger intracellular signaling via multiple pathways (Fig. 5-37). These include activation of PI-3 kinase (PI-3K; see above), which phosphorylates phosphatidylinositol-4,5-bisphosphate (PIP2) to produce phosphatidylinositol-3,4,5-trisphosphate (PIP3). PIP3 then activates downstream signaling via Akt and mTOR to drive cell division. A key tumor suppressor protein, PTEN, dephosphorylates PIP3, and so impedes cell activation initiated by mitogenic extracellular signaling (Fig. 5-38). PTEN is a major tumor suppressor, second only to p53 in the frequency with which loss of a tumor suppressor function is observed in human cancers.

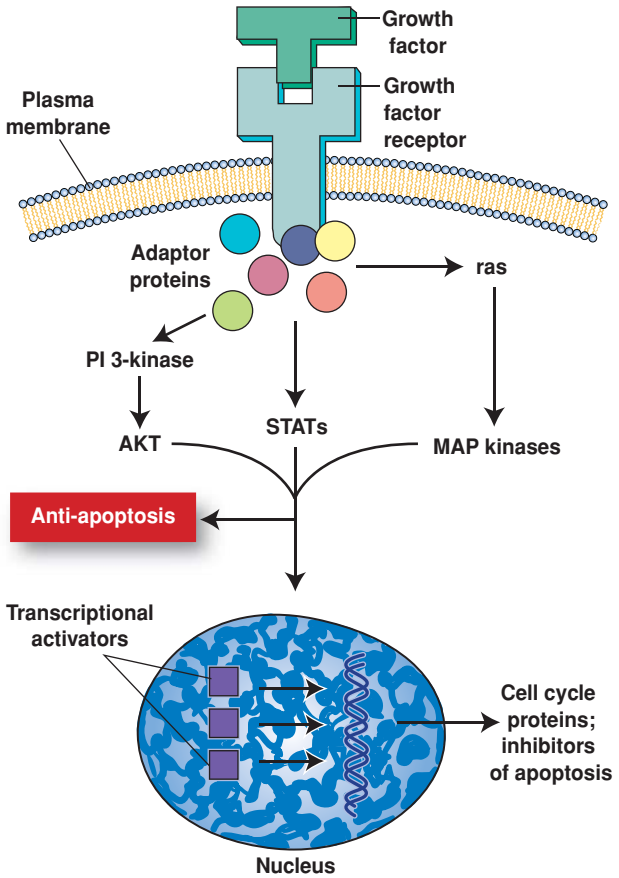

FIGURE 5-37. Signaling pathways controlling proliferation and apoptosis. The activation of growth factor receptors by their ligands causes the binding of adaptor proteins and the activation of a series of intracellular signaling molecules, leading to transcriptional activation, the induction of cell cycle proteins and inhibition of apoptosis. Key targets include *ras*, mitogen-activated protein (MAP) kinases, signal transducer and activator transcription factors (STATs), phosphatidylinositol-3-kinase (PI3-kinase) and the serine/threonine kinase Akt.

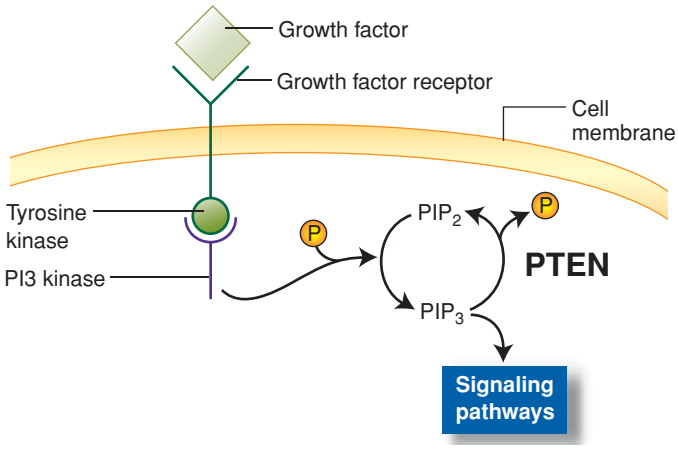

FIGURE 5-38. Signaling function of PTEN. Normal binding of a growth factor to its receptor leads to phosphorylation of phosphatidylinositol-4,5-bisphosphate (PIP2) to produce the important signaling molecule phosphatidylinositol-3,4,5-trisphosphate (PIP3). The level of PIP3 is regulated by its dephosphorylation by PTEN.

Many tumor suppressors act downstream from receptor–ligand interactions. Key tumor suppressor targets include the various transitions in the cell cycle (see above) and activation/inactivation of gene transcription. Thus, pRb blocks cell cycle transit, unless it is hyperphosphorylated, to release the E2F transcription factor that drives cell division. The enzymes that phosphorylate pRb (CDKs 2, 4 and 6, complexed with various cyclins; see above) are inhibited by the tumor suppressors $p16^{INK4a}$ and $p21^{WAF1}$. Once pRb is phosphorylated, however, it may be dephosphorylated. Thus (see above), pRb can be dephosphorylated to restore its ability to inhibit E2F.

E2F-mediated transcription of many genes that drive cell division (e.g., *c-myc*) is powerfully inhibited by TGF-β. TGF-β binds its receptor to activate a series of intermediary signaling molecules called Smads (Fig. 5-39A). Smad4 is a key effector of TGF-β–induced transcriptional activity. It first blocks transcription of the *c-myc* proto-oncogene, thus inhibiting cell cycle transit and allowing Smad4 to upregulate expression of genes that block cell division, $p16^{INK4a}$ and $p21^{WAF1}$ (Fig. 5-39B). TGF-β signaling is among the most potent endogenous mechanisms that inhibit cell division and is commonly mutated in human cancers.

Tumor suppressors also inhibit cell division at stages that follow transcriptional activation or repression. Thus, TGF-β signaling activates molecules that impede translation of mRNAs for proteins that drive cell cycle progression. Another tumor suppressor, FBW7, is part of a ubiquitin ligase complex that eliminates many proteins that drive cell division, such as Myc, cyclin E and Jun.

Many other tumor suppressors, far too numerous to mention, also regulate cell division. The above descriptions illustrate the diversity of mechanisms that protect the organism from runaway cell proliferation.

Programmed Cell Death Destroys Cells at the Cusp of Becoming Dangerous

The several signaling networks that culminate in cell death have been described in Chapter 1. They are all relevant to

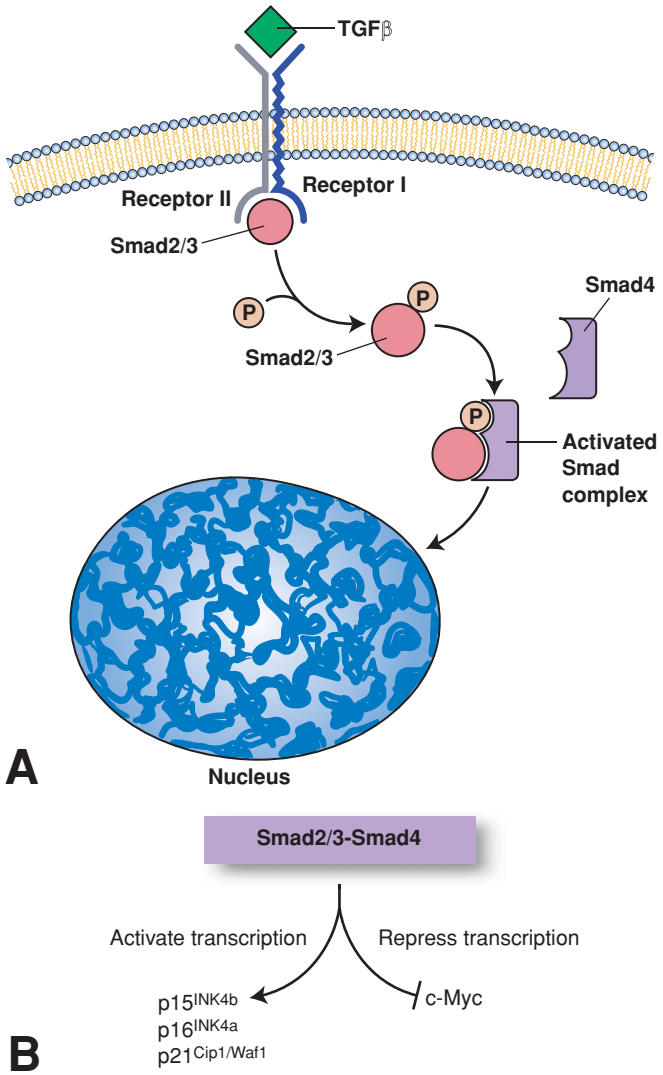

FIGURE 5-39. Transforming growth factor-β (TGF-β) as a tumor suppressor. A. Signaling. TGF-β binds its heteromeric receptor to phosphorylate and so activates Smads 2 and 3. These bind Smad4, to form an activated Smad complex that translocates to the nucleus to mediate transcriptional activation and repression. **B. Consequences.** The Smad2/3–Smad4 complex activates transcription of cell cycle suppressors, as shown, and represses transcription of the proliferation activator *c-Myc*.

protecting from tumor development, but the most critical of these is the PCD pathway that is activated by altered DNA structure. This pathway, in which there are several key participants—including ATM and ATR (see above) and, most critically, p53—is illustrated in Figs. 5-17 and 5-18.

The p53 tumor suppressor is a principal mediator of growth arrest, senescence and apoptosis (Figs. 5-17 and 5-18). In response to DNA damage, oncogenic activation of other proteins and other stresses (e.g., hypoxia), p53 levels rise and prevent cells from entering the S phase of the cell cycle, thus allowing time for DNA repair to take place. p53 thus acts as a "guardian of the genome" by restricting uncontrolled cellular proliferation under circumstances in which cells with abnormal DNA might propagate.

Acquired mismatches in DNA bases are detected by ATM if they occur in resting cells damaged by, for example, radiation or by ATR if they occur during DNA replication (see above). These proteins then activate one of two kinases, Chk2 or Chk1, respectively. The latter phosphorylates p53 (see above and Fig. 5-17), causing it to dissociate from its inhibitor, MDM2, and activating the p53 damage response.

p53 protein is a transcription factor that promotes expression of other genes involved in controlling cell cycle progression and apoptosis. DNA damage and other stresses (e.g., hypoxia) upregulate the expression of *p53,* which in turn enhances the synthesis of CKIs. The latter inactivates cyclin/CDK complexes, thus leading to cell arrest at the G_1/S checkpoint. Cells arrested at this checkpoint may either repair the DNA damage and then reenter the cycle, or undergo apoptosis. The stimulation of gene transcription by p53 results in the synthesis of proteins (CIP1, GADD45) (Fig. 5-18B) that enhance DNA repair by binding to proliferating cell nuclear antigen (PCNA; see above). Thus, *upregulation of p53 as a tumor suppressor has two important and related consequences: arrest of cell cycle progression and promotion of DNA repair.*

If it is not possible to return the cell's DNA to its correct sequence, p53 may then trigger cell death. It may do this in several ways (see Chapter 1). Largely, p53 induces apoptosis by activating the intrinsic apoptosis pathway. It does this in the following ways:

- As a transcription factor, it increases production of pro-apoptotic proteins (e.g., Bad, Bax, PUMA and others) and represses transcription of prosurvival proteins (e.g., Bcl-2, Bcl-xL, Mcl-1).
- It may directly activate cytosolic Bax, which in turn moves into mitochondria and triggers release of cytochrome C (CytC).
- p53 may act as a BH3-only (see Chapter 1), proapoptotic Bcl-2 family member by directly binding to Mcl-1, therefore freeing Bak to release CytC and other proapoptotic mitochondrial proteins.

By whatever means p53 activates apoptosis, the cell death program is executed by caspases, especially caspases-3, -6 and -7 (see Chapter 1).

The issue of apoptosis and protection from cancer is further complicated by the phenomenon of **oncogene-mediated apoptosis**. Myc transcription factor drives cell proliferation. However, activated Myc can be a blessing in disguise. It also induces a default apoptosis pathway. That is, deregulated production of Myc promotes cell proliferation but is usually balanced by increased apoptosis. Myc-induced apoptosis acts as a "molecular safety valve" that blocks cancer development. If Myc-stimulated tumor development is to occur, cells producing Myc at high levels must also overcome PCD-inducing mechanisms by overexpressing Bcl-2 or other antiapoptotic proteins.

Tumor Suppressors and Senescence

No single paradigm explains all of OIS. The centrality of DNA damage response (DDR) via Rb and p53 is generally accepted, but senescence entails complex signaling (Fig. 5-27), and perturbation of any member of this could facilitate development of malignancy.

As described above, ongoing telomere shortening in normal cells eventually leads to senescence. Tumor suppressor activities that elicit senescence are critical defenses against oncogenesis. They include components of the DDR system, such as ATM, ATR, Chk 1 and 2, the cell cycle regulators p53 and Rb and many others.

Inhibitors of Tumor Angiogenesis Limit Tumor Growth

There are many potent endogenous suppressors of tumor-related blood vessel growth:

- **VHL:** This protein is part of a ubiquitin ligase that targets transcription factors, called HIFs (see Chapter 1), for degradation. Inactivation of the *VHL* gene leads to a defect in Ub conjugation, which leads to increased HIF-1α (see above), an angiogenic factor that activates transcription of genes important in cellular responses to low oxygen environments. These include those that (1) increase cellular intake of glucose for anaerobic glycolysis, (2) stimulate angiogenesis (VEGF; see Chapter 16) and (3) activate several critical growth factors.

  The carcinogenicity associated with the inactivation of VHL is caused in large part by the action of HIF-1α in promoting tumor growth. Interestingly, similar activation of HIF-1α occurs in the often oxygen-starved cores of many tumors, even in the absence of *VHL* mutation. In those settings, HIF-1α degradation is impaired by decreased activity of a cofactor for the ubiquitination reaction.

  The normal VHL protein has additional tumor suppressor activities independent of HIF-1α. These include (1) promoting apoptosis, (2) increasing cellular immobilization by adherence to matrix proteins and (3) repressing certain cell activation responses.
- **NOTCH:** Although it is an important stimulator of embryonic blood vessel development, the NOTCH family of endothelial cell receptors, together with their cognate cell surface–bound ligands (especially DLL4), inhibits tumor angiogenesis. In fact, VEGF stimulation elicits DLL4 production as a negative feedback mechanism. Its conversion to angiogenesis inhibitor in postembryonic life notwithstanding, the NOTCH/DLL4 system is thought to represent a mechanism by which tumors outwit VEGF-targeted antiangiogenic therapies.
- **ECM and other angiogenesis inhibitors:** ECM constituents and clotting factors, and their breakdown products, all suppress tumor angiogenesis. **Thrombospondin** (TSP-1), derived from a large ECM glycoprotein, is a powerful inhibitor of blood vessel formation. **Angiostatin,** a breakdown product of plasminogen, and numerous fragments of ECM constituents (endostatin, inhibin and many others) restrain tumor-related blood vessel growth as well.
- **p53:** While p53 is not known to interfere with tumor angiogenesis itself, it upregulates TSP-1 expression, as noted above, and so has a strong antitumor angiogenic function. TSP-1 inhibition of tumor angiogenesis is a casualty of loss of p53.
- **SIRT:** Sirtuin deacetylases are important in stress responses and longevity. One of the sirtuins, SIRT3, increases the mitochondrial antioxidant, manganese superoxide dismutase (MnSOD; see Chapter 1). As a result, mitochondria produce less reactive oxygen species (ROS), causing decreased HIF-1 activity and thus less angiogenesis.

For Each Step of Invasion and Metastasis, There Are Antagonists That Hinder the Ability of Tumors to Spread

Just as the body arrays its defenses to prevent cancers from arising, it has developed mechanisms to impede every step of the process of invasion and metastasis. Metastasis inhibitors are conceptually distinct from tumor suppressors. To qualify as a metastasis suppressor, a molecule must impede one of the invasion- or metastasis-related processes without necessarily affecting growth and survival of the primary lesion. To date, about 30 metastasis suppressor proteins are known, plus an increasing family of miRNAs that show metastasis suppressor activity. Some suppressors act at multiple steps, while others are known to act at only one. Also, some molecules may inhibit certain processes in some tumors or tumor types but have the opposite effects in others. Finally, there are some metastasis suppressors that have additional, separate activities directed against the primary tumor (e.g., proapoptotic, antiproliferative).

Impairing EMT

Cadherins are a family of cell–cell adhesion molecules, the best characterized of which is E-cadherin. It is expressed on the surface of all epithelia and mediates cell–cell adhesion by mutual **zipper** interactions. Catenins (α, β and γ) are proteins that interact with the intracellular domain of E-cadherin and create a mechanical linkage between that molecule and the cytoskeleton, which is essential for effective epithelial cell interactions. Overall, cadherins and catenins are paramount in the suppression of invasion and metastasis. Expression of both E-cadherin and catenins is reduced or lost in most carcinomas, owing in large part to downregulation by the transcription factors mentioned above, Snail, ZEB1 and so forth. The miRNAs, miR-101 and the miR-200 family, help maintain the epithelial phenotype. The latter does so by repressing ZEB1 and ZEB2 levels, thus relieving their repression of E-cadherin levels (see above). (Nothing, of course, is so simple: the ZEBs also downregulate miR-200.)

Not to be outdone, TGF-β, which is an inhibitor of tumorigenesis, is also a promoter of metastasis. It acts in part by downregulating miR-200s. As a result, in most carcinomas, loss of E-cadherin is associated with the development of an invasive and aggressive phenotype. Clinically, there is an inverse correlation of levels of E-cadherin with tumor grade and patient mortality. Interestingly, β-catenin also binds to the APC gene product, an effect that is independent of its interaction with E-cadherin and α-catenin. Mutations in either the APC or β-catenin gene are implicated in the development of colon cancer (see later and Chapter 19).

Inhibitors of Tumor Cell Invasiveness

Nm23-H1. This was the first metastasis suppressor discovered. Its mechanism of action is still not fully understood, but it is known to inhibit tumor cell motility. Nm23-H1 achieves this by blocking cellular mobility signaled by Ras-related cell activation pathways.

p63. This member of the p53 family of tumor suppressors (see below) helps to restrain cellular invasiveness. p63 is often expressed in some in situ carcinomas, such as those of the prostate and breast. It is often repressed or lost in aggressive, metastatic carcinomas. Furthermore, mutants of p53 (see below) may bind and inactivate p63 by forming heterotetramer aggregates. Acting as a transcriptional regulator, p63 also upregulates expression of certain genes that inhibit metastasis (e.g., miR-130B).

Movement through connective tissue is a key function of tumor cells after EMT. This passage depends on the ability of

cells to wiggle through the ECM, which in turn depends on integrin-α5 as a mediator of EMT and RhoA, which helps to direct ameboid movement. These invasive characteristics are inhibited by miR-31 (see below).

Suppressors of Intravasation

Notch is a key inhibitor of tumor angiogenesis (see above). Mechanisms that impede intravasation also involve Notch. Thus, a protein called Aes (for amino-terminal enhancer of split) helps to inhibit migration of tumor cells through vascular walls via signaling networks that include Notch activation.

Limiting Tumor Cell Survival in the Circulation

Life for a tumor cell as a vagabond is no simple matter. Anoikis (see Chapter 1) is a form of apoptotic cell death triggered by loss of cells' usual liaisons with familiar ECM constituents. To add to the dangers of a cell's metastatic pilgrimage, many endothelial cells express the Duffy blood group glycoprotein, **DARC**. Upon recognizing KAI1 on tumor cell membranes, DARC triggers senescence programs, thus condemning the wandering tumor cell to a short, sterile existence. In addition, cells of the innate immune system can trigger cell death programs via TRAIL and CD95 (see Chapter 1).

As mentioned above, tumor cells tend to be significantly larger than the caliber of many vascular spaces they encounter. This disparity can stimulate the cells lining liver sinusoids to secrete nitric oxide (NO). NO triggers apoptosis in the overly large tumor cells trying to slog their way through channels that are too small for them.

Impeding Extravasation

The versatile miR-31 (see above), which inhibits tumor cell invasiveness, also blocks extravasation. This miRNA targets both integrin-5α and RhoA in the process.

Metastatic Colonization

Colonization and subsequent growth may be the major rate-limiting process in tumor metastasis. Several documented and likely metastasis suppressors act at this point, including KISS1 and its receptor, KISS1R. This pair derives their names from their discovery in Hershey, PA, home of chocolate kisses. KISS1, made by tumor cells, binds its cell membrane receptor, KISS1R. The result of this interaction is tumor cell apoptosis.

Other suppressors of metastatic colonization include GATA3 in breast cancers, which promotes cellular differentiation and impedes multiplication, and Psap in prostate cancers, which induces stromal cell production of the antiangiogenic substance thrombospondin-1 (see above). MiR-31, which has multiple antimetastatic activities, also inhibits the ability of cancer cells to colonize distant sites effectively.

Many metastasis suppressors have documented antimetastatic function, but the mechanisms by which these properties are exerted are uncertain. Once a primary tumor is removed, almost all therapy is aimed at suppressing metastases. Thus, it is not surprising that activating endogenous metastasis suppressive functions and trying to mimic them pharmacologically represent key targets of pharmaceutical investigation.

Diverse Mechanisms Participate in Compromising the Effectiveness of Tumor Suppressors

Of course, despite the body's best efforts, tumors still develop. In order to do so, they must either inactivate or circumvent the formidable defenses described above. There are a number of mechanisms by which this treachery occurs:

- **Loss of heterozygosity**
- **Spontaneous mutation**
- **Dominant negative mutations**
- **Fragile site translocations**
- **Altered levels or activities of tumor suppressor proteins**
- **Functional blockade by other related proteins**
- **Epigenetic changes that alter tumor suppressor expression or function**

These mechanisms are described and illustrated below. Epigenetic changes in cancer are discussed in a subsequent section.

Retinoblastoma Gene and Loss of Heterozygosity

Inactivation of tumor suppression may occur in many ways and is incriminated in the pathogenesis of both hereditary and spontaneous cancers in humans. It should be kept in mind that inherited defects in tumor suppression are fortunately rare. However, they help to identify tumor suppressors, to delineate how the affected tumor suppressor gene (TSG) products act and to identify mechanisms of tumor suppressor inactivation. Acquired impairments in tumor suppression are common.

Many more TSGs are known than can be described here, and their numbers are increasing. In addition, inherited mutations in TSGs are responsible for many named tumor susceptibility syndromes, some of which are listed in Table 5-6 (see below).

Retinoblastoma Gene

Retinoblastoma is a rare childhood cancer, about 40% of which reflect a germline mutation; the remainder are not hereditary. In patients with the hereditary form, all somatic cells carry a single missing or mutated allele of a gene (the *Rb* gene) on the long arm of chromosome 13. In the retinoblastoma tumors they develop, however, both alleles of the *Rb* gene are inactive. As mentioned above, the protein product of this *Rb* gene, $p105^{Rb}$, *is a critical checkpoint in the cell cycle, and inactive* Rb *proteins permit unregulated cell proliferation.*

Knudson's Two-Hit Hypothesis

A child with hereditary retinoblastoma is heterozygous at the *Rb* locus. The child inherits one defective *Rb* allele, plus one normal allele (Fig. 5-40). This heterozygous state is not associated with any observable changes in the retina, because 50% of the *Rb* gene product in the heterozygous child is sufficient to prevent a retinoblastoma. However, heterozygosity in some TSGs is unstable, because a subsequent, randomly acquired deletion or mutation may inactivate the remaining normal *Rb* allele. If that occurs, there is no residual Rb tumor suppressor function remaining to protect from unregulated cell proliferation. The child then develops a retinoblastoma. Thus, even though the child inherits a heterozygous Rb genotype, susceptibility to retinoblastoma is inherited in a dominant fashion: it is the heterozygote who develops the tumor.

Precisely the same susceptibility to LOH occurs when there is an acquired mutation in *Rb*. Cells carrying the newly

TABLE 5-6
SELECTED HEREDITARY CONDITIONS ASSOCIATED WITH AN INCREASED RISK OF CANCER

Syndrome	Gene	Predominant Malignancies	Gene Function	Inheritance[a]
Chromosomal Instability Syndromes				
Bloom syndrome	*BLM*	Many sites	DNA repair	R
Fanconi anemia	?	Acute myelogenous leukemia	DNA repair	R
Hereditary Skin Cancer				
Familial melanoma	*CDKN2 (p16)*	Malignant melanoma	Cell cycle regulation	D
Xeroderma pigmentosum	*XP group*	Squamous cell carcinoma of skin; malignant melanoma	DNA repair	R
Endocrine System				
Hereditary paraganglioma and pheochromocytoma	*SDHD*	Paraganglioma; pheochromocytoma	Oxygen sensing and signaling	D
Multiple endocrine neoplasia (MEN) type 1	*MEN1*	Pancreatic islet cell tumors	Transcriptional regulation	D
MEN type 2	*RET*	Thyroid medullary carcinoma; pheochromocytoma (MEN type 2A)	Receptor tyrosine kinase; cell cycle regulation	D
Breast Cancer				
Breast/ovary cancer syndrome	*BRCA1*	Carcinomas of ovary, breast, fallopian tube and prostate	DNA repair	D
Site-specific breast cancer	*BRCA2*	Female and male breast carcinoma; carcinomas of prostate, pancreas and ovary	DNA repair (Fanconi pathway)	D/R
Breast cancer	*PALB2*	Breast, pancreas	DNA repair (Fanconi pathway)	D/R
Nervous System				
Retinoblastoma	*RB*	Retinoblastoma	Cell cycle regulation	D
Phacomatoses				
Neurofibromatosis type 1	*NF1*	Neurofibrosarcomas; astrocytomas; malignant melanomas	Regulator of ras-mediated signaling	D
Neurofibromatosis type 2	*NF2*	Meningiomas; schwannomas	Regulator of cytoskeleton	D
Tuberous sclerosis	*TSC1*	Renal cell carcinoma; astrocytoma	Regulator of cytoskeleton	D
Gastrointestinal System				
Familial adenomatous polyposis	*APC*	Colorectal carcinoma	Cell cycle regulation; migration and adhesion	D
Hereditary nonpolyposis colorectal carcinoma (HNPCC; Lynch syndrome)	*hMSH2, hMSH6, MLH1, hPMS1, hPMS2*	Carcinomas of colon, endometrium, ovary and bladder; malignant melanoma	DNA repair	D
Juvenile polyposis coli	*DPC4/Smad4*	Colorectal carcinoma; endometrial carcinoma	TGF-β signaling	D
Peutz-Jeghers syndrome	*LKB1/STK11*	Stomach, small bowel and colon carcinomas	Serine threonine kinase	D
Kidney				
Hereditary papillary renal cell carcinoma	*MET*	Papillary renal cell carcinoma	Receptor tyrosine kinase; cell cycle regulation	D
Wilms tumor	*WT*	Wilms tumor	Transcriptional regulation	D
Von Hippel-Lindau	*VHL*	Renal cell carcinoma	Regulator of adhesion	D
Multiple Sites				
Carney complex	*PRKARIA*	Testicular neoplasms; thyroid carcinoma	cAMP signaling	D
Cowden syndrome	*PTEN*	Colorectal, breast and thyroid carcinomas	Protein tyrosine phosphatase	D
Li-Fraumeni syndrome	*TP53*	Breast carcinoma; soft tissue sarcomas; brain tumors; leukemia	Transcriptional regulation	D
Werner syndrome	*WRN*	Soft tissue sarcomas	DNA repair	R
Ataxia-telangiectasia	*ATM*	Lymphoma; leukemia	Cell signaling and DNA repair	R

[a]D = autosomal dominant; R = autosomal recessive.
ATM = mutated AT (gene); cAMP = cyclic adenosine 3′,5′-monophosphate; PTEN = phosphatase and tensin homolog; TGF-β = transforming growth factor-β.

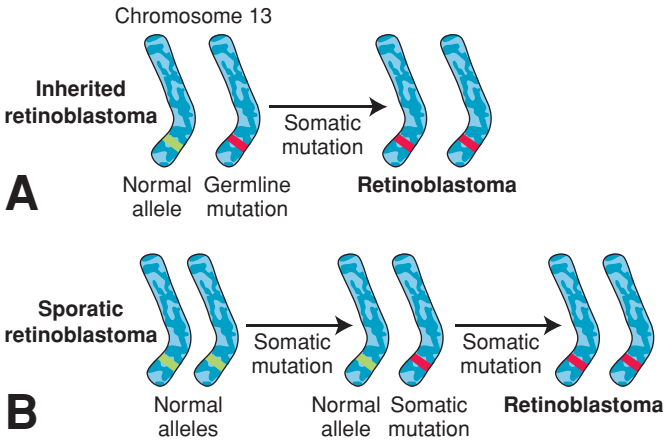

FIGURE 5-40. The "two-hit" origin of retinoblastoma. A. A child with the inherited form of retinoblastoma is born with a germline mutation in one allele of the retinoblastoma gene located on the long arm of chromosome 13. This mutation is not sufficient for tumorigenesis, but the absence of two wild-type alleles weakens protection from tumor development in the event that the remaining allele becomes altered. Then, a second somatic mutation in the retina leads to the inactivation of the functioning *RB* allele and the subsequent development of a retinoblastoma. **B.** In sporadic cases of retinoblastoma, the child is born with two normal *RB* alleles. It requires two independent somatic mutations to inactivate *RB* gene function and allow the appearance of a neoplastic clone.

acquired mutation become similarly susceptible to inactivation of the remaining *Rb* allele.

The principle, then, is that the presence of one mutant *Rb* TSG predisposes to eventual LOH and consequent development of malignancy. A mutation in one allele (whether inherited or acquired) facilitates clonal expansion of cells bearing a mutation in the other allele. This fact underscores an essential paradox of tumor suppressor genes: even if a wild-type phenotype is dominant, heterozygous cells are at high risk for LOH and becoming homozygous mutant cells, with tumor development likely to ensue.

While Rb is named for its signature tumor, an inherited *Rb* mutation affects every cell in the body and confers a more general increase in malignancies. Such patients have a 200-fold increased risk of developing mesenchymal tumors in early adult life. As well, *Rb* is not infrequently mutated in sporadic tumors, including 70% of cases of osteosarcoma and in many instances of small cell lung cancer; carcinomas of the breast, bladder and pancreas; and other organs.

Many types of *Rb* mutations have been described, including point mutations, insertions, deletions and translocations. Epigenetic events, such as promoter hypermethylation (see below), may also decrease *Rb* expression and contribute to a tumorigenic phenotype.

p53, Acquired Point Mutations and Dominant Negative Mutants

The *TP53* gene is located on the short arm of chromosome 17, and its protein product, p53, is present in virtually all normal tissues. *TP53* is deleted or mutated in 75% of human colorectal cancers and frequently in carcinomas of the breast, lung (small cell), liver, brain (astrocytomas) and many others. *In fact, mutations of* TP53 *are the most common genetic change in human cancer.* Inactivating mutations found in human cancers are largely missense mutations that impair the ability of p53 to bind to DNA (Fig. 5-41A). Affected cells may then progress through the cell cycle despite having damaged DNA. While in some cancers both *TP53* alleles are inactivated by the mechanism described above, this is not always the case. Often, one mutant *TP53* gene is sufficient.

The active form of p53 protein is a homotetramer (i.e., a composite of four individual p53 proteins) (Fig. 5-41B). For the complex to be functional, all four p53 monomers must be functional. Mutant p53 subunits therefore can inactivate the whole tetramer (Fig. 5-41C). When the protein product of a mutant allele inactivates that of the wild-type allele, the mutant is said be a **dominant negative**. A cell carrying one mutant *TP53* allele (i.e., a heterozygote) should have a growth advantage over normal cells, and so predominate in vivo with a high risk of then becoming cancerous.

Additional Mechanisms of Inactivating p53

Because p53 is so intensively studied, much of the diversity of mechanisms by which tumor suppression can be inactivated has been uncovered for this protein. Normally, p53 activity is regulated by its binding to the E3 ubiquitin ligase, MDM2. The MDM2–p53 complex prevents p53 from functioning and targets it for degradation via the ubiquitin–proteasome pathway. In turn, MDM2 is inhibited (see above) by binding $p14^{ARF}$. Any oncogenic stimulus (e.g., *myc, ras*) upregulates the $p14^{ARF}$ tumor suppressor protein, which in turn induces Rb phosphorylation.

Some cancers in which both *p53* alleles are structurally normal may overexpress MDM2, consequently increasing p53 degradation. Other tumors in which p53 is intact do not express functional $p14^{ARF}$, and so allow unopposed MDM2-mediated proteolysis of p53. As in the case of *Rb,* certain DNA viral products in tumors (e.g., human papillomavirus [HPV] E6, see below) bind to p53 and promote its degradation. In addition to numerous feedback loops, there are posttranslational modifications (phosphorylation, acetylation, etc.), natural antisense transcripts, binding proteins and small regulatory RNAs. It is no surprise, then, that *most human cancers display either inactivating mutations of p53 or abnormalities in the proteins that regulate p53 activity.*

p53 directs cell cycle arrest, apoptosis and cellular senescence, but these activities are only a part of a more complex tapestry of p53 functions. p53 also regulates responses to metabolic stress; regulation of autophagy and the redox state; production of ROS; and both promotion and limitation of longevity.

The p53 Family

Like a gathering of relations among whom one is the most boisterous, the family of p53-like proteins has largely been dominated by its most conspicuous member—that is, p53. However, there are several important cousins, p63 and p73, as well as some derivative proteins that deserve mention. Just as the region on chromosome 17 that encodes p53 is often mutated or deleted in human cancers, so are the regions on chromosomes 1 and 3 where p73 and p63 reside, respectively. If p63 and p73 are intact, they may partly compensate for loss of p53. Both are now considered to be a tumor suppressor in their own rights, with functions that partly overlap, and that are partly distinct from, those of p53. p63 is a transcriptional regulator, directly increasing levels of the proapoptotic proteins, CD95 (FasR; see Chapter 1) and Bax. It is also important for effective chemotherapy using agents like *cis*-platinum.

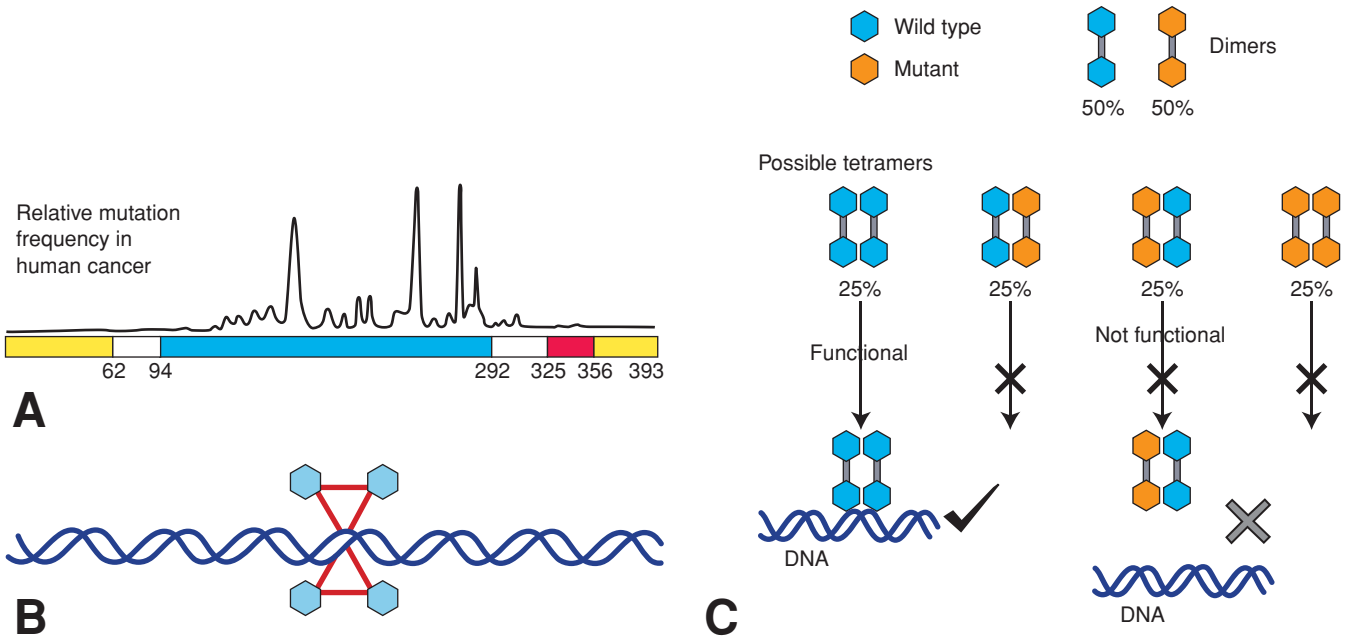

FIGURE 5-41. Mutations in TP53 and stoichiometry of impaired function of p53 tumor suppressor. A. Locations and frequency of mutations in different p53 protein regions. There are multiple domains of the p53 protein. The largest domain is the DNA-binding domain, which is where the vast majority of known mutations in p53 are located. **B. p53 binding to DNA.** To regulate transcription, p53 binds DNA as a tetramer. The tetramer is composed of two dimers. Each dimer is the product of one of the two alleles of the *TP53* gene. **C. Consequences of heterozygous mutation in *TP53* gene.** If one of the two alleles of the p53 gene is mutant, the result is that one dimer is completely mutant (and hence inactive) and the other is wild type (and hence active). However, as p53 transcriptional activity requires a fully functional tetramer, and as the sorting of the dimers into a tetramer is random, 3/4 of the resulting tetramers will be inactive, as shown. Thus, one mutant allele of p53 inactivates 3/4 of p53 activity.

There are many variants of each of these proteins. These may affect the protection afforded by these three proteins in diverse ways (see below).

Treacherous Mutant p53

Interestingly, the mischief of mutant p53 molecules extends far beyond simple inactivation of tumor suppressor function. The aberrant protein also functions as an oncogene, modulating gene transcription. In addition, it protects cells from apoptosis. Mutant p53 also activates proinflammatory cytokines and extracellular matrix modulators. It blocks ATM-mediated (see above) protection against double-stranded DNA breaks. A common denominator underlying the effects of mutant p53 is its widespread stimulation of genes involved with cell proliferation. Moreover, mutant p53 activates cellular mechanisms that are responsible for resistance to chemotherapeutic drugs. In many cases, including tumors of the hematopoietic system, breast, urinary bladder and head and neck, mutant p53 is associated with a poorer prognosis. Along these lines, it should be noted that some splice variants of p53 and p73, particularly those lacking the N-terminal domains, appear to inhibit aspects of their tumor suppressor activities and to act in part as oncogenes.

Fragile Site Translocation

The human genome contains a number of more or less universally shared **common fragile sites** (CFSs) that are inordinately structurally unstable. (Small percentages, 5% or less, of the population also possess rare fragile sites that are prone to the same fragility.) Gene amplification, chromosomal translocations, sister chromatid exchanges, deletions and other kinds of chromosomal malfunctions occur inordinately often at these sites. This instability may be implicated in tumor development, via resultant loss of TSG integrity.

The most active CFS is called FRA3B, and deletions or translocations there are associated with many human malignancies, including solid tumors and leukemias. A gene that is often inactivated or deleted in that setting is the **fragile histidine triad (FHIT)** tumor suppressor. It encodes a protein that cleaves certain nucleotides into adenosine monophosphate (AMP) and adenosine diphosphate (ADP), but it is not clear how much its tumor suppressor activity relates to this enzymatic function. Unlike most tumor suppressors except for APC, the FHIT protein does not bind DNA. Rather, it (like APC) enhances microtubule assembly. It is also felt to promote apoptosis via caspase-8 activation (see Chapter 1). Lack of *FHIT* expression is associated with enhanced resistance to apoptosis. FRA3B alterations are particularly common in human cancers associated with environmental carcinogens.

Other important tumor suppressors that are commonly inactivated during genomic alterations involving CFSs include Wwox, Parkin and caveolin-1. The gene encoding Wwox spans the FRA16D common fragile site. Wwox is important in growth regulation and some forms of apoptosis. Levels of this protein are decreased in most human malignancies. Parkin, an E3 ubiquitin ligase, plays an important role in autophagy (see later and Chapter 1) and is often lost in certain solid tumors. **Caveolin-1** is one of two tumor suppressors (the other being testin) located at FRA7G. Caveolins regulate several cellular functions, including signal transduction. This site is often lost in diverse human cancers, both solid and hematopoietic tumors.

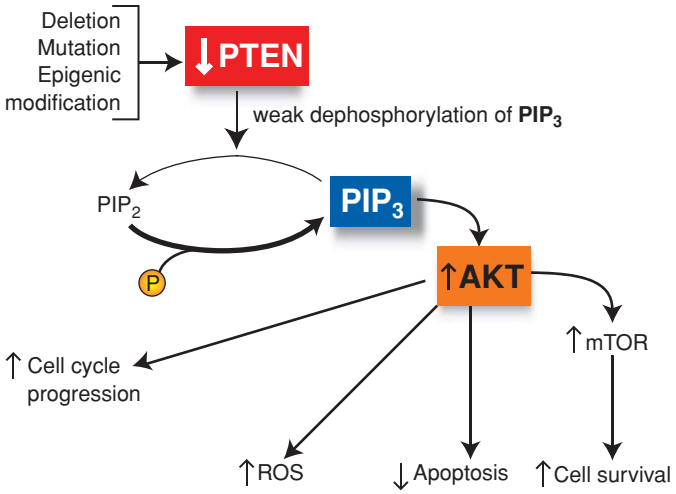

FIGURE 5-42. The consequences of decreased PTEN activity. If activity of PTEN is decreased by mutation or by epigenetic means, phosphatidylinositol-3,4,5-trisphosphate (PIP3) accumulates, activating Akt, a central signaling intermediate. As a result, certain regulators—p27, Bad and FOXO—are not activated, thus promoting cell cycle progression and decreasing apoptosis. At the same time, activation of mTOR (mammalian target of rapamycin) stimulates cell survival. Loss of PTEN activity therefore facilitates the development of uncontrolled cell proliferation and cancer.

Altered Levels of Tumor Suppressor Proteins and/or Activity

It would be tempting to understand loss of effective tumor suppression as basically a matter of altered TSG structure, or LOH, as above. It would also be wrong. For some important tumor suppressors, the critical parameter is the level of tumor suppressor activity, the presence or absence of mutations being important mainly insofar as it determines protein level. Such a tumor suppressor is PTEN (phosphatase and tensin homolog detected on chromosome 10).

PTEN Function

PTEN is a phosphatase that dephosphorylates both proteins and lipids. It regulates the many signals that connect growth factor–triggered signals from receptors at the cell surface to nuclear transcription factors that mediate many cellular functions. PTEN dephosphorylates the highly active signaling intermediate, PIP3, to its inactive 3,4-bisphosphate (PIP2) form. In so doing, PTEN inhibits the AKT-mTOR pathway (Figs. 5-38 and 5-42). As well, PTEN and p53 physically interact and regulate each other. PTEN may be necessary for p53 to be functional and protects p53 from MDM2-mediated degradation. Overall, by virtue of both its lipid phosphatase and other activities, PTEN protein is critical for the DNA damage repair response, apoptosis, regulation of cell cycle progression, maintenance of epithelial polarity and inhibition of EMT. It also regulates cell metabolism to limit glycolysis, as opposed to oxidative phosphorylation (see later).

PTEN protein is normally maintained at a steady, high concentration. Thus, anything that changes PTEN protein levels even slightly, whether inactivation of one or both alleles, altered promoter activity or other epigenetic or post-translational change, may lower the concentration of the protein to a point where it is unable to modulate levels of PIP3 effectively. Decreased PTEN activity permits PIP3 to accumulate and constitutively activate a variety of signaling pathways involved in cell proliferation and survival, which are key in cancer development.

Alterations in PTEN Levels and Function

PTEN is the second most frequently mutated gene in human cancers, after p53. However, it is the level of PTEN activity that is the key to its tumor suppressor activity, and even small decreases in PTEN activity may allow some tumors to develop.

There are many mechanisms, and many points in the pathway from gene to functional PTEN activity, at which the levels of that activity are subject to upregulation or, mostly, downregulation (Fig. 5-43):

- **Regulation of transcription:** Several epigenetic mechanisms (see below) are known to decrease levels of

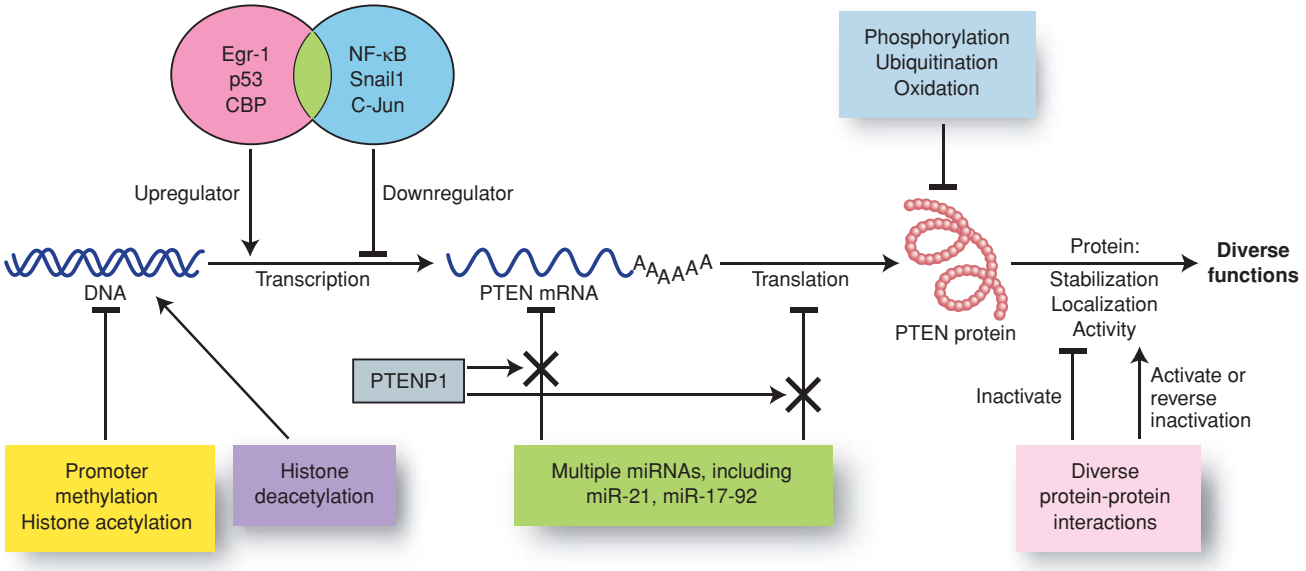

FIGURE 5-43. Regulation of levels of PTEN expression and activity. PTEN is a fundamental regulator of many cellular activities involved in oncogenesis (Fig. 5-42). The levels of PTEN expression and activity are crucial to cellular homeostasis. PTEN can be regulated by multiple mechanisms, as illustrated here, from altered transcription to messenger RNA (mRNA) stability to protein modifications.

transcription of the *PTEN* gene. These include altered histone structure and promoter DNA methylation. Concentrations of proteins that increase or decrease promoter activity are also important.

- **miRNAs:** MicroRNAs (see below) bind mainly the 3′ untranslated region of the PTEN transcript and may cause that mRNA to be degraded, or may prevent its translation.
- **Pseudogene transcripts as decoys:** A gene, called *PTENP1,* which does not code for a protein, produces an untranslated RNA that closely resembles PTEN mRNA. This transcript is representative of a class of transcripts called **competing endogenous RNAs (ceRNAs)**. Sequence homology between the PTENP1 ceRNA and the PTEN mRNA allows the former to bind to miRNAs that would otherwise target and inhibit PTEN transcripts. The likely significance of this decoy to tumor suppression is illustrated by the fact that the *PTENP1* gene is commonly lost in some human cancers, leading to lower PTEN protein levels in such tumors.
- **Protein modifications:** Known posttranslational modifications of PTEN protein can inactivate it (acetylation, oxidation), target it for degradation (polyubiquitination), direct it to subcellular sites where its activity is particularly needed (monoubiquitination) or reverse inactivating modifications (e.g., SIRT1 deacetylates PTEN).

This intricacy and diversity of systems that control amounts of active PTEN protein maintain its functionality in normal tissues within very narrow tolerances. Data suggest that a decrease of only 20% in PTEN levels contributes to oncogenesis. In this context, some tissues (e.g., endometrium, hematopoietic) are more susceptible than others (e.g., prostate) to tumorigenesis when PTEN activity is slightly reduced. These observations underscore two important facts: (1) loss of protective tumor suppressor function may occur when levels of a tumor suppressor protein are reduced by as little as 20%, in the absence of an inactivating mutation in the TSG itself; and (2) different tissues vary greatly in their susceptibility (see below) to oncogenic stimuli—be they decreased tumor suppression or increased tumor promotion.

PTEN is not the only such protein to which these conclusions apply. Protection afforded by several tumor suppressors, like the breast cancer susceptibility proteins BRCA1 and BRCA2, is impaired when one allele is mutant while the other is still active, and so does not necessarily require LOH.

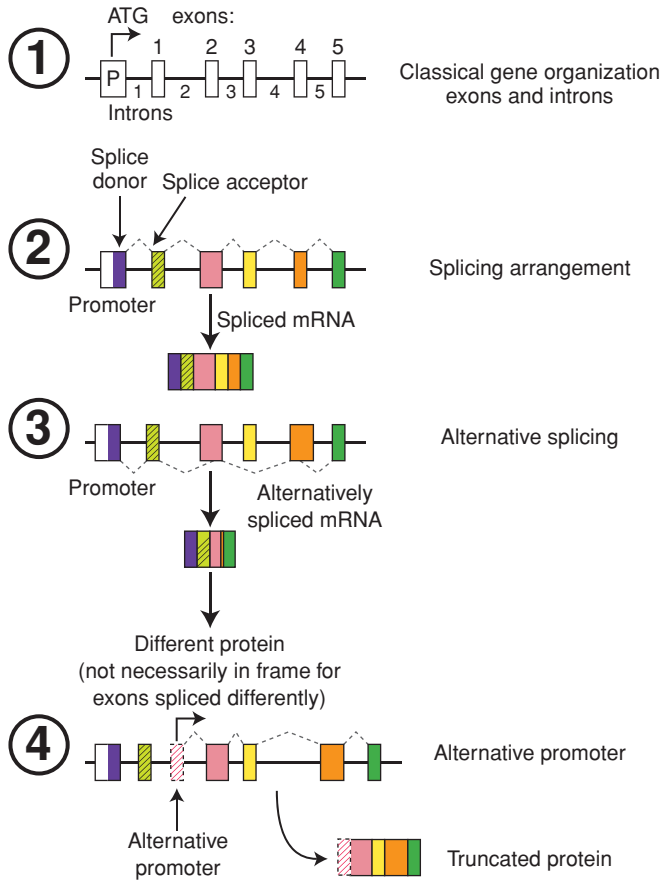

FIGURE 5-44. How alternate splicing affects a gene's products and their activities. RNA splicing is an important mechanism by which gene activity is controlled. It is illustrated here. **1.** The organization of exons and introns in a hypothetical gene is shown. **2.** Transcribed RNAs are spliced; that is, a splice "donor" site at the 3′ end of one exon is linked to a splice "acceptor" site at the 5′ end of the following exon, with the RNA corresponding to the intervening intron removed. The result is a messenger RNA (mRNA) that is exported from the nucleus for translation by ribosomes. **3.** However, there may be alternative splice donor and acceptor sites at different points within the several exons, so that an entirely different mRNA may be generated. The resulting protein may have variable sequence homology to the protein produced in **2,** depending on whether the alternate splice sites result in an mRNA that is in frame with the original or not. **4.** Another strategy for generating a different protein from the same gene is alternate promoters. In this situation, a promoter different from the promoter in **2** mediates transcriptional activation, and transcription begins from a completely different site in the DNA sequence. The result may be a partial protein, a protein that is spliced differently from the original (in **2**) and thus potentially completely different or some variation thereof.

Effects of Alternate or Aberrant Forms of Tumor Suppressors

Mechanisms

A single gene may encode multiple proteins, independent of alterations in DNA structure. Among the most important of these are alternate splicing and the activities of multiple promoters (Fig. 5-44 frames 1,2). About 95% of human genes with multiple exons are known to be spliced in multiple ways, generating proteins of different sizes, often containing different amino acid sequences and having diverse functions.

Two characteristically important aspects of alternative splicing are shown in Fig. 5-44 frames 3,4. What is important here is that the same genomic DNA sequence is responsible for generating multiple variants of an individual protein. Alternative splice donor and acceptor sites may cause an entirely, or partially, different protein to be produced, depending on whether the resulting splicing is in frame or not, compared to the original, "classical," transcript and its derivative protein.

Alternatively, transcription may be initiated from a second promoter (often designated P2). This may yield a protein homologous to the "classical protein," yet truncated at its amino terminus. Such amino terminal variants are often designated ΔN. Of course, these two mechanisms may operate in tandem to produce an array of variant proteins of different sizes, compositions and degrees of homology.

The factors that determine how splicing occurs, what sites are suitable donors and acceptors and so forth are quite complex. They involve many participant molecules. Some of

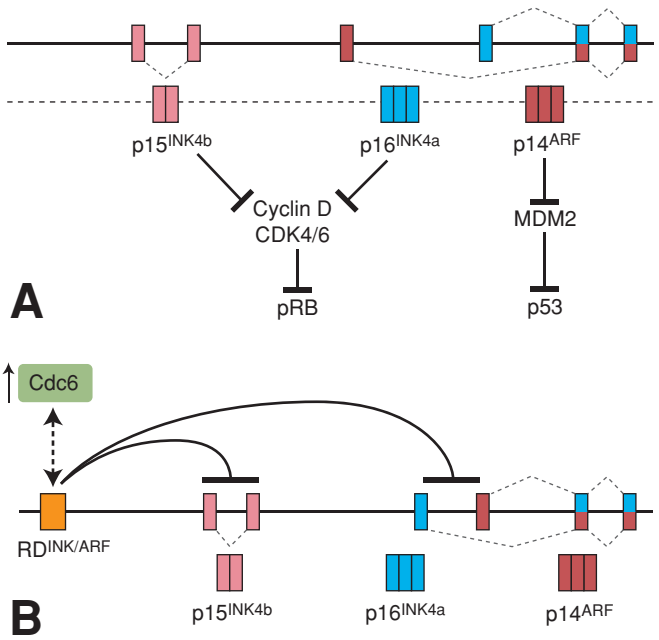

FIGURE 5-45. Multiple tumor suppressors from one locus. A. The organization of the INK/ARF locus. This gene encodes three major and different tumor suppressors, as shown. $p15^{INK4b}$ and $p16^{INK4a}$ are both critical regulators of cyclin D and cyclin-dependent kinases (CDKs) 4 and 6. p15 is transcribed separately from p16. However, p16 and $p14^{ARF}$ (ARF stands for alternate reading frame) coding sequences overlap. Owing to alternate splicing (Fig. 5-44), their coding sequences are totally different. The functions of p16 and p14 are also distinct, as shown. **B.** The area $RD^{INK/ARF}$ represents a region 5′ to the transcriptional start sites that is the target for Cdc6-mediated transcriptional silencing of all of these proteins. All three tumor suppressors are silenced by Cdc6, however, as Cdc6 binds the promoter for p15 and recruits histone deacetylases to the entire gene complex, inhibiting transcription of all three tumor suppressors.

these are tissue specific, so that different mRNA alternatives and resulting variant proteins may be dissimilar in different cell or tissue types.

Alternative Splicing, Tumor Suppression and Interference with Tumor Suppression

Alternative splicing, etc., is important in generating specific tumor suppressor proteins, in determining their ability to protect from cancer and the spread of cancer, in regulating tumor suppression and in escape from tumor suppression.

The ARF-INK4 Locus. One of nature's more impressive mistakes was to have concentrated three major (and several minor) tumor suppressors at the same locus (Fig. 5-45A). This renders them all simultaneously susceptible to elimination with a single deletion event. Even worse, these tumor suppressors can all be turned off by a single interaction between a repressor protein and one specific area in the gene complex. Thus, $p14^{ARF}$, $p15^{INK4b}$ and $p16^{INK4a}$ (see above) are all encoded on chromosome 9p21. Loss of this locus is very common in human cancers and leads to deregulation of Rb-related cell cycle control and excessive inhibition of p53 (Fig. 5-45A).

The tumor suppressor transcripts are all driven by different promoters, $p15^{INK4b}$ being upstream of the others. However, some of the exons for $p14^{ARF}$ and $p16^{INK4a}$ are shared (Fig. 5-45A). The shared coding sequences are in different reading frames, though, so that the two proteins have no sequence homology.

Despite having different promoters, these three open reading frames all share a common repressor site (Fig. 5-45B). The protein, Cdc6, binds a common site prepressor and can simultaneously extinguish expression of the three critical tumor suppressors.

An additional mechanism of tumor suppression is exemplified at this locus, that is, **long, noncoding RNAs** (**lncRNAs**; see below). An important lncRNA, called *ANRIL*, suppresses expression of $p15^{INK4b}$ and is particularly important in some leukemias and prostate cancers.

p53 and Its Cousins. As mentioned above, p53 is the most prominent member of a family of tumor suppressors with diverse functions. All of them are transcriptional activators and repressors, and all inhibit one or more cancer attributes (see above). Like p53, p63 and p73 are active in this mode as homotetramers. The p53/p63/p73 story is more complex than that, however. Each of these genes gives rise to multiple transcripts, for which diverse, sometimes antagonistic, functions have been identified.

The best understood of these variants are shortened transcripts, generated by alternative splicing and/or different internal promoters. These variant mRNAs encode proteins lacking variable amounts of the full-length proteins. Transcriptionally deficient forms of each family are known: ΔNp53, ΔNp63, ΔNp73. Many splice variants, designated with α, β and so forth, are also known. These ΔN and splice variants may oligomerize with the full-length proteins to form transcriptionally inactive tetramers. Furthermore, these variants, especially the ΔN variants, can bind to promoters normally activated by the full-length proteins (e.g., proapoptotic proteins such as Bax, Puma) and block access to these promoters (Fig. 5-46). The presence of multiple additional promoters and many splice variants for each protein further complicates matters.

Nonetheless, ratios of full-length:ΔN variants are tightly regulated in normal tissues. Although the genes for p63

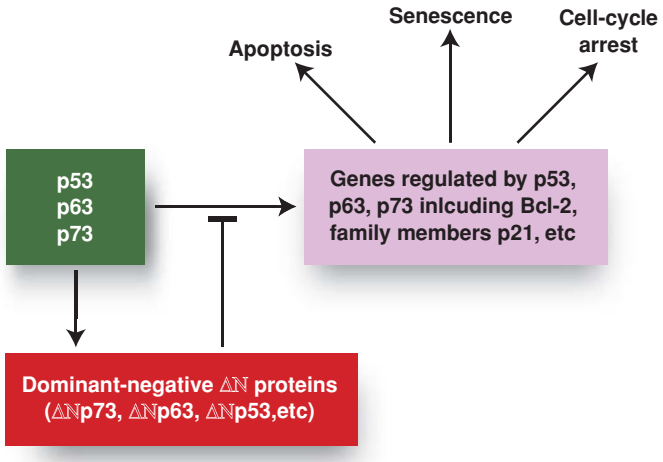

FIGURE 5-46. The isoforms of the members of the p53 family and their interactions. All members of the p53 tumor suppressor protein family have alternate isoforms deleted at their amino termini (ΔN), which act as dominant negative proteins, and impede the transcriptional and other activities of the full-length p53, p63 and p73.

and p73 are not often mutated in cancers, the ΔN forms of p53 family member proteins are upregulated—or ΔN:full-length ratios altered—in many tumors. For example, ΔNp63 predominance is associated with poor response to certain chemotherapies that target DNA and may portend poor prognosis.

Thus, complex as it is, the availability of alternate transcripts, and resulting variants or different proteins, encoded by the same locus represents an important means by which cancers can evade tumor suppression mechanisms.

INHERITED CANCER SYNDROMES

Cancer syndromes attributed to inherited mutations make up only 1% of cancers. These mutations principally involve tumor suppressor and DNA repair genes. As previously discussed for *Rb,* inheritance of a single mutated allele of a tumor suppressor gene results in a heterozygous state and high risk for LOH (i.e., inactivation of the normal allele). What is inherited in this setting is a high degree of susceptibility to developing cancer. Although the germline genotype of such people is heterozygous, both tumor suppressor alleles are inactivated in the tumors that develop in these individuals.

Hereditary tumor syndromes can be arbitrarily divided into three categories:

1. Inherited malignant tumors (e.g., Rb, WT, many endocrine tumors)
2. Inherited tumors that remain benign or have a malignant potential (e.g., APC)
3. Inherited syndromes associated with a high risk of malignant tumors (e.g., Bloom syndrome, ataxia telangiectasia)

These syndromes highlight tumor suppressor activities and the genes that cause them. However, many inherited syndromes entail a different spectrum of tumors than the significance of the mutated gene(s) would suggest. For example, decreased PTEN is very common in many malignancies (see above), but germline loss of PTEN (Cowden syndrome) is mainly associated with benign hamartomas.

Most of these are discussed in chapters dealing with specific organs, and selected examples are given in Table 5-6.

Some disorders, called **phacomatoses** (e.g., tuberous sclerosis, neurofibromatosis), are difficult to classify. These have both developmental and neoplastic features. Tumors associated with these syndromes mostly involve the nervous system.

Only a small proportion of all cancers show Mendelian inheritance, but certain malignancies undeniably tend to run in families. For many tumors, other family members of an affected person have a twofold to threefold increased risk of developing that type of cancer. This predisposition is particularly marked for cancers of the breast and colon, but is also exemplified in the interplay of heredity and environment. Thus, smokers who are closely related to someone with lung cancer have a higher risk of developing lung cancer than do smokers without this familial background.

Organ Specificity in Inherited Cancer Syndromes

Many of the inherited germline mutations cited above (e.g., *BRCA1* or *VHL* genes) lead to specific tumor syndromes. However, it remains unclear why alterations in certain genes tend to affect some organs but not others. Thus, the importance of BRCA1 in repair of DNA double-strand breaks is well established, but it is obscure why germline *BRCA1* mutations lead mainly to breast and ovarian cancers and not other types of cancer, and why women are so profoundly affected, as compared to men.

EPIGENETIC MECHANISMS AND CANCER

Structural changes in the coding sequences of genes, the study of which is called **genomics,** are important determinants of cancer development. It has, however, become clear that tumorigenesis and tumor suppression cannot be understood solely in terms of changes in DNA sequence leading either to dysfunctional proteins or loss of proteins entirely. Rather, regulation of the amounts of proteins in cells influences cell behavior at least as profoundly as the DNA sequences that encode those proteins. **Epigenetics** is the umbrella term for the mechanisms that control gene expression, independently of DNA base sequences.

The most important epigenetic mechanisms that are involved in neoplasia, to suppress tumor development, to facilitate it or both, are listed in Table 5-7. Some were mentioned above. These are physiologic processes that are obligatory parts of normal cellular equilibrium. *It is when these processes go awry that problems, including cancer, develop. Thus, no individual modality is necessarily cancer promoting or cancer suppressing, but may act both to inhibit tumor development and to promote it, the net result depending on the specific genes involved and how they are affected.* These mechanisms interact with each other, so that effects of one may require others to participate.

DNA Methylation at CpGs Regulates Promoter Activity

The amounts of a protein in a cell can be at least as important as the structure of that protein in determining how effectively it, for example, repairs DNA or restrains cell proliferation. The level of transcription of a gene is among the most basic determinants of how much protein is made. Transcription, in turn, depends on promoter activity. The promoters of many genes contain disproportionate concentrations of CpG dinucleotides, called "**CpG islands**." (The *p* represents the interbase phosphodiester bond.) These islands are inhomogeneously distributed in the genome. They predominate in

TABLE 5-7
MAJOR MECHANISMS OF EPIGENETIC REGULATION THAT AFFECT ONCOGENESIS

Mechanism	Example
Covalent modifications of DNA	CpG methylation
Covalent modifications of histones	Acetylation
Remodeling/repositioning of nucleosomes	Incorporation of histone variants
Small noncoding RNAs	MicroRNAs
Long noncoding RNAs	Pseudogene transcripts

the promoter regions of many genes and in repetitive DNA sequences, particularly transposable elements (see below).

DNA Hypermethylation. DNA methylation is the work of a family of enzymes called DNA methyl transferases (DNMTs). DNMTs, especially DNMT3A, are recruited in part by modified histones (see below) to the specific CpG islands to be methylated. Methylation of cytosines at promoter CpGs generally silences the gene immediately downstream. This occurs both because CpG methylation prevents transcription factors from binding the promoter and because methylation may recruit transcriptional suppressors to the site. In many cancers, methylation inactivates TSG activity and is generally more common as a means by which tumors evade suppression than TSG mutations. Some genes, especially $p15^{INK4b}$, FHIT and BRCA1 (see above), are highly susceptible to downregulation by promoter methylation. CpG methylation may also complement mutation, to complete the inactivation of both of a pair of TSG alleles. Thus, if one allele of the DNA mismatch-repair gene *MLH1* is mutated in a colon cancer, the other is likely to be inactivated by promoter methylation.

It should be noted that DNA methylation patterns are not automatically transmitted to both daughter cells after mitosis. A special enzyme, DNMT1, is responsible for perpetuating parental cellular DNA methylation patterns to mitotic progeny. This enzyme is lost or impaired in some tumors.

Hypomethylation: On average, the DNA of most cancer cells is hypomethylated, compared to their normal tissue counterparts. This occurs in repetitive DNA sequences, as well as in exons and introns of protein-encoding genes. The extent of DNA hypomethylation may increase as oncogenesis advances from a benign proliferation to a malignant tumor. Undermethylation destabilizes DNA structure and favors recombination during mitosis, leading to increased deletions, translocations, chromosomal rearrangements and aneuploidy, all of which contribute to malignant progression. Transposable DNA sequences are particularly prone to undergo translocation when hypomethylated. Decreased methylation of genes associated with cell proliferation may increase transcription of such genes. The same principle applies to latent human tumor viruses (e.g., HPV, Epstein-Barr virus), hypomethylation of which may lead to tumor development.

Mechanisms of Methylation and Demethylation

Lest the above appear too straightforward, reality is always more complex. In fact, even though tumors may benefit from overall hypomethylation, in fact, levels of CpG methylation vary considerably, from one gene to the next. Some genes' promoters are hypermethylated (often TSGs), while others, such as oncogenes, transposable sequences and other repetitive DNA stretches, are likely to be hypomethylated.

Demethylation may also occur, although it tends to be more complex and may involve nonenzymatic reactions (see below), increased oxidation and removal of affected cytosines by DNA damage repair pathways.

DNMTs are also not immune to tumor-related genomic instability. Mutations in DNMT3A are important in allowing leukemic hematopoietic stem cells to proliferate, and so are also associated with poor prognosis. Thus, *the basic alteration is **aberrant methylation** and is site specific. CpG methylation patterns in every tumor and every gene are different.*

MicroRNAs May Act as Oncogenes and as Tumor Suppressors

Not too long ago, researchers noticed that a specific area in a B-lymphocytic leukemia (see Chapter 26) tended to be disrupted, but the affected region did not code for any known protein. On further analysis, they determined that the disrupted gene encoded not a protein, but a tiny RNA species that acted as a tumor suppressor. Loss of that miRNA tumor suppressor was linked to development of that type of leukemia. Since then, over 1000 miRNAs have been discovered. Functions relating to neoplasia have been ascribed to many of these (Table 5-8).

TABLE 5-8
EXAMPLES OF MICRORNAS (miRNAs) THAT ACT AS ONCOGENES, TUMOR SUPPRESSORS OR BOTH, AND THE TUMOR TYPES FOR WHICH THEY DISPLAY THOSE ACTIVITIES

Oncogenic miRNAs		Tumor Suppressor miRNAs		miRNAs That Act as Both Suppressors and Oncogenes	
miRNA	**Organ**	**miRNA**	**Organ**	**miRNA**	**Organ**
miR-21	Breast, CLL, colorectal, esophagus, glioblastoma, liver, lung, pancreas, prostate	miR-143	Breast, CLL, colorectal, lung, prostate	miR-23 group	Bladder (o), breast (o), CLL (o), prostate (s)
miR-23	Bladder, breast, CLL	let-7group[a]	ALL, breast, CLL colorectal, lung, pancreas	miR-23 group	Bladder (o), breast (o), CLL (o), prostate (s)
miR-221	AML, bladder, CLL, glioblastoma, liver, pancreas, prostate, thyroid	miR-145	Bladder, breast, colorectal, lung, ovary, prostate	miR-181 group	ALL (o), AML (s), breast (o), CLL (s), glioblastoma (s), pancreas (o), prostate (o), thyroid (o)
miR-17–92 cluster[b]	ALL, CML, colorectal, lung, ovary			miR-125 group	ALL (o, s), AML (o), breast (s), glioblastoma (s), liver (s), ovary (s), pancreas (o), prostate (s), thyroid (s)

[a]The let-7 group includes let-7-a-a1 through -a3, -b through -g, -i and miR-98.
[b]The miR17-92 cluster includes structurally homologous miRs 17-3p, 17-5p, 18a, 19a, 19b-1, 20a and 92a-1.
ALL = acute lymphoblastic leukemia; AML = acute myeloblastic leukemia; CLL = chronic lymphocytic leukemia; CML = chronic myeloid leukemia.

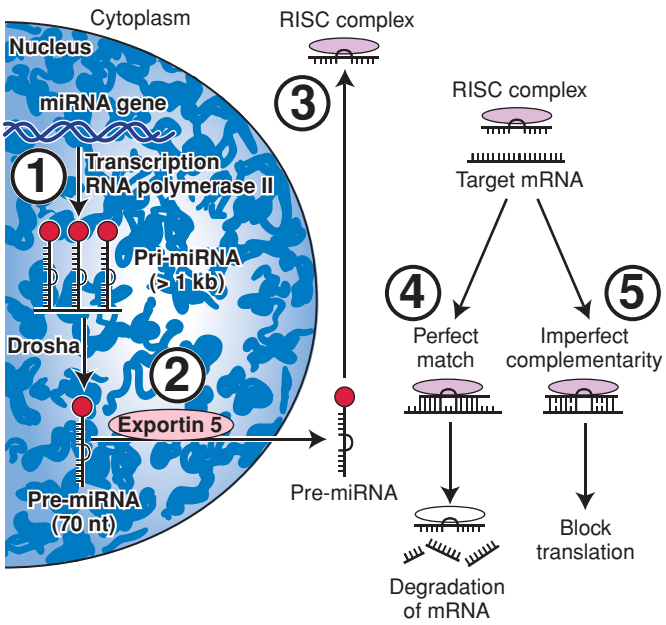

FIGURE 5-47. Production, modification and activities of microRNAs (miRNAs). 1. Most miRNAs are transcribed by RNA polymerase II, the same enzyme that transcribes messenger RNAs (mRNAs) for protein production. **2.** However, the original transcript, which is often more than 1 kb in length, is processed by an enzyme, Drosha, to a shorter form, which is called a pre-miRNA. **3.** This form is exported from the nucleus. In the cytosol, it joins an RNA-induced silencing complex (RISC), where the pre-miRNA is tailored further to the final miRNA by an enzyme called Dicer. A member of this complex, a protein called Argonaute, or Ago, can cleave targeted mRNAs. The nature of the effect of miRNAs depends on the extent of complementarity with a particular mRNA. **4.** If the nucleotides 2–8 of the miRNA align with the 3′-untranslated region of a target perfectly, the target is digested and degraded. **5.** If, on the other hand, the complementarity is imperfect, the miRNA inhibits translation of the target mRNA.

Generation and Actions of miRNAs

MicroRNAs may be encoded anywhere in the genome: intergenic DNA, introns, exons, 3′ untranslated regions (UTRs) and so forth. They are usually transcribed by RNA polymerase II (pol II), the same enzyme that transcribes protein-encoding genes. The initial transcripts that will eventually become miRNAs are often long (>1 kb). These are processed to precursor miRNAs about 70 bases long, which are exported (Fig. 5-47) to the cytosol. There, they are processed further and incorporated as single strands about 22 bases long into an RNA-induced silencing complex **(RISC)**. RISC includes an enzyme (Argonaute, or Ago) that can cleave target mRNAs.

If the recognition sequence (bases 2–8) of an miRNA matches an mRNA—usually the 3′ UTR—perfectly or nearly perfectly, Ago may degrade the targeted transcript. If miRNA complementarity for an mRNA is imperfect, translation of the latter is blocked without degrading the target. miRNAs are thus promiscuous, and any individual miRNA may regulate many different transcripts.

miRNAs and Cancer

miRNAs are critical controllers of many activities, such as embryogenesis and development, cell cycling, differentiation, apoptosis and maintaining stem cell pluripotency ("stemness"). They also regulate many steps in oncogenesis.

miRNAs may inhibit tumor suppressor proteins or may themselves act as tumor suppressors. In the latter case, they may perform several functions, including directly targeting oncogene transcripts. They may also upregulate cell proliferation, and so act as oncogenes. In some cases, one miRNA species, or clusters of related species, may promote tumor development in some tissues but suppress it in others. This context dependence recalls the ambidexterity of some proteins that may be tumor suppressors sometimes and tumor activators at other times (see above). Examples of cancer-related activities for a small number of the more than 1000 known miRNAs are shown in Table 5-8.

miRNAs That Promote Oncogenesis

The cluster of homologous miRNAs designated miR-17–92 is commonly increased in certain hematologic cancers. Expression of these miRNAs is induced by c-Myc. The miR-17–92 cluster protects cells from oncogene-induced apoptosis (see above) in several ways, including by tightly regulating Myc-induced proliferation and downregulating the proapoptotic protein Bim (see Chapter 1). These miRNAs also inhibit the tumor suppressor PTEN and the cell cycle regulator $p21^{WAF1/CIF1}$ (see above).

MiR-21 also restricts apoptosis and other tumor suppressor functions. It downregulates p53 and proteins important in mitochondrial apoptosis. MiR-21 also targets key regulators of cell proliferation, such as TGF-β signaling and PTEN pathways (see above). In various tumor types, miR-21 reduces other tumor suppressor and proapoptotic activities, underscoring both the context dependence and promiscuity of miRNA actions. This miRNA is overexpressed in many human tumors, including those in lung, pancreas and colon cancers.

Tumor Suppression by miRNAs

The let-7 family of miRNAs contains 12 highly conserved members. They have overlapping specificities and target ranges, especially downregulating proteins that activate cell proliferation, such as K-Ras, N-Ras and Myc. miRNAs of this group also target CDK6 and CDC25A, thus blocking cell cycle transit through $G_1 \rightarrow S$ transition. Levels of let-7 members are reduced in many human tumors, especially lung cancers.

Important miRNAs that target the prosurvival (anti-apoptotic) branch of the Bcl-2 family include the cluster of miR-15/16 species. These directly inhibit Bcl-2, the main mitochondrial antiapoptotic protein (see above, Chapter 1). They also block production of important cell cycle drivers, including cyclins D and E. MiR-15/16 are often decreased or absent in solid tumors and certain lymphomas.

Histone Modifications Alter the Ability of Nonhistone Regulators to Reach the DNA

Chromatin is a complex of DNA and proteins that promotes DNA stability and allows it to fit in a small space (the nucleus). It contains repeating units, **nucleosomes,** periodically spaced structures that consist of a combination of 4 histone proteins (H2A, H2B, H3, H4), wrapped in DNA. Covalent alterations to histones include methylation, acetylation, ubiquitination, phosphorylation and others. These occur via specific histone-modifying enzymes,

and are reversible. The operation of histone methylases can be undone by histone demethylases. The work of histone acetylases (HACs) can be reversed by histone deacetylases (HDACs). Covalent changes to histone structure control such gene activities as transcription, DNA repair and DNA replication. Not surprisingly, then, the enzymes that acetylate or deacetylate and methylate or demethylate histones are key regulators of many activities, including oncogenesis.

Histone methylation. Lysines are the principal targets of histone modifications, including acetylation and methylation. However, there are many lysines on several histone species, so the consequences of histone methylation (etc.) depend on where (on which histone, on what amino acids and near what gene) and how much the histone is methylated. In some cases, a specific transcriptional repressor complex, the **polycomb repressor complex-2** (PRC2), is recruited to promoters that are to be inactivated. This complex methylates a specific residue on H3 and silences transcription. If, by different means, a different H3 lysine is methylated, the opposite effect (transcriptional activation) occurs. The histone methylating enzyme, EZH2, is part of PRC2. Altered expression of EZH2 occurs in many cancers and has been associated with a poor prognosis. Cells may gain or lose EZH2 function by mutation or by altered levels of a miRNA that inhibits it (miR-101).

Histone acetylation. Histone acetylation tends to open chromatin and is generally associated with increased transcriptional activity. Histone deacetylation causes chromatin condensation, making it inaccessible for transcription, and so is associated with transcriptional silencing. HDACs are often dysregulated in cancers, causing both silencing of tumor suppressor genes and derepression of oncogenes. The combination of histone modifications and DNA methylation constitutes an intricate regulatory network whose disruption plays an important role in oncogenesis.

The role of histone acetylation status in regulation cannot, apparently, be overestimated. A recent report indicates that histone acetylation is a key determinant of monogamous mating behaviors in prairie voles. Apparently, monogamy in these animals occurs (at least in part) because of histone acetylation near oxytocin and vasopressin receptor genes in the nucleus accumbens in their brains.

Modified Histones and DNA Methylation

As indicated above, the acetylation state of histones affects the transcriptional activity of the gene in question. Histone methylation and DNA methylation also regulate transcription. Histone methylases may directly recruit DNMTs to a gene to be silenced. DNMTs, in turn, can bring HDACs to these sites to deacetylate histones and silence expression. These relationships are complex, however. In some cases, DNA methylation appears to precede histone methylation and deacetylation, and vice versa. Thus, the three processes are linked, but the sequence of events and the final status of the DNA and histones at a site are probably all specific for individual genes.

Nucleosome Positioning and Histone Composition Influence Gene Activity

Chromatin structure is dynamic and varies with a cell's needs at the moment. Nucleosomes tend to leave open those parts of genes where the transcriptional apparatus binds to start gene expression, and again where that apparatus releases the DNA at the end of transcription. Remodeling complexes busily modify nucleosome position and composition, causing nucleosomes to slide or be removed as needed to tailor gene expression to changing cellular circumstances.

The process of synchronizing nucleosome positioning entails incorporation of modified or variant histones into chromatin. These also substitute for their more conventional cousins on an ongoing basis and strongly influence the susceptibility or resistance of associated DNA to silencing by methylation. Such histones help to determine nucleosome positioning itself. Continued modification of histone proteins, as well, is part of the dynamic of chromatin remodeling. For every histone acetylating, methylating, ubiquitinating or phosphorylating an enzyme, there is another that undoes these modifications. As we will see below, these modifiers of histone structure, as well as the mechanisms that sense them, are often central to tumor development.

Long Noncoding RNAs Play Major Regulatory Roles

About 3% of the human genome encodes proteins. Not long ago, it was thought that most of the rest was inactive, or "junk" DNA. Nothing could be further from the truth. It is now clear that over 90% of the human genome is actively transcribed, almost all of it as transcripts that do not make proteins. Furthermore, many DNA sequence changes associated with cancer and other diseases occur within the regions that encode these untranslated RNAs.

These RNAs are called ***long noncoding RNAs,*** *which are defined as RNAs, either primary or spliced transcripts, that do not fit into recognized classes such as structural, protein-coding or small RNAs.* DNA sequences almost anywhere can encode lncRNAs, including intergenic regions, introns, exons and even antisense to coding regions. LncRNAs may be quite large, often 1000s or 10,000s of bases. About 5000 are currently cataloged, and over 20,000 different species may exist. However many there are, they are very low in abundance, poorly understood and almost completely uncharacterized. They do, though, play many important regulatory epigenetic roles, including processing of small RNAs, controlling transcription and acting as organizers, decoys, signal transducers and scaffolds that bind to proteins, DNA or other RNAs. For example, inactivation of one of the pair of X chromosomes in females is the work of an lncRNA called Xist. LncRNAs also help direct chromatin remodeling and DNA methylation and determine the stability and fate of protein-coding RNAs.

We have mentioned lncRNAs in several contexts (above), including as the products of pseudogenes (e.g., PTENP1). These pseudogene lncRNAs may act as decoys for regulatory miRNAs (i.e., as alternative targets for degradative miRNAs), allowing their protein-coding tumor suppressor cousin (here, PTEN mRNA) to survive unmolested. Examples of lncRNAs involved in cancer are shown in Table 5-9.

Epigenetic Regulators Are Distorted in Cancers

The intricacy of epigenetic control over normal cellular processes should be abundantly evident, as should the limitations of our understanding of it. Tumor development, progression and dissemination all entail extensive disequilibrium at every level of epigenetic activity. The explanations above touch on many of these, both in principle and specifically. *It should be emphasized, in summarizing this topic,*

TABLE 5-9
REPRESENTATIVE LONG NONCODING RNAs (lncRNAs) THAT ARE ALTERED IN CANCERS

lncRNA	Tumor Type	Alteration	Function/Consequence
MALAT1	NSCLC, colorectal	↑	Tumor progression and dissemination
ANRIL	Prostate, leukemias	↑	Silences TSG $p15^{INK5b}$ by recruiting PRC2 to methylate promoter
PTENP1	Lung, prostate, endometrium	↓	Pseudogene decoy protecting PTEN mRNA from miRNA-mediated destruction
HOTAIR	Pancreas, colorectal, breast, liver	↑	Recurrence; metastasis; recruits PRC2 to silence tumor suppressors
HULUC	Liver	↑	Represses expression of tumor suppressor miR-372

miRNA = microRNA; mRNA = messenger RNA' NSCLC = non–small cell lung cancer; PRC2 = Polycomb repressor complex-2; TSG = tumor suppressor gene.

that the devil is always in the details, and that overarching generalizations about how tumors develop may be conceptually useful but often break down when one attempts to apply them to specific situations. Thus, a transcriptional activating function may be overactive in a tumor and so upregulate an oncogene, but the same function may be blocked with respect to a tumor suppressor in the same cancer. With that caveat, it is reasonable to summarize the impact of epigenetics on cancer as follows:

- **DNA methylation:** Generally, cancer cell genomes are hypomethylated. This causes general genomic instability and extensive derepression of transcription affecting many genes, especially oncogenes. At the same time, site-specific hypermethylation (e.g., of tumor suppressor genes) also characterizes cancers. The role of PRC2 (see above) is emerging as fundamental to these changes.
- **Histone modifications:** Many tumors show general loss of histone acetylation, especially associated with silencing of TSGs. HDAC overexpression is common in cancers. This has stimulated development of therapeutic HDAC inhibitors. However, HACs are also often abnormal in cancers, and it is the specific interplay of both HACs and HDACs relative to tumor suppressor genes and oncogenes that determines the end result: which genes are activated and which repressed. Other types of histone-modifying enzymes, such as the methylating enzyme EZH2, are also often involved in silencing tumor suppressor genes.
- **Nucleosome positioning:** Altered chromatin structure in cancer accompanies changes in DNA methylation and histone derivatives. Thus, nucleosome localization in tumor cells differs from that in their nonmalignant cellular counterparts.
- **Noncoding RNAs:** Levels of specific noncoding RNAs, both short and long noncoding RNA species, in cancer differ greatly from those in normal cells. These disturbances of normal equilibrium play central roles in regulating almost all facets of cancer cell behavior.

Environmental Stimuli Shape Epigenetic Regulators

The epigenome is highly dynamic and responds to modulation by nutrition, stress, pharmacologic and toxic agents and other influences. For example, identical twins diverge increasingly over time in patterns of DNA methylation. In fact, patterns of CpG methylation of specific genes change over the course of years in any given individual. The ways in which the cellular milieu influences epigenetic regulation are largely obscure. But what is known suggests that this impact may be fundamental to the processes by which tumors originate and spread.

Epigenetic Remodeling as a Function of Metabolism

Tumor cell metabolism is fundamentally different from that of normal cells (see below). The key differences known to affect epigenetic regulation are (1) reliance on glycolysis for energy (as opposed to oxidative phosphorylation), (2) increased levels of HIF-1α, (3) a highly oxidant-rich environment, (4) mutations in key enzymes in the Krebs cycle and (5) abnormally high levels of fatty acid biosynthesis. These factors influence epigenetic regulators as follows:

- **Histone acetylation:** The net result of HACs' and HDACs' actions on histones largely determines gene expression (see above). The acetyl donor for acetylation is acetyl-coenzyme A (CoA). A combination of decreased Krebs cycle effectiveness, via mutations and other means, and high need for acetyl-CoA for fatty acid synthesis reduces the pool of acetyl-CoA available for histone acetylation. This may increase transcriptional repression, especially of TSGs.
- **Histone deacetylation:** A key class of HDACs (class III) are sirtuins, which use NAD^+ to deacetylate histones. Cancer cells' excessive reliance on glycolysis decreases the pool of available NAD^+, restraining this group of HDACs and causing further disequilibrium in histone acetylation. This situation is exacerbated further by metabolic consequences of HIF-1α upregulation, which occurs often in tumors and further limits NAD^+ availability.
- **Methylation:** DNMTs and histone methyl transferases (HMTs) require S-adenosylmetionine (SAM) as a methyl group donor. High levels of oxidative stress in transformed cells lower SAM levels in several ways and accelerate its conversion to other species (especially the antioxidant glutathione). Reduced SAM availability unbalances both histone and DNA methylation.
- **Base changes and oxidation:** Several changes associated with DNA oxidation and modification may result in base changes, particularly affecting CpGs. Thus, methylated cytosine (5-methylcytosine) can undergo two changes that alter DNA structure. It may be spontaneously deaminated to thymine, thus creating a C→T base change transition. In an oxidant-rich environment, it may also be oxidized to 5-(hydroxymethyl) cytosine. This reaction, catalyzed by an enzyme called **Tet methylcytosine dioxygenase (TET2)**, is of note because the *TET2* gene is specifically mutated in certain hematologic malignancies and premalignant conditions. TET2 activity is also affected by certain metabolic aberrations (see below). The added hydroxyl group may then be further oxidized to a carboxyl group, which is enzymatically removed to regenerate the original, unmethylated, cytosine.

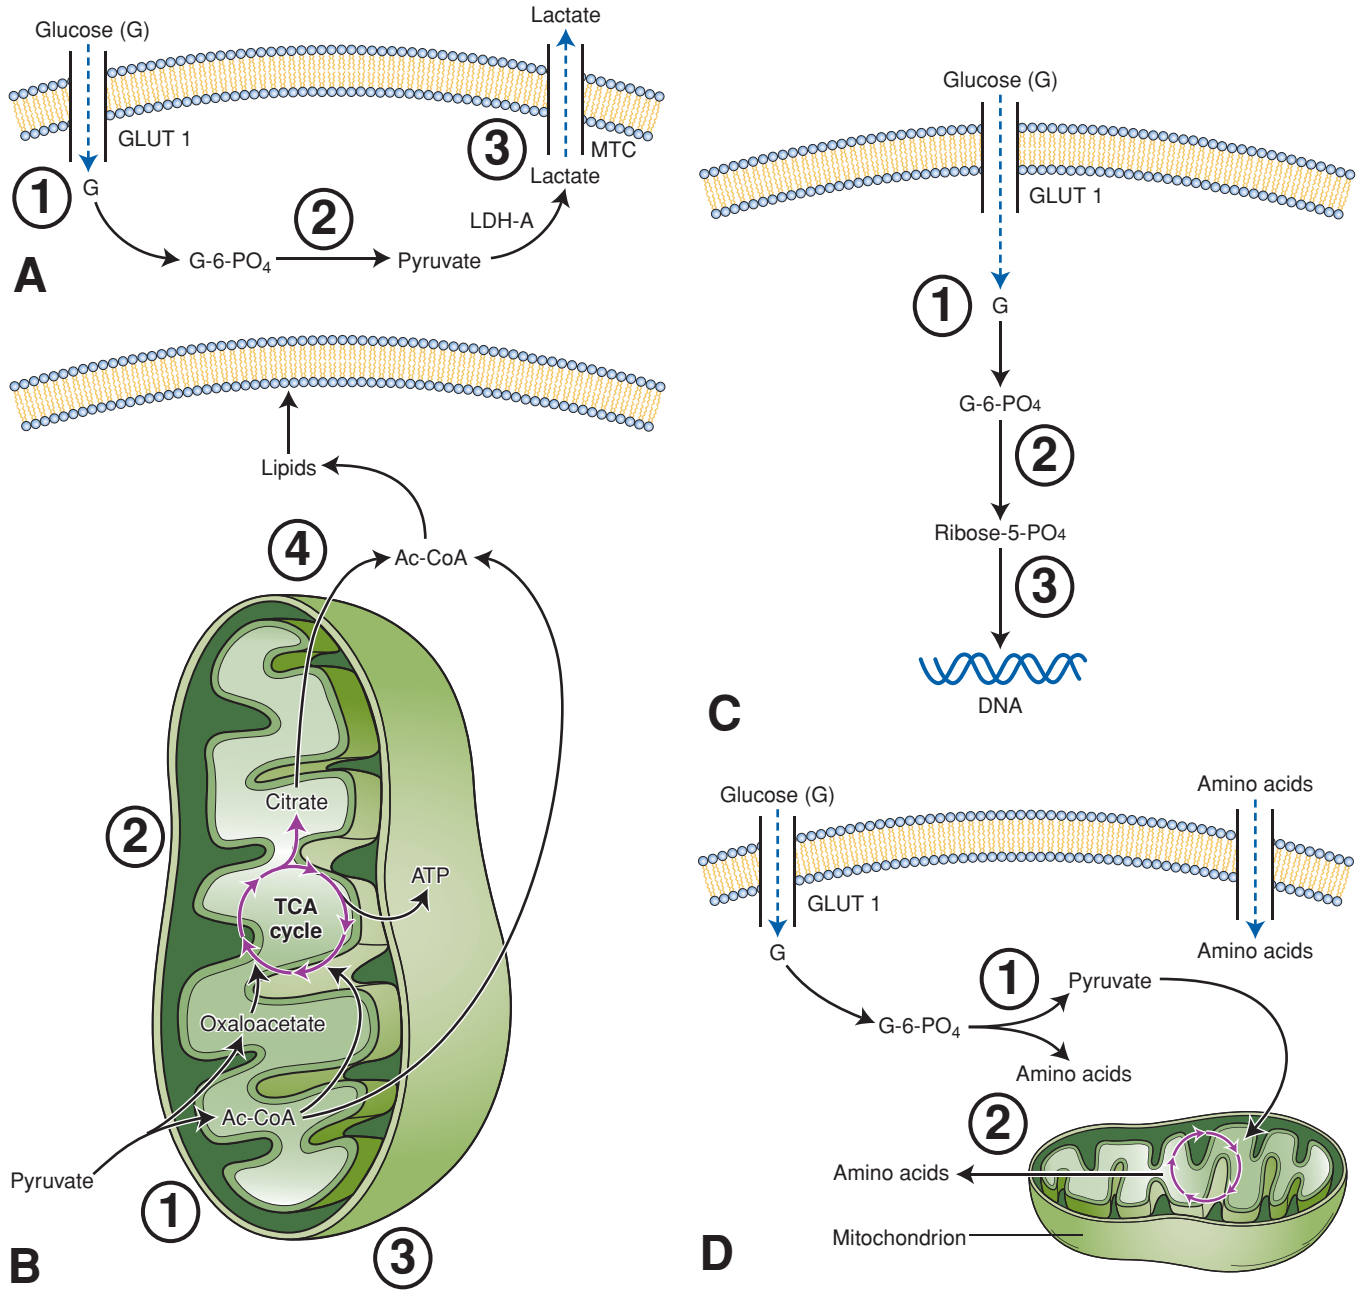

FIGURE 5-48. Cell metabolism. A. Glucose entry. 1. Entry of glucose (G) into the cell is mediated by the glucose transporter, GLUT1. Upon entry, it is converted to glucose-6-phosphate. **2.** Most of the glucose-6-phosphate is metabolized by glycolysis, which leads to production of pyruvate. Pyruvate, in turn, is converted by lactic dehydrogenase-A (LDH-A) to lactate. **3.** Lactate is exported from the cell by a transporter called MTC. **B. Pyruvate utilization in mitochondria. 1.** Some of the pyruvate generated from glucose metabolism enters mitochondria, to become oxaloacetate and to join the tricarboxylic acid (TCA) cycle, which drives oxidative phosphorylation to produce adenosine triphosphate (ATP). **3.** Pyruvate may be converted as well to acetyl-coenzyme A (acetyl-CoA). **4.** Either this acetyl-CoA or citrate from the TCA cycle is exported to the cytosol, where it is incorporated into lipids. **C. Incorporation into DNA. 1.** Glucose-6-phosphate undergoes a number of enzymatic alterations. **2.** It is a precursor for ribose-5-phosphate (ribose-5-PO_4). **3.** Ribose-5-PO_4 enters the nucleus and is an important building block in nucleic acid synthesis. **D. Incorporation into amino acids. 1.** Glucose-6-phosphate metabolism products may be directly converted into certain amino acids. **2.** Alternatively, after pyruvate enters mitochondria, products of the TCA cycle may be converted into amino acids.

As well, oxidation of the G in CpGs may produce 8-oxoguanine. Not only does this disrupt CpG methylation, but also it is highly mutagenic, because 8-oxo-G may be read by polymerases as either G or A.

Therefore, epigenetic regulators are central to normal cellular equilibrium. They become unbalanced during carcinogenesis, but unevenly so: opposite changes in these regulators affect tumor suppressors as compared to oncogenes. Thus, epigenetics is both important and complex: as central as it is to tumor development and spread, there is as yet no single general principle that applies to all aspects of epigenetic regulation.

CANCER CELL METABOLISM

All cells must engage in several critical activities, including to generate energy; produce and repair DNA, RNA, membrane and other lipids; make proteins; and so forth. The proportions of the substrates that cells import or synthesize and that the cell devotes to these different pursuits depends on what the cell does. Most of these functions begin with a source of carbon, which is used to generate energy and build cellular constituents.

Normal Cell Metabolism Favors ATP Generation

Normal cells utilize glucose as their main (but not only; see below) carbon source, both to produce ATP and to synthesize macromolecules. Energy production from glucose includes the following (Fig. 5-48):

- **Glucose entry:** Glucose enters cells via transporters, the best understood being GLUT1 (Fig. 5-48A), although GLUT2, GLUT3 and GLUT4 may also participate.
- **Aerobic glycolysis:** These enzymatic reactions transform glucose to pyruvate and generate 2 net ATPs.
- **Pyruvate:** This product of aerobic glycolysis is the linchpin of metabolism in normal and malignant cells. Pyruvate enters mitochondria, where it may become acetyl-CoA, in a reaction catalyzed by pyruvate dehydrogenase (PDH; see below). Pyruvate may enter the tricarboxylic acid (TCA) cycle in two ways—after conversion to oxaloacetate or after conversion to acetyl-CoA (Fig. 5-48B).
- **Ribose-5-phosphate:** This sugar is produced from a product of the first reaction that is performed upon glucose after it enters the cell (i.e., its conversion to glucose-6-phosphate). Ribose-5-phosphate is then incorporated into nucleic acids (Fig. 5-48C).
- **Acetyl-CoA:** Pyruvate enters mitochondria and is converted to acetyl-CoA by PDH. This step allows entry into the TCA cycle, which eventually produces 36 ATPs (Fig. 5-48D). Acetyl-CoA can also exit mitochondria to participate in lipid biosynthesis.
- **Amino acid synthesis:** Many amino acids enter the cell via cell membrane transporters. Some are so-called essential amino acids, which humans cannot synthesize and need to derive from foodstuffs. Other amino acids, however, can be synthesized by cells from pyruvate or its metabolites that are part of, for example, the TCA cycle.

Therefore, glucose metabolism provides the cell with much more than just energy. It furnishes key building blocks required for virtually all types of cellular structural and functional constituents.

Glucose Uptake Helps Determine Cellular Metabolism

Cells import glucose (and other carbon sources; see below) in response to both intracellular and extracellular signals. Many of these signals are significantly altered in cancers, contributing to tumor cells' deviant metabolism.

Exogenous signals. The key outside regulators of cellular metabolism are insulin and IGF-I. Upon binding their receptors, these hormones activate intracellular signals that drive many of the processes and mediators that participate in oncogenesis.

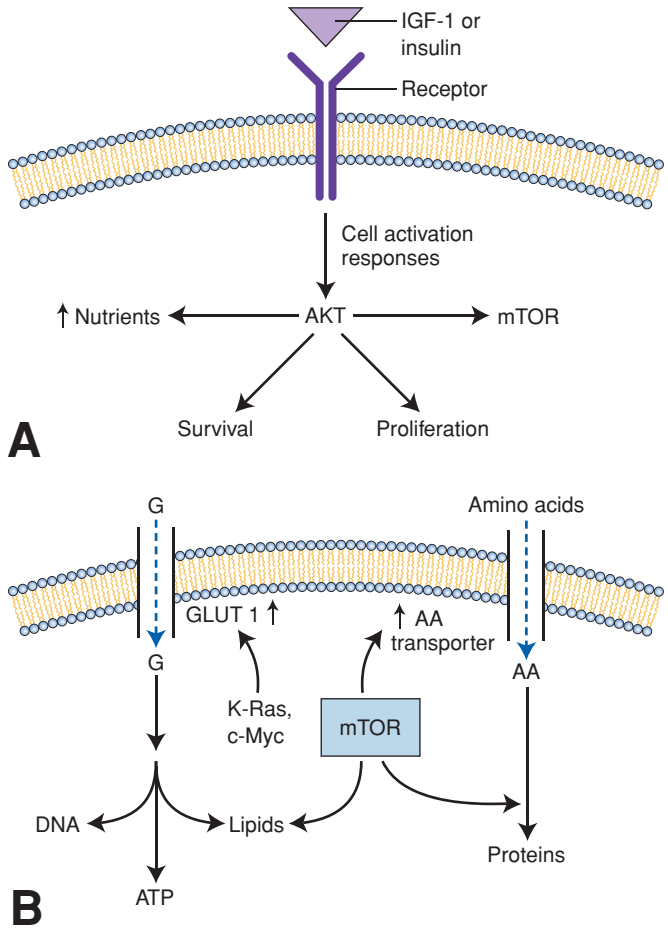

FIGURE 5-49. Effects of metabolic activation on cancer cell metabolism. A. Insulin-like growth factor-I (IGF-I) activation. When IGF-I or insulin binds its receptor, it activates Akt, which in turn elicits many downstream responses. Among the key mediators of Akt effects on cancer cell metabolism is mTOR. **B. Consequences of mTOR activation for cancer cell metabolism.** Operating in tandem with K-Ras– and c-Myc– activated increases in the GLUT1 glucose transporter, mTOR increases synthesis of lipids. It also increases the activity of cell membrane transporters so that increased amino acids are available to support the increased proteosynthetic needs of cancer cells.

Endogenous mediators. At the center of the intracellular response is Akt (Fig. 5-49A). By virtue of the many pathways downstream from Akt (see above and Chapter 1), the cell is protected from apoptosis, stimulated to proliferate and so forth. Akt function is antagonized by the PTEN tumor suppressor. In terms of metabolism, the key downstream effector of Akt is mTOR. This protein stimulates production of amino acid transporters and uptake of amino acids (Fig. 5-49B). It also causes increased lipid and protein synthesis. C-Myc, also upregulated by IGF-I, increases production of GLUT1 and importation of glucose.

Metabolism in Cancer Cells

Cancer cells have different needs from normal cells. As their proliferative rate generally far exceeds that of their normal cousins, they must produce the structural components of their soon-to-be daughter cells at a rate that sustains their mitotic activity. Thus, synthesis of protein, lipid and so forth must march to a much faster drummer than normal.

In 1930, Otto Warburg observed that tumor cells generated energy mainly by aerobic glycolysis in the cytosol, producing pyruvate and 2 ATPs, rather than by mitochondrial oxidative phosphorylation, which generates 36 ATPs, CO_2 and H_2O. The seeming paradox between tumor cells' greater metabolic needs and their preference for a pathway that produces much less energy may be resolved, at least in part, by noting that pyruvate contributes to protein, lipid and other macromolecular synthesis. Furthermore, lactate generated by LDH from pyruvate (Fig. 5-48) may be exported via a special cell membrane channel (monocarbohydrate transporter [MCT]).

Like an athlete who uses an array of different power bars, tumor cells can also generate energy from multiple carbon sources. Lactate, excreted via the MCT by some tumor cells after aerobic glycolysis, may be imported via the same channel. LDH converts this lactate back into pyruvate, for use in any of the several ways described above. Acetate may also be taken up by tumor cells, where it can be made into acetyl-CoA, to be used mostly for lipid synthesis. Another important energy source for cancer cells is glutamine, which is converted to α-ketoglutarate, a TCA intermediate. Although normal cells, depending on their functions, may also exploit these other molecules similarly, cancer cells have turned this multiplicity of carbon sources into an art form.

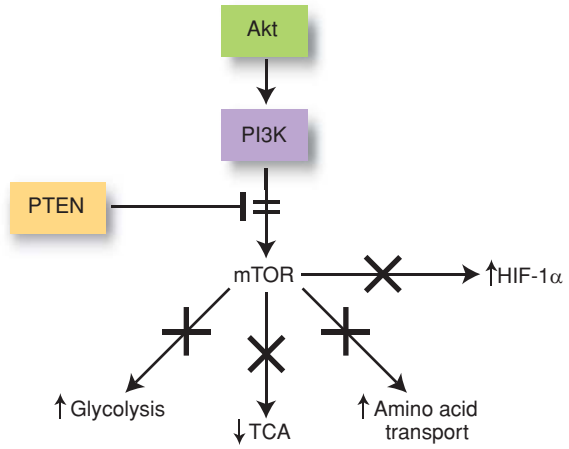

FIGURE 5-50. PTEN controls cellular metabolism and is a suppressor of the metabolic changes that power cancer cell activity. PTEN downregulates mTOR by dephosphorylating phosphatidylinositol-3,4,5-trisphosphate (PIP3) (Fig. 5-38). All downstream effects of mTOR are thus restricted: upregulation of hypoxia-induced factor-1α (HIF-1α), increased glycolysis, increased amino acid transport and decreased tricarboxylic acid (TCA) activity. Thus, PTEN's regulation of mTOR makes it impossible for cancer cells to generate the biosynthetic building blocks they need to sustain proliferation.

Cancer Cells Use Increased Amounts of Glucose

As noted above, cells import more glucose in response to stimulation by exogenous insulin. This phenomenon may explain in part the increased cancer incidence in obese patients with high levels of circulating insulin. Many studies relate both the hyperglycemia and the hyperinsulinemia of type 2 diabetes mellitus (Chapter 13) to worse prognosis for diverse tumors. However, GLUT1, the main glucose importer, is upregulated by several oncoproteins, especially c-Myc, B-Raf and K-Ras. Interestingly, c-Myc also increases glutamine transport into cancer cells and upregulates LDH, which catalyzes the (bidirectional) interconversion of lactate and pyruvate. Myc-dependent tumors are often inhibited if LDH or glutamine is decreased.

HIF-1α helps mediate increased metabolism in cancer cells. It upregulates GLUT1, increases cellular importation of glutamine and stimulates glycolysis. It also inhibits movement of pyruvate into mitochondria by blocking PDH, thus favoring glycolysis over the TCA cycle in energy production. HIF-1α is increased when oxygen tension is low or when its inhibitor, the tumor suppressor VHL, is lost. Activation of mTOR, even in the absence of hypoxia, also augments HIF-1α levels.

Tumor Suppressors Regulate Metabolism

The ability of oncoproteins to accelerate anabolism is normally balanced by the effectiveness of tumor suppressors in preventing runaway metabolism:

- **VHL:** This E3 ubiquitin ligase component is responsible for directing polyubiquitination—and thence degradation—of HIF-1α. VHL thus prevents HIF-1α from redirecting the cell's energy production toward glycolysis.
- **PTEN:** Activation of mTOR, leading to enhanced glycolysis, among other things, is a direct consequence of increased Akt triggering of PI3K (see above). PTEN strongly inhibits PI3K. It decreases mTOR activity, reduces HIF-1α and limits GLUT1 production (Fig. 5-50). Because it inhibits HIF-1α, PTEN also prevents HIF-1α–induced blockage of mitochondrial use of pyruvate to drive the TCA cycle forward.
- **p53:** In addition to its many other regulatory functions, p53 controls and directs cellular metabolism. It has been suggested, in fact, that the main reason for the Warburg phenomenon is that many tumors inactivate p53. The actions of p53 in orchestrating cellular metabolism are summarized in Fig. 5-51 and described below. *It is instructive not only to view p53 activities as directing certain energy-producing functions but also to appreciate how loss of p53 activity (e.g., by mutation) affects all of these activities.* p53 is activated by AMPK in response to metabolic stress. As a result, p53:
  - upregulates a glycolysis regulator, **TIGAR** (TP53-induced glycolysis regulator) that blocks aerobic glycolysis and shunts its intermediates to other pathways;
  - decreases glucose transporter (mainly GLUT1) synthesis and so impedes glucose entry into cells;
  - blocks nuclear factor-κB (NFκB), thus hindering its direct and indirect activation of glycolysis (NFκB upregulates HIF-1α);
  - increases the synthesis of a stimulator of cytochrome oxidase, **SCO_2,** which then increases mitochondrial electron transport and thus
  - increases pyruvate and glutamine importation into mitochondria and incorporation into the TCA cycle by upregulating PDH;
  - lowers c-Myc levels by activating miR-145, a direct inhibitor of c-Myc; this, in turn, decreases c-Myc-stimulated HIF-1α production and increases oxidative phosphorylation;
  - indirectly impedes fatty acid biosynthesis; and
  - upregulates intermediate molecules that can trigger autophagy (see below).

  The net metabolic effect of p53, acting in all of these ways, is to shunt energy production away from glycolysis and toward oxidative phosphorylation. Thus, loss of p53 leads directly to the Warburg phenomenon.

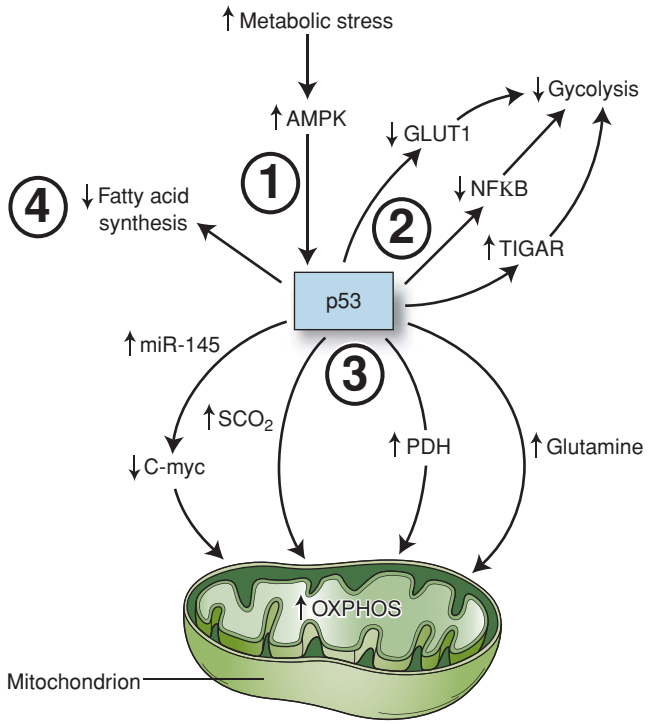

FIGURE 5-51. p53 regulation of cellular metabolism. In addition to its other functions, p53 is a critical metabolic regulator. It prevents cancer cells from achieving their malignant potential by multiple pathways. **1.** p53 is activated by the increased metabolic stress attendant to increased cellular proliferation. This activates adenosine monophosphate (AMP)-protein kinase (AMPK), which in turn activates p53. **2.** p53 directly downregulates transcription of GLUT1 and nuclear factor-κB (NFκB). It also upregulates TIGAR (TP53-induced glycolysis regulator), which impedes glycolysis and directs glycolytic intermediates into other pathways. **3.** It increases TCA cycle activity in several ways. p53 upregulates SCO_2, a stimulator of cytochrome oxidase that directly increases mitochondrial electron transport. It also increases pyruvate and glutamine incorporation into the tricarboxylic acid (TCA) by upregulating pyruvate dehydrogenase (PDH). As well, it upregulates miR-145, which directly downregulates c-Myc and so prevents Myc-mediated metabolic effects (Fig. 5-49). **4.** As well, p53 downregulates a key enzyme that mediates fatty acid synthesis.

It is worth noting in this context that p53-related metabolic protection is triggered by a sequence of events in which AMPK is activated. AMPK directly inhibits mTOR (see above), and pharmacologic stimulation of AMPK (e.g., with metformin) has been used in tumor therapy.

- **Isocitrate dehydrogenase (IDH):** This TCA enzyme has turned out to be a potent tumor suppressor. One allele of IDH is mutated in a high percentage of malignant gliomas (see Chapter 32) and in myelodysplastic syndromes (MDSs; see Chapter 26). The oncogenic mutation results in a gain-of-function alteration, which leads to generation of large amounts of a new product (called **R-2-hydroxyglutarate, or R2HG)**. R2HG directly inhibits the TET family of DNA hydroxylases and also a family of histone demethylases (see above). The result is that TET2-related histone demethylation and 5-methylcytosine hydroxylation (see above) are not available to undo the downregulation of tumor suppressor gene promoters by CpG and histone methylation, such as occurs during oncogenesis. This inactivation of TET tumor suppressors facilitates tumor development.

Tumor-Associated Stroma Supports Cancer Cell Metabolism

The Warburg effect, which is based on observations of cultured cancer cells, is generally accepted as reflecting cancer cell metabolism. It may not, however, be the whole story. In vivo, cancers contain tumor cells and stromal cells. These latter both strongly influence, and are strongly influenced by, the metabolism of their malignant neighbors.

Stromal Cell Responses to Tumor Cell–Derived Triggers

Tumor cells create a milieu of oxidative stress. Stromal fibroblasts respond to this in a sequence of events that involves impaired mitochondrial function. This, in turn, increases their ROS levels. Increased ROS further damages stromal cells' mitochondria, which leads to increased ROS and even greater impairment of mitochondrial function, in a vicious cycle (Fig. 5-52A). Resulting ROS generated by the stromal cells affect adjacent tumor cells by promoting even greater destabilizing changes in their already destabilized cancer cell DNA.

The mitochondrial injury that stromal cells sustain in this process eventually leads to autophagic destruction of the damaged organelles (mitophagy; see Chapter 1). Deprived of much of the machinery of oxidative phosphorylation, stromal cells engage in more aerobic glycolysis. They therefore produce and export more lactate (see above), which is used as a source of energy and a biosynthetic substrate by nearby cancer cells, as detailed above (Fig. 5-52B). Therefore, tumor cells induce metabolic alterations in their nonmalignant stromal neighbors that cause them to undergo oxidant injury and autophagy, and to supply tumor cells with abundant lactate for use in sustaining multiple nefarious cancer cell activities.

Autophagy Is Closely Regulated in Cancer Cells

Autophagy (see Chapter 1) is a process of recycling and removing, mostly of cellular constituents. It was first noted to be a cellular response to supplying metabolic needs in times of stress (e.g., starvation). As such, it might be of considerable utility to tumors that experience episodic depletion of energy and metabolic substrates. However, perhaps counterintuitively, the key activator of autophagy, Beclin-1, is among the genes most commonly mutated in human cancers. Mice with one or both Beclin-1 genes deleted develop far more cancers than do animals with both genes intact.

Why? To date, the best understanding of the explanation focuses on functions of autophagy not directly related to cellular nutrition. Autophagy is a key means by which oxidant-damaged cell proteins and organelles are recognized and removed. If autophagy is impaired, oxidant injury accumulates, with two important consequences. First, oxidatively damaged cellular molecules can accumulate, aggregate and mediate further oxidant injury (see Chapter 1), eventually increasing the DNA mutation rate and leading to genomic instability (see below). Accumulation of damaged cell constituents relies on the autophagy-related protein, p62 (see Chapter 1). p62 is in fact central to tumorigenesis and is overexpressed in many human tumors. Without it, the oxidized aggregates do not form and resultant oxidant genetic damage does not occur.

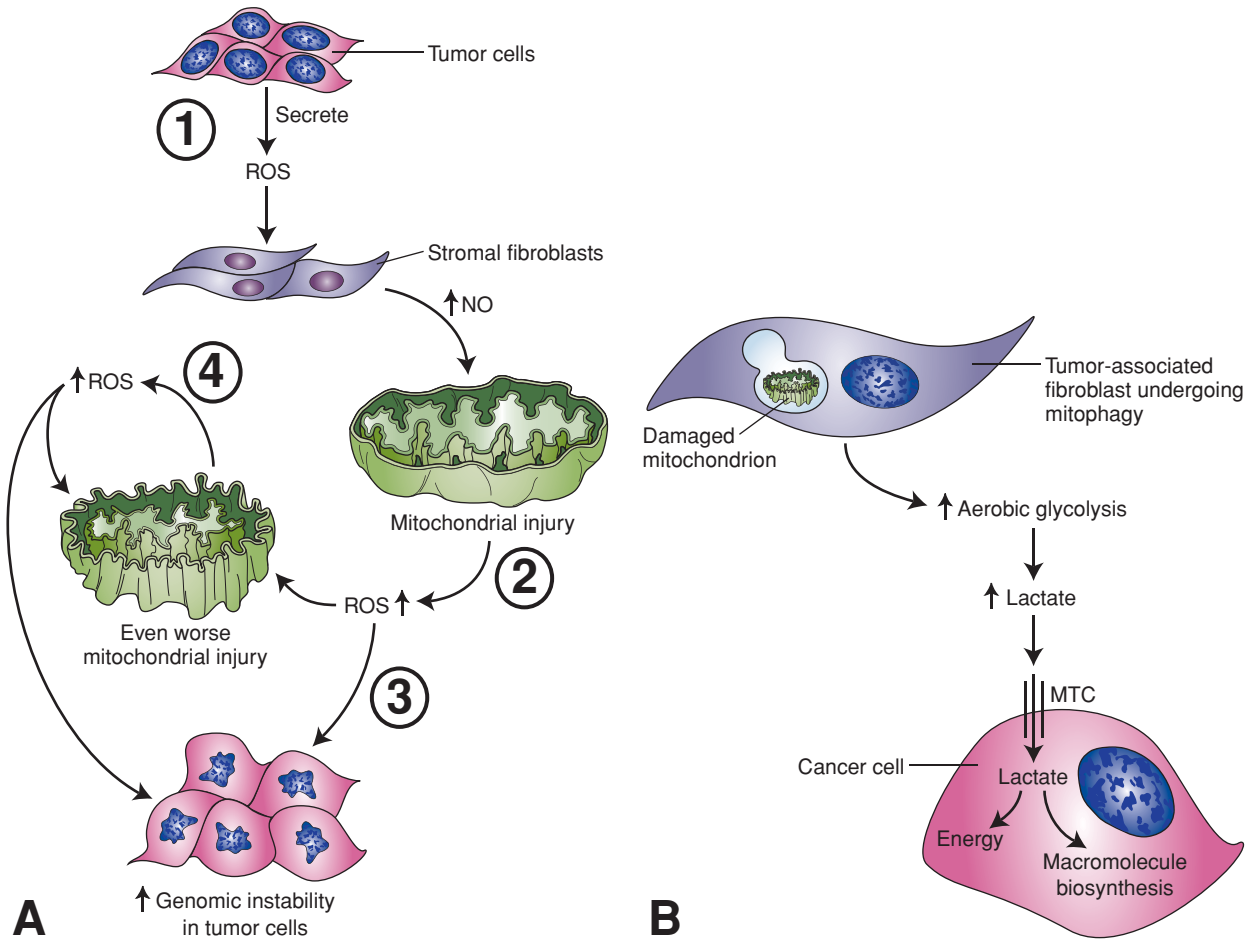

FIGURE 5-52. Stromal cell responses to tumor cell–derived signals. A. Role of reactive oxygen species (ROS). Tumor cells manipulate stromal cells so as to augment tumor cell metabolic activity. **1.** ROS elaborated by tumor cells stimulate stromal cells to increase their production of nitric oxide (NO). This NO causes mitochondrial injury in the stromal cells. **2.** As a result, stromal cells generate excessive ROS. **3.** Increased stromal cell ROS generates more oxidative injury in neighboring cancer cells, leading to increased genomic instability in the tumor. **4.** Increased stromal cell ROS also increases stromal cell mitochondrial injury, creating a vicious circle and magnifying tumor cell genomic instability. **B. Altered metabolism in tumor-associated fibroblasts.** Mitochondrial damage in tumor-associated fibroblasts leads to autophagy of damaged mitochondria (mitophagy). Resulting loss of mitochondria directs more fibroblast metabolism toward glycolysis, producing lactate, which is secreted by the stromal cells. Lactate is taken up by tumor cells, via MTC, and used for macromolecule biosynthesis and other tumor cell metabolic activities.

Second, if autophagy is impaired, accumulation of damaged and damaging cell components will lead to cell death. But p53-dependent apoptosis in such settings requires that the process of autophagy is intact. As a consequence, the cell dies, not by apoptosis, but by necrosis. Unlike apoptosis, necrotic cell death elicits inflammatory responses, including such shady characters as tumor-associated macrophages that facilitate and further tumorigenesis (see above).

Many tumor suppressors, such as PTEN and the tuberous sclerosis proteins (TSC1, TSC2), constitutively facilitate autophagy. The supreme tumor suppressor, p53, has an ambiguous relationship with autophagy, stimulating it in some ways and inhibiting it in others. Several oncogenic proteins (Akt, Bcl-2, mTOR) impair autophagy, underscoring its importance as an antioncogenic process. Important genes involved in autophagy, such as Beclin-1, are commonly mutated in many human cancers. Interestingly, several antineoplastic medications strongly promote autophagy. Although the connection between autophagy and cancer is not fully understood, impairment of the tumor suppressor function of autophagy may result in accumulation of materials within the cell that cause chromosomal instability, which ultimately may lead to cancer development.

GENETIC INSTABILITY IN CANCER

The pathogenesis of cancer involves multiple genetic—and, undoubtedly, epigenetic—changes, and genomic instability is a key contributor to these processes. Although not universal in tumors, **chromosomal instability (CI)** entails additions or deletions of entire chromosomes, or portions thereof, to yield variable cellular karyotypes. CI may result in **aneuploidy** (abnormal chromosome number), **gene amplification** (increased copy number of a gene) and **loss of heterozygosity** (loss of one allele out of a pair). LOH may reflect loss of a whole chromosome, deletion of a bit of DNA bearing the gene in question or inactivation of that gene. As a result, the remaining allele is the only one for that locus and controls the phenotype. If that remaining allele is rendered abnormal, the lack of a second allele to counterbalance it means that its abnormal phenotype is unopposed. Moreover, the phenotype of

the remaining allele may promote the development of cancer. Typically, about one fourth of alleles are lost in malignancies.

Mechanisms of Altered Activation of Cellular Genes

There are three general mechanisms by which proto-oncogenes become activated:

- A mutation in a proto-oncogene leads to **constitutive production of an abnormal protein.**
- Increased expression of a proto-oncogene causes **overproduction of a normal gene product**.
- Activation or expression of proto-oncogenes is regulated by numerous auto-inhibitory mechanisms that safeguard against inappropriate activity. Many mutations in proto-oncogenes render them **insensitive to normal auto-inhibitory and regulatory constraints** and lead to constitutive activation.

The converse processes apply to inactivation of tumor suppressors (see above). That is, (1) they may suffer mutations that increase production of an abnormal protein that either lacks or interferes with tumor suppression; (2) their effectiveness is rendered useless when a regulatory target is overexpressed, overwhelming a normally expressed suppressor; or (3) their expression is impaired, whether by an inactivating mutation or epigenetic inactivation.

Multiple Mechanisms Generate Genetic Instability

Several mechanisms of genetic instability contribute to tumorigenesis. These include (1) point mutations, (2) translocations, (3) amplifications and deletions, (4) loss or gain of whole chromosomes and (5) epigenetic changes. These types of instability occur in many ways. Among the most important is the loss—whether by inheritance, mutation or epigenetic inactivation—of proteins that protect the cell from mutations. These include cell cycle regulatory proteins (checkpoints, proofreaders, mitosis-related chromosomal sorting proteins, etc.) and proteins that mediate DNA repair functions.

Role of Defects in DNA Repair Systems

An understanding of how defects in DNA repair contribute to oncogenesis was derived in part from observations made in familial cancer syndromes. For example, a type of colon cancer syndrome, hereditary nonpolyposis colon cancer (HNPCC, Lynch syndrome), entails a 75% lifetime risk for colon cancer. The large majority of HNPCC patients have mutations in MLH1 or MSH2 DNA mismatch repair enzymes (see above).

Xeroderma pigmentosum (XP), a hereditary syndrome characterized by enhanced sensitivity to UV light and development of skin cancer, reflects defects in nucleotide excision repair (NER) enzymes. In some common types of spontaneous lung cancer, a majority of cases exhibit mutant proteins involved in NER.

Double-Strand Break Repair and Cancer

As mentioned above, detection of DSBs and initiation of repair processes involve the ATM protein. Mutations in ATM and other enzymes involved in DSB repair are associated with a high frequency of malignant tumors.

Point Mutations

Although humans have evolved highly efficient mechanisms to recognize and repair DNA base changes, single base changes do occur normally, at the rate of 10^{-9}/base/cell division in somatic cells and 10^{-11} in germ cells. Application of advanced DNA sequencing techniques has allowed detection of many of these single base changes—called single nucleotide polymorphisms, or SNPs—in tumors.

Activation by Point Mutation

Conversion of proto-oncogenes into oncogenes may involve (1) point mutations, (2) deletions or (3) chromosomal translocations. The first oncogene identified in a human tumor was activated *HRAS* in a bladder cancer. This gene had a remarkably subtle alteration—a point mutation in codon 12. This change led to the substitution of valine for glycine in the H-ras protein. Subsequent studies of other cancers have revealed point mutations involving other codons of the *ras* gene, suggesting that these positions are critical for the normal function of the ras protein. Since the discovery of mutations in *HRAS*, alterations in other growth-regulatory genes have been described.

Activating, or gain-of-function, mutations in proto-oncogenes are usually somatic rather than germline alterations. Germline mutations in proto-oncogenes, which are known to be important regulators of growth during development, are ordinarily lethal in utero. There are several exceptions to this rule. For example, c-*ret* is incriminated in the pathogenesis of certain heritable endocrine cancers, and c-*met*, which encodes the receptor for hepatocyte growth factor, is associated with a hereditary form of renal cancer.

Chromosomal Translocation

Chromosomal translocations involve joining of a piece of one chromosome with a part of another. These rearrangements generally contribute to tumorigenesis in one of two ways. Sometimes they place a normal gene, like a proto-oncogene, under the control of a promoter that is regulated less effectively than the native proto-oncogene promoter.

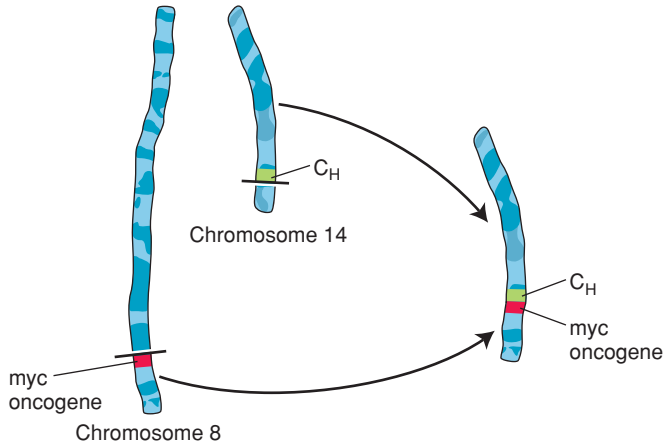

FIGURE 5-53. Schematic representation of the t(8;14) translocation in Burkitt lymphoma. In this disorder, chromosomal breaks involve the long arms of chromosomes 8 and 14. The c-*myc* gene on chromosome 8 is translocated to a region on chromosome 14 adjacent to the gene coding for the constant region of an immunoglobulin heavy chain (C_H). The expression of c-*myc* is enhanced by its association with the promoter/enhancer regions of the actively transcribed immunoglobulin genes.

In 75% of patients with Burkitt lymphoma (see below and Chapter 26), there is a translocation of c-*myc*, a proto-oncogene involved in cell cycle progression, from its site on chromosome 8 to a position on chromosome 14 (Fig. 5-53). This translocation places c-*myc* adjacent to genes that control transcription of the immunoglobulin heavy chains. As a result, the c-*myc* proto-oncogene is activated by the promoter/enhancer sequences of these immunoglobulin genes and is consequently expressed constitutively rather than in a regulated manner. In 25% of patients with Burkitt lymphoma, the c-*myc* proto-oncogene remains on chromosome 8 but is activated by translocation of immunoglobulin light-chain genes from chromosome 2 or 22 to the 3′ end of the c-*myc* gene. In either case, a chromosomal translocation does not create a novel chimeric protein but stimulates the overproduction of a normal gene product. In Burkitt lymphoma, the excessive amount of the normal c-*myc* product, probably in association with other genetic alterations, leads to the emergence of a dominant clone of B cells, driven relentlessly to proliferate as a monoclonal neoplasm. Many other hematopoietic malignancies, lymphomas and solid tumors reflect activation of oncogenes by chromosomal translocation. Although some malignant conditions are **initiated** by chromosomal translocations, during the **progression** of many cancers, myriad chromosomal abnormalities take place (translocations, breaks, aneuploidy, etc.).

Activation by Chromosomal Translocation

In addition, chromosomal translocation may lead to production of a new, abnormal, protein. Thus, a part of one chromosome including part or all of the coding region from a protein (e.g., a proto-oncogene) moves to another chromosome, into the coding region of another gene. The result is a new protein, sharing sequence homology with the original ones, but active in driving oncogenesis in a way that the originals are not.

This process has been implicated in the pathogenesis of several human leukemias and lymphomas. The first and still the best-known example of an acquired chromosomal translocation in a human cancer is the **Philadelphia chromosome,** which is found in 95% of patients with chronic myelogenous leukemia (CML; Fig. 5-54). The c-*abl* proto-oncogene

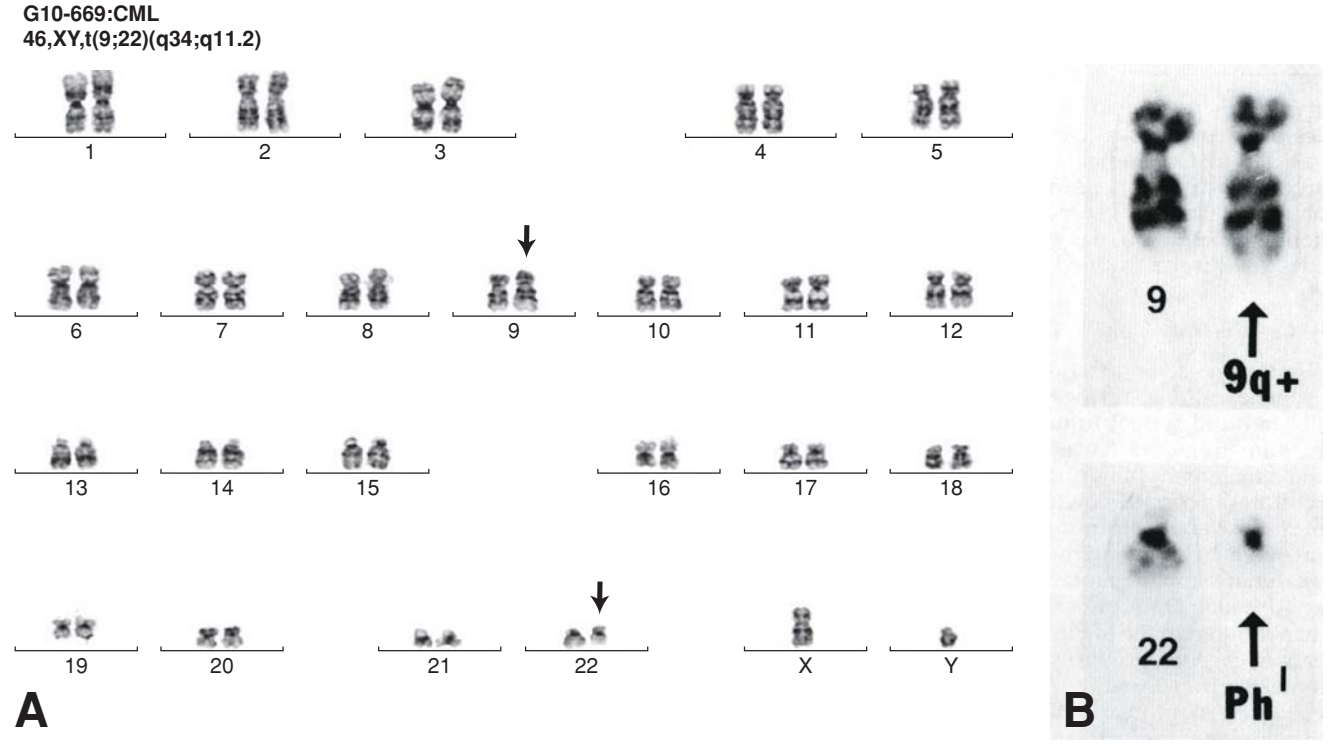

FIGURE 5-54. The t(9;22) translocation in chronic myelogenous leukemia. A. Abnormal karyotype with the shortened chromosome 22 and the longer chromosome 9 highlighted. B. Higher magnification of the translocated chromosomes. C. Fluorescence in situ hybridization (FISH). This assay demonstrates the fusion chromosome using a red ABL chromosome 9 probe and a green BCR chromosome 22 probe, the joining of which yields a yellow signal. Two tumor cells are shown. Each has one normal chromosome 9 and one normal chromosome 22.

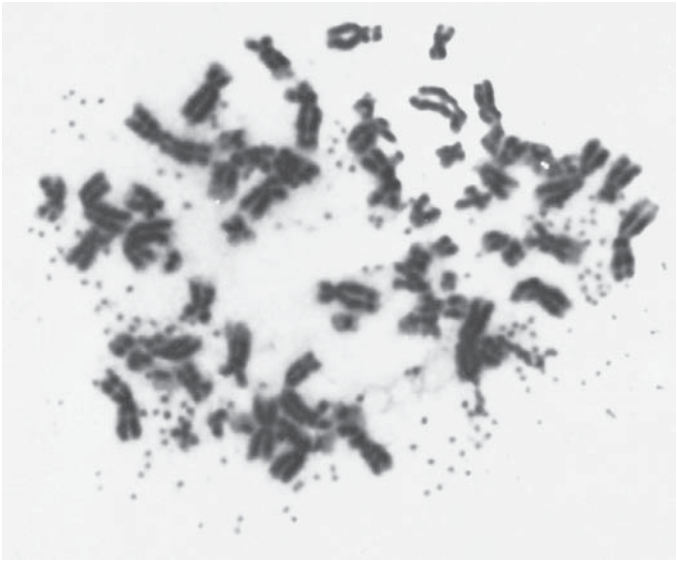

FIGURE 5-55. Double minutes in human cancers. Double minutes in a karyotype of a soft tissue sarcoma appear as multiple small bodies.

on chromosome 9 is translocated to chromosome 22, where it is placed in juxtaposition to a site known as the breakpoint cluster region (*bcr*). The c-*abl* gene and *bcr* region unite to produce a hybrid oncogene that codes for an aberrant protein with very high tyrosine kinase activity, which generates mitogenic and antiapoptotic signals. The chromosomal translocation that produces the Philadelphia chromosome is an example of oncogene activation by formation of a chimeric (fusion) protein. Inhibition of the resulting abnormal kinase by imatinib causes long-term remissions in CML.

Amplifications and Deletions

Genetic amplifications are duplications of variable-sized regions of chromosomes. Cytogenetically, such modifications appear as small DNA fragments that are not part of any chromosome, called "double minutes" (Fig. 5-55), or as increased signal intensity when fluorescent probes for specific regions hybridize with chromosomes. These changes not infrequently affect oncogenes, drug resistance genes or related nefarious characters along with adjacent genomic fragments.

Activation by Gene Amplification

The *ERBB2* proto-oncogene is amplified in up to a third of breast and ovarian cancers. The *ERBB2* gene (also called *HER2/neu*) encodes a receptor-type tyrosine kinase that structurally resembles the EGF receptor. Amplification of *ERBB2* in breast and ovarian cancer (Fig. 5-56) may be associated with poor overall survival and decreased time to relapse. In this context, an antibody targeted against *HER2/neu* (trastuzumab) is now used as adjunctive therapy for breast cancers that overexpress this protein.

Inactivation by Deletion

Deletions, naturally, are lost chromatin. These can vary from tiny pieces to whole arms of chromosomes. Just as amplifications tend to occur at sites of oncogenes, deletions that come to our attention in cancer cells tend to affect tumor suppressor genes.

Alterations in Chromosome Number

Addition or loss of whole chromosomes generally occurs during mitosis and is thought to reflect defects in binding of the mitotic spindle to chromosomal kinetochores (see above), possibly due to malfunctioning of the Aurora B kinase apparatus (see above). As a consequence, chromosomes attach too avidly to mitotic spindles and fail to separate and segregate appropriately.

Almost all solid tumors have abnormal karyotypes. Commonly, tumors lose one copy of a chromosome 10, where the gene for PTEN (see above) resides, or possess extra copies of chromosomes that carry particular oncogenes.

A tumor with a normal karyotype may still have experienced chromosomal loss, however. One parental chromosome of any particular pair may be lost, only to be replaced by a reduplicated copy of the copy of that chromosome derived from the other parent. That is, one parent's copy of a chromosome may be replaced by a duplicated copy of the other parent's chromosome of the same number. The resulting so-called copy-neutral loss of heterozygosity (CN-LOH) is called **uniparental disomy**, and is common in many malignancies. CN-LOH has prognostic significance in several cancer types, such as acute myeloid leukemias.

Epigenetic Modifiers in Cancer Genomic Instability

There are, as discussed above, many heritable factors that can affect gene expression without necessarily changing DNA base sequence. The scope of epigenetic alterations in human cancers is barely understood, but all evidence to date indicates that such modifications impact cancer development and progression profoundly.

A mutation in a gene that participates in chromatin remodeling is seen in most malignant rhabdoid tumors. This mutation occurs in diploid cells without obvious genomic

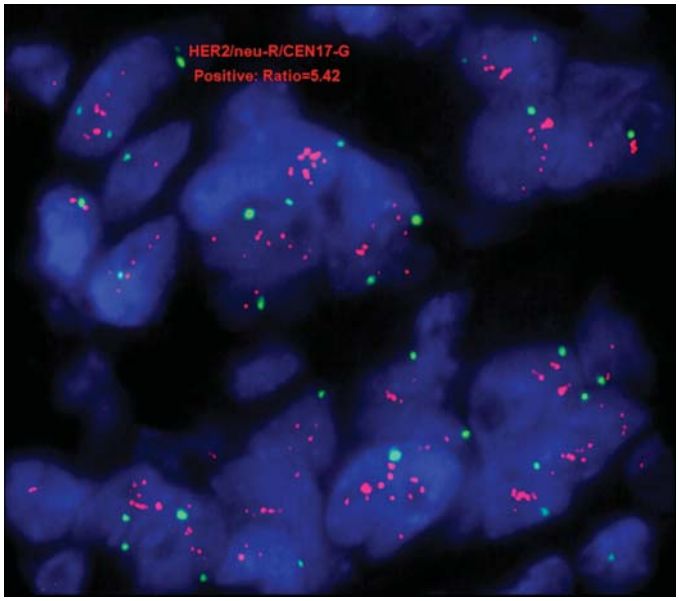

FIGURE 5-56. *ERBB2* amplification in human cancers. ERBB2 also called HER2/neu amplification in a human breast cancer (fluorescence in situ hybridization [FISH]), showing the multiple copies (red fluorescence) as minute bodies. As a chromosome control, a green probe for chromosome 17 is shown.

alterations or gene amplifications/deletions. It is, however, associated with profound changes in gene expression.

Epigenetic modifiers need not only involve direct mechanisms of cell proliferation. They may, for example, affect cellular sensitivity to chemotherapeutic agents or provide escape routes if an enabling mutation is targeted by a particular drug.

The Role of the Immune System in Carcinogenesis Is Unclear

The immune system distinguishes self from nonself molecules and is very effective in combating infectious agents. The notion that it plays a role in suppressing tumor development is rooted in the concept of tumors as nonself entities, with unique "tumor-specific antigens" that can elicit protective immunologic responses. This principle has been extensively demonstrated in experimental animals.

Experimental systems in which tumors are induced by powerful chemical carcinogens have shown that such tumors may be highly immunogenic, particularly when transplanted into immunocompetent recipients. Mice with defects, whether in innate or adaptive immunity (see Chapter 4), develop tumors more often than immunocompetent animals. Similarly, people with immune deficiencies, such as patients with AIDS, are also more prone to cancers than are immunocompetent individuals.

The tumors that develop in these settings, however, bear little resemblance to most human cancers. Potent carcinogens are powerful mutagens and can cause new tumor antigens to arise because of substantial genetic alterations. There is little evidence that spontaneous human tumors bear such antigens. As well, the tumors that occur in immunocompromised humans and animals are almost always virus induced and, again, dissimilar to the tumors that normally afflict people (lung, colon, etc.) that are not connected to infectious agents. The immune deficits thus can be seen as defects in virus clearance (or removal of virus-infected cells), rather than as antitumor surveillance or defense mechanisms.

Inflammatory Cells Nearby Tumors: Friends or Foes?

Pathologists have observed for many years that mononuclear inflammatory cells often accompany cancers (Fig. 5-57). Once an understanding of the role of lymphocytes in immune function had developed, it was a short step to conclude that these lymphocytes (and other cells) were part of a host response to the presence of tumor. The conclusion that tumors produced antigens that elicited such a response was seemingly inescapable.

There are reports that, for certain kinds of tumors, abundant mononuclear infiltration near the tumor may correlate with a good prognosis. Such observations led to many attempts at "immunotherapy," either to elicit or to magnify immune responses against tumors. Immunotherapy was particularly attempted for tumors for which such infiltrates were common, if not invariable, concomitants. Melanomas are an example. To date, immunotherapy of any type of tumor remains experimental, with effectiveness as a treatment modality still unproven.

Even the presence of mononuclear infiltrates near tumors does not necessarily mean that those mononuclear cells signify host immunity against the tumor. Tumor-associated mononuclear infiltrates may not, in fact, be inflammatory. Rather, as indicated above, such cells—far from representing host defenses against a foreign invader—often actually serve the purposes of developing tumors. In short, the function of tumor-associated mononuclear infiltrates is not settled.

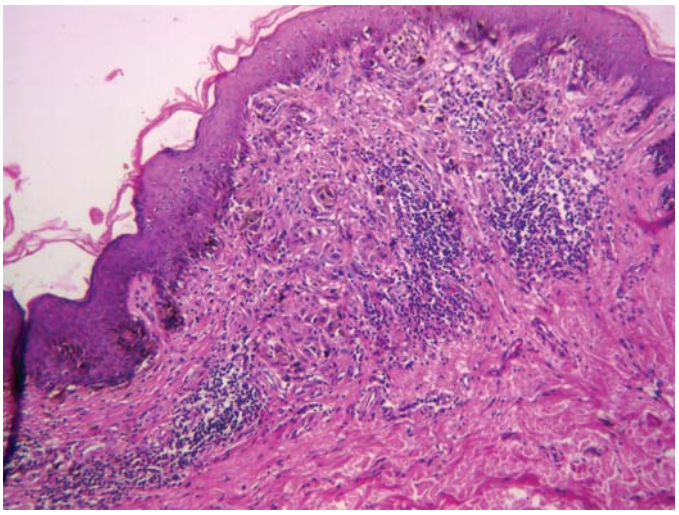

FIGURE 5-57. Mononuclear infiltrate adjacent to a malignant melanoma. Extensive mononuclear cell (mostly lymphocytes) near a primary malignant melanoma in the skin. The significance of the mononuclear cells, traditionally considered to represent host immune responses to the presence of a "foreign tumor antigen", is unclear.

Tumor Antigens

Most human cancers reflect somatic mutations that may theoretically produce mutant proteins, which in turn serve as targets of the immune system. In addition, normal proteins may be overexpressed, and posttranslational modifications of normal proteins may produce altered antigens. Tumor antigens not associated with oncogenic viruses may be categorized as follows:

- **Tumor-specific antigens (TSAs):** These represent somatic mutations or alterations in protein (and other) processing, unique to tumors.
- **Tumor-associated antigens (TAAs):** These reflect the production of normal proteins, either in excess or in a setting different from their normal expression.

Tumor-Specific Antigens

Most tumor-related mutations occur in intracellular proteins, which could theoretically offer immunologic targets. However, most TSAs tend to be specific for individual patients' tumors, and not for tumor types, making immunologic targeting for therapy complicated and highly personalized. Nevertheless, since TSAs are expressed only by the cancer cells and not in normal tissues, there should be no preexisting immune tolerance to them and they are theoretically excellent candidates for tumor immunotherapy. These conclusions hold true for normal proteins that undergo aberrant posttranslational modifications, such as altered glycosylation, lipid association and so forth.

Tumor-Associated Antigens

TAAs are molecules that are shared between cancer cells and normal cells and include:

- **Oncospermatogonial antigens:** These molecules are normally only seen in testicular germ cells but may be produced by malignant cells. Since the testis is an immunologically privileged site, such molecules are not normally exposed to the immune system. However, immune reactivity of both cell- and antibody-mediated limbs to these antigens tends to be weak.
- **Differentiation antigens:** These molecules are seen on normal cells of the same derivation as the cancer cells. As an example, CD20, which is a normal B-cell differentiation antigen, is expressed by some lymphomas, and anti-CD20 antibody (rituximab) is effective treatment for such tumors.
- **Oncofetal antigens:** These antigens are made by normal embryonic and fetal structures and by several cancers (e.g., carcinoembryonic antigen, α-fetoprotein).
- **Overexpressed antigens:** These are normal proteins that are overproduced in certain malignant cells (e.g., prostate-specific antigen, HER2/neu).

Since TAAs represent a class of antigens that is principally recognized as "self" by the immune system, and so have elicited tolerance, they do not lead to effective immunologic responses.

To date, the evidence for natural control of neoplasia by immunologically mediated mechanisms (immune surveillance) in humans is scanty. Most interest in this area is directed toward possible therapeutic applications.

The potential development of effective cancer immunotherapy is complicated by tumor mechanisms to evade immunologically mediated destruction (Table 5-10). Among tumors' escape routes from immune attack are production of immunosuppressive cytokines, resistance to lysis by cytotoxic lymphocytes, inhibition of apoptotic signaling and changes in antigenic profiles. Interestingly, there is substantial evidence implicating mutant p53 as protecting cancer cells from granzyme-mediated apoptosis (see Chapter 1) caused by cytotoxic T lymphocytes (CTLs).

Another effect of cancer immunotherapy that must be overcome is related to tumor heterogeneity. Antibodies or CTLs directed against tumor antigens may lead to selective emergence of malignant clones that have lost these antigens. Nevertheless, major efforts to develop new immune therapies for cancer continue.

TABLE 5-10
POTENTIAL PATHWAYS FOR TUMOR CELL AVOIDANCE OF IMMUNOLOGICALLY MEDIATED DESTRUCTION

Related to CTLs
Development of immune tolerance
Failure of helper T cells
Low numbers of sensitized CTLs
Lack of specificity for malignant cells
Barriers to entry of CTLs into tumor environment
Impairment of signal transduction in T cells
Deficiencies in CTL cytolytic activity
Regulatory T cells block antitumor activity
Related to Tumor Cells
Failure of tumor cells to stimulate latent lymphocyte reactivity
Low levels of tumor antigen production
Weak immunogenicity of tumor antigens
Decreased MHC antigens on tumor cell membranes
Elaboration of immunosuppressive molecules by tumors
Resistance of cancer cells to apoptosis and other cell death mechanisms
Tumor cells cause CTLs to undergo apoptosis

CTL = cytotoxic T lymphocyte; MHC = major histocompatibility complex.

CANCER STEM CELLS AND TUMOR HETEROGENEITY

Most Cancers Are of Monoclonal Origin

Studies of human and experimental tumors indicate that most cancers arise from single transformed cells. This conclusion is best established for proliferative disorders of the lymphoid system, in which clonality is easiest to assess. Neoplastic plasma cells in multiple myeloma produce a single immunoglobulin species, unique to each individual patient and consistent in that patient over time. Monoclonal T-cell receptor and immunoglobulin gene rearrangement, as well as monoclonal cell surface markers, establish a monoclonal origin for many lymphoid malignancies. The cells of B-cell lymphomas exclusively display either κ or λ light chains on their surfaces, while polyclonal lymphoid proliferations—which are almost always benign—contain a mixture of cells, some with κ, and some with λ, light chains.

Monoclonality has also been demonstrated for many solid tumors. One of the best examples of this principle utilized glucose-6-phosphate dehydrogenase in women who were heterozygous for its two isozymes, A and B (Fig. 5-58). These isozymes are encoded by genes located on the X chromosome. Since one X chromosome is randomly inactivated, only one of the two alleles is expressed in any given cell. Thus, although the genotypes of all cells are the same, half of cells express only A; the rest express only B. Examination of benign uterine smooth muscle tumors (leiomyomas, or "fibroids") revealed that in any individual tumor all cells expressed either A or B. No tumor included a mixture of A-expressing cells and B-expressing cells. Thus, each tumor was derived from a single progenitor cell. Oligoclonal tumors have been described, but they are rare and are usually caused by infection with oncogenic viruses (see below).

Cancer Stem Cells Are Primordial Malignant Cells from Which Tumors Arose and Which Can Generate, and Regenerate, the Tumors

Only a minute proportion of the cells in a malignant tumor can produce a new tumor when they are transplanted

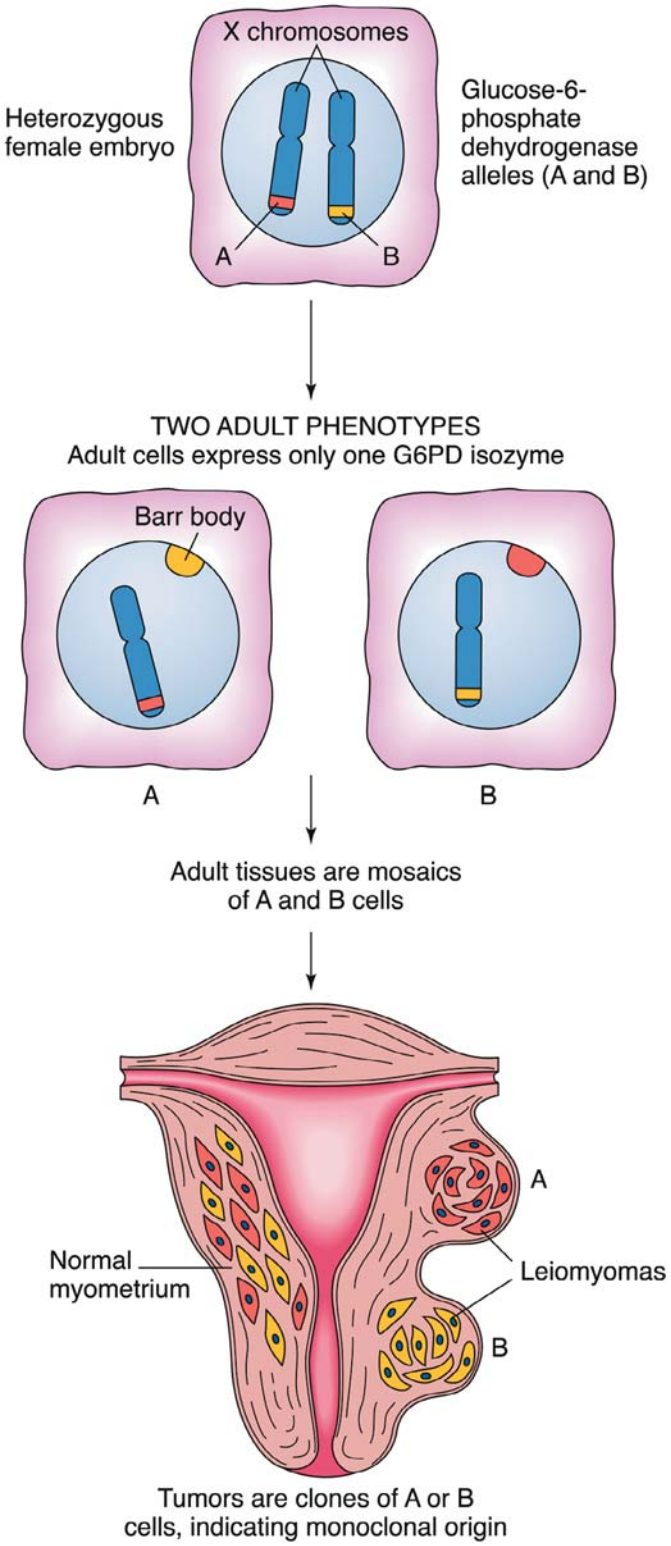

FIGURE 5-58. Monoclonal origin of human tumors. Some females are heterozygous for the two alleles of glucose-6-phosphate dehydrogenase (G6PD) on the long arm of the X chromosome. Early in embryogenesis, one of the X chromosomes is randomly inactivated in every somatic cell and appears cytologically as a Barr body attached to the nuclear membrane. As a result, the tissues are a mosaic of cells that express either the A or the B isozyme of G6PD. Leiomyomas of the uterus have been shown to contain one or the other isozyme (A or B) but not both, a finding that demonstrates the monoclonal origin of the tumors.

into immunologically deficient animals. Normal tissues contain pluripotent somatic stem cells, which can both replenish their own numbers (self-renewal) and differentiate into more mature derivative cells. Cancers also have a small population of malignant cells with such capabilities. These are called **cancer stem cells (CSCs)**. Their existence has been most convincingly demonstrated in hematologic malignancies like acute myeloblastic leukemia (AML), but there is also strong evidence for their existence in an increasing number of solid tumors.

In AML, far less than 1% of leukemic cells express hematopoietic stem cell membrane markers ($CD34^+$, $CD38^-$). Only these cells among the entire leukemic population can reestablish leukemia in an appropriate transplant recipient host. Comparable, but not identical, data have been obtained from studies of cancers of the breast, colon and brain, in which different markers identify CSC-rich cell populations and exclude the vast majority of tumor cells, which cannot recapitulate tumorigenesis. CSCs are defined functionally. The respective markers allow us to identify populations that are enriched for stem cells, but not pure CSCs. Only some of the cells in those populations function as cancer stem cells.

Derivation of CSCs

The origins of CSCs are murky. In some cases, they may derive from the pluripotent somatic stem cells of the affected organ, for example, hematopoietic stem cells in the case of AML (Fig. 5-59A). In other cases, lineage-committed progenitor cells may be the culprits. Such cells are multipotent, but not pluripotent, at the time of transformation. They may reacquire a degree of "stemness," allowing them both to repopulate their own numbers and to differentiate into more committed cells (Fig. 5-59B). Therefore, it is most likely that CSCs can arise both from tissue stem cells and from slightly differentiated immediate progeny of these tissue stem cells. Lurking within the tumor, they function as a reservoir of cells that continue to provide more differentiated tumor cells and that can regenerate the entire tumor, should that become necessary.

Tumor Cells Derived from CSCs

Although almost all tumors begin as single clones of neoplastic cells, as they grow, their cells show considerable variation in appearance (Fig. 5-60) and behavior. Diversity of cells among a tumor population has broad implications for tumor progression and dissemination, as well as for responses to chemotherapy and the development of resistance to these agents. Several theories, which are not necessarily mutually exclusive, and which all may be correct in some cases, have been proposed to account for the development of phenotypic diversity of cells in tumors.

It is critical to understand that the overwhelming majority of tumor bulk is composed of these derivative cells. Treatments that reduce tumor volume mostly target these cells, and consequent reduced tumor volume reflects the susceptibility of these cells—not CSCs—to the therapies employed. However, as will become clear (see below), reduced tumor volume does not equate with elimination of CSCs, nor does it necessarily affect the ability of CSCs to regenerate the tumor after treatment.

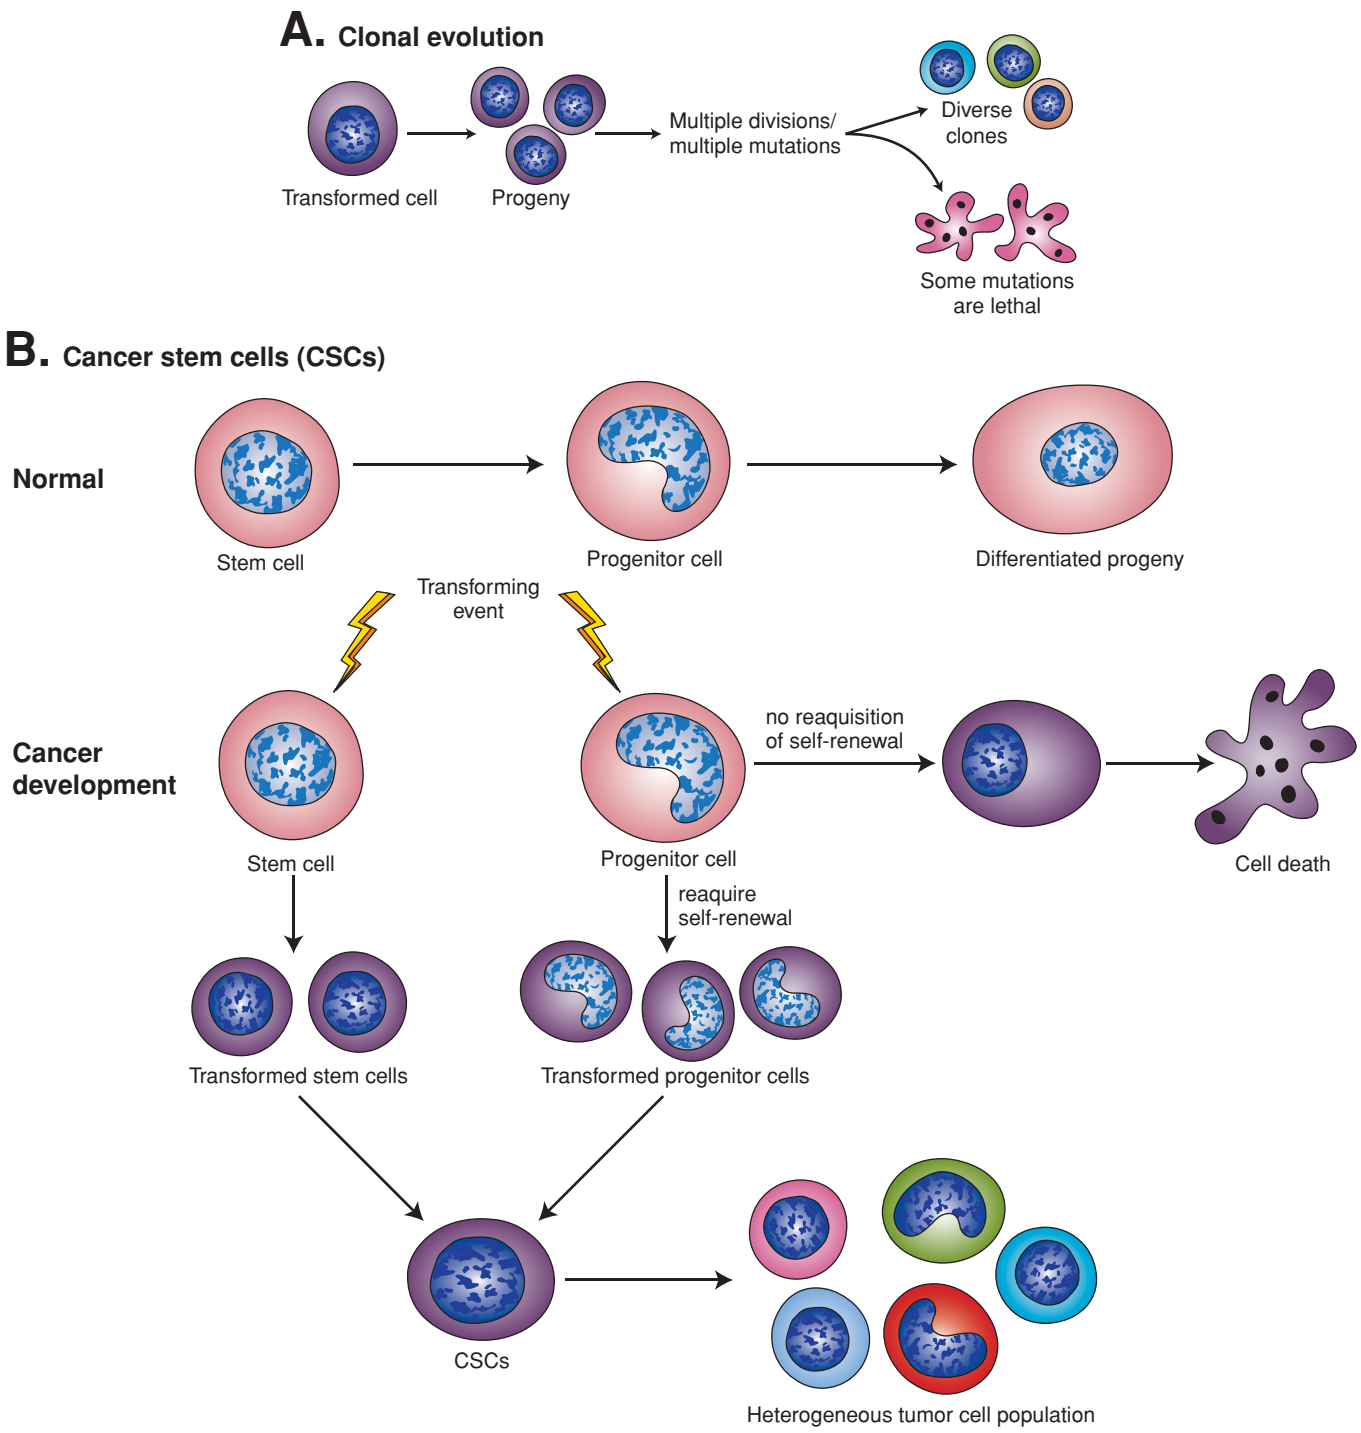

FIGURE 5-59. Tumor stem cells and tumor heterogeneity. A. Linear progression of tumor clonal evolution. Proliferating cancer progenitor cells eventually develop a variety of mutations, with different individual cells acquiring different mutations, leading to heterogeneity in the tumor cell population. Some such mutations are inconsistent with cell survival, while others facilitate cancer progression. This model is most consistent with critical enabling primordial mutations in a stem cell that must be retained throughout subsequent tumor evolution. **B. Cancer stem cells and progenitor cells.** Normally (*above*) stem cells give rise to committed progenitor cells. These then produce terminally differentiated cells. An oncogenic stimulus (*below*) to a stem cell may lead to an expanded pool of transformed stem cells. These become cancer stem cells (CSCs). Alternatively, the oncogenic stimulus may affect a committed progenitor cell. If the latter recapitulates a program of self-renewal, the resulting transformed progenitor may become a CSC. If it does not activate the self-renewal program, resulting differentiated progeny will be produced and eventually die. CSCs generated either via transformation of stem cells or transformation of committed progenitors may then be the antecedents of a heterogeneous malignant cell population.

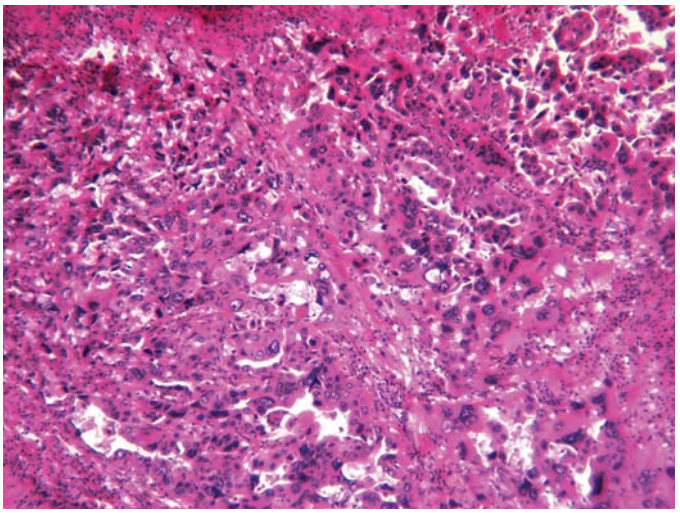

FIGURE 5-60. Phenotypic diversity in human tumors. Human tumor cells show great heterogeneity in their appearance, proliferative activity and so forth. Thus, most human tumors are mixtures of small and large cells, often with diverse shapes, varying nuclear appearances and differences in mitotic activity.

Clonal Evolution

The original explanation of tumor heterogeneity holds that tumor cells progressively accumulate new mutations as they proliferate. A tumor in which many cells are dividing can thus, over time, generate a diverse population of genetically different cells. Some of these cells may be destined for ignominious death, while others may flourish as genetically distinct subclones of the original malignant cells (Fig. 5-59A). Darwinian-style selection—whether due to localized hypoxia, differences in proliferation rates, potential for invasion and metastasis, therapy and so forth—governs which subclones will succeed and which will perish, which will metastasize and which will remain localized.

Epigenetic Cancer Cell Plasticity

Cancer's evil machinations have led to even more devious ways for tumors to maintain themselves and to grow and spread. Thus, for some tumors (e.g., malignant melanomas), tumors adapt to the progressive challenges to survival and dissemination via epigenetic changes (e.g., noncoding RNAs, or expression of proteins that modify histones) (Fig. 5-61). A mass of slowly proliferating tumor cells may alternate among

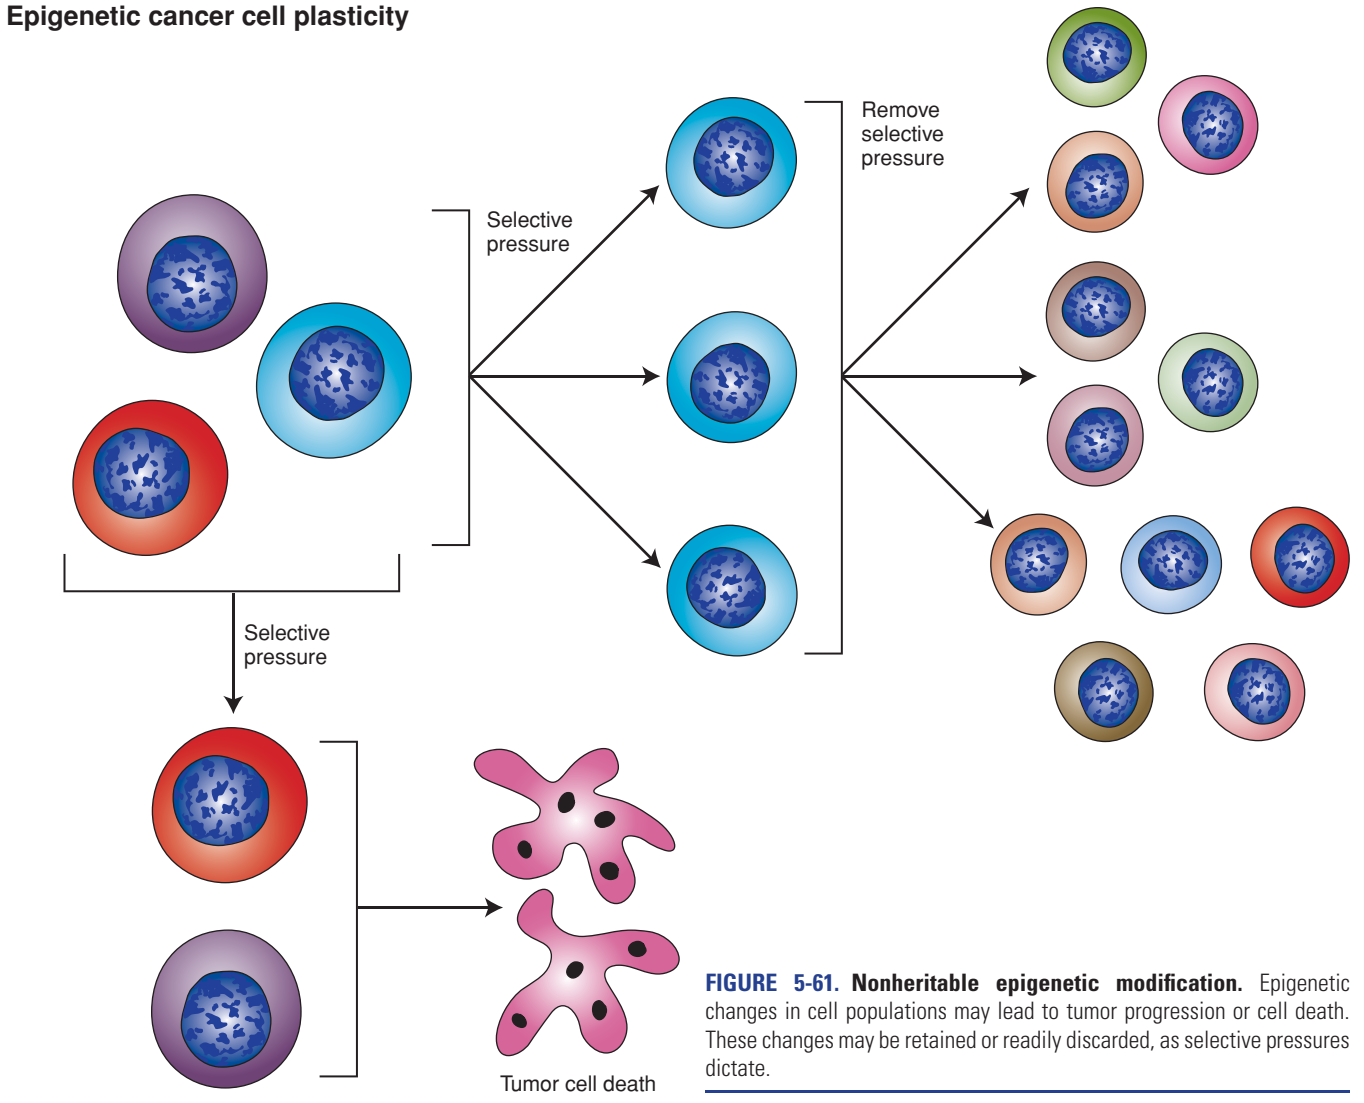

FIGURE 5-61. Nonheritable epigenetic modification. Epigenetic changes in cell populations may lead to tumor progression or cell death. These changes may be retained or readily discarded, as selective pressures dictate.

different epigenetic states, and so fluctuate between the ability to reconstitute a tumor (stem cell–like) and the lack of such ability. This type of deviousness allows for diverse populations of tumor cells to alternate between stemness—slowly dividing, tumor-reconstituting cells—and rapidly dividing, nonreconstituting cells. Furthermore, tumor cells may achieve such metamorphoses without incurring further mutations.

The implications of this phenomenon are substantial. Some malignant tumors may represent constantly shifting therapeutic targets, with incredible plasticity in adapting to a changing chemotherapeutic milieu via the ability to shift phenotypes rapidly to evade antineoplastic drugs, and then to shift back to reemerge from a defensive posture and reassert an aggressive nature.

The Significance of CSCs

CSCs are not merely an experimental curiosity. They are the cells from which many human tumors arise. They divide infrequently, which allows them to evade destruction by cytotoxic chemotherapeutic agents that preferentially kill rapidly dividing cells. Thus, while chemotherapy may destroy the bulk of the rapidly dividing cells in a malignant tumor mass, residual CSCs may survive to regenerate the cancer.

Even more significantly, CSCs in many ways are closer to their normal tissue counterparts than to the cells that make up the bulk of the tumor. They may be far more capable of, for example, repairing DNA damage than their more differentiated malignant derivative cells. Also, because they proliferate less, they rely less on mutant cell activation signaling pathways and resemble normal cells more than do their highly mitotically active progeny. Thus, the main determinants of their survival make them more likely to persevere through treatments, even kinase inhibitors, that kill the rapidly dividing cells that make up the vast majority of the tumor. Radiation of glioblastomas may kill the great majority of the tumor cells, but CSCs are radioresistant. Their numbers, as a percentage of remaining viable tumor cells, increase after radiation. They survive and repopulate the tumor. In this sense, therapy may destroy 99.9%, or 99.99%, of a tumor, shrinking its mass correspondingly, but may do little more than buy the patient a few months more of life.

CSCs have evolved to evade apoptosis and senescence and therefore are likely to be less sensitive to cancer therapies than their normal tissue counterparts. Thus, tumor stem cells are better suited to survive cytotoxic therapy that is likely to kill the normal tissue stem cells from which the CSCs probably derived.

It is therefore critical to bear in mind that the goal of tumor therapy is not to eliminate the bulk of the tumor, but to save the patient's life. This requires approaches that are effective against CSCs because it is these cells, and not the aggregate of their highly proliferating progeny, that will regenerate the tumor after cytoreductive or other therapy. The CSCs, then, are the true enemies; it is they that will kill the patient.

Tumors Are Heterogeneous

We have alluded above to phenotypic heterogeneity in tumor cell morphology and to divergent evolution after tumor cells arise from CSCs (Fig. 5-62). In fact, however, the term "tumor heterogeneity" has two basic and different meanings. **Intertumor heterogeneity** describes the variation (genetic, epigenetic, phenotypic) between tumors that develop in one patient and those that arise in others. **Intratumor heterogeneity** refers to variation in the same parameters among different tumor cells and areas, and between a primary tumor and its metastases, within one patient.

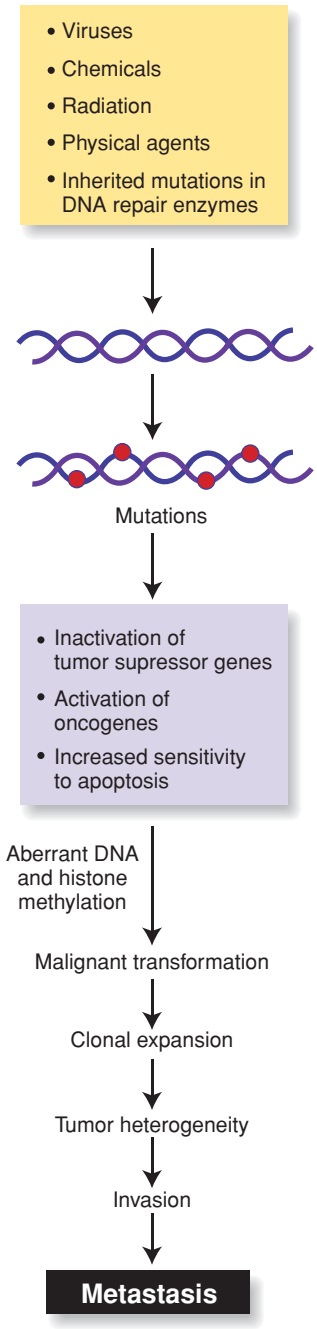

FIGURE 5-62. Summary of the general mechanisms of cancer.

Intertumor Heterogeneity

> Walter Donovan: "…We're on the verge of completing a quest that began [many] years ago. We're just one step away."
>
> Indiana Jones: "That's usually when the ground falls out from underneath your feet."
>
> *Indiana Jones and the Last Crusade*

There are distinct patterns of alterations that are both characteristic of certain tumor types and that offer useful therapeutic

targets, at least for hematologic malignancies. For example, almost every case of Burkitt lymphoma has chromosome rearrangements involving the *MYC* gene on chromosome 8. These tumors seem to follow the paradigmatic sequence shown in Fig. 5-59A: one initial set of mutations triggers the tumor and is needed to carry it through whatever follows. Similarly, almost all cases of chronic myeloid leukemia show the t(9;22) translocation to generate mutant bcr-abl protein. The successful targeting of bcr-abl is emblematic of the goal of developing agents that are specific for mutations that are necessary for tumor survival.

As comforting as this paradigm is for hematologic malignancies (at least selected ones), the situation for characteristic mutations in solid tumors has been more problematic. Even though some studies that have focused on selected individual genes have found mutational patterns, these studies in retrospect may have exercised such high levels of selectivity that many other, perhaps more important, mutations were not detected. More extensive genetic analysis of the protein-coding parts of the genome (whole exome sequencing) have shown wide diversity among individual solid tumors. One study of almost 200 lung cancers showed that only 4 genes were mutated (all SNPs or point mutations) in more than 10% of tumors, and 15% of tumors showed no mutations at all.

Our increasing awareness of the roles of untranslated RNAs in human cancer (see above) underscores this problem. The wider a net we cast, the more we find and the more restricted the applicability of the simple step-wise model shown in Fig. 5-59A appears to be. The extensive tumor-to-tumor diversity (e.g., Fig. 5-61) in patterns of genetic changes in solid tumors underscores the potential complexity of developing effective targeted therapies.

Intratumor Heterogeneity

In addition to variability of one tumor type from one person's tumor to someone else's tumor, all models predict that there will be variability within the tumor of a single individual. If a stochastic (i.e., random) mutation model (e.g., Fig. 5-61) applies to solid tumor evolution, rather than a linear step-wise model in which all cells are progressively derived from identically altered progenitors (as in Fig. 5-59A), one would expect the cells of any individual tumor to be highly heterogeneous, one to the other.

Although only a few such studies have been reported, they generally confirm our worst fears along these lines. It is clear that, at least for some solid tumors, variability is enormous. In one study of renal cell carcinomas, multiple biopsies of a single tumor mass showed that only 34% of protein-coding genetic alterations were concordant *between different pieces of that one tumor mass.* When analyses also included metastases, or comparison of pre- and posttreatment tumor samples, concordance was even lower.

Therefore, sophisticated tools to analyze tumors have not exactly allowed us to impose a man-made paradigm—either analytical or therapeutic—on the field of cancer biology. Rather, these technologies have illuminated the fact that cancers, especially solid ones, are highly diverse genetically and that each patient's individual tumor presents a vast, nonuniform array of mutations. When patient-to-patient variations in tumor genotypes are considered, it is clear that tumors are incredibly more complicated than we had imagined. We are only beginning to lift the veil on that heterogeneity.

Agents Implicated in Causing Cancer

VIRUSES AND HUMAN CANCER

Despite the existence of viral oncogenes and many viruses that are known to cause cancers in mice and other animals, only a few viruses demonstrably cause human cancers. Thus, viral infections are responsible for an estimated 15% of human cancers. The strongest associations between specific viruses and tumors in humans involve:

- Human T-cell leukemia virus type I (HTLV-I) **(RNA retrovirus)** and T-cell leukemia/lymphoma
- Hepatitis B virus (HBV, **DNA**) and hepatitis C virus (HCV, **RNA**) and primary hepatocellular carcinoma
- HPV **(DNA)** and carcinomas of the cervix, anus and vulva, and some oropharyngeal cancers
- Epstein-Barr virus (EBV, DNA) and certain forms of lymphoma and nasopharyngeal carcinoma
- Human herpes virus 8 (HHV8, **DNA**) and Kaposi sarcoma

Worldwide, infections with hepatitis B and C viruses and HPVs alone account for 80% of all virus-associated human cancers.

Human T-Cell Leukemia Virus Type I Is Lymphotropic

The one human cancer that has been firmly linked to infection with an RNA retrovirus is the rare adult T-cell leukemia, which is endemic in southern Japan and the Caribbean basin and occurs sporadically elsewhere. The etiologic agent, HTLV-I, is tropic for $CD4^+$ T lymphocytes and has also been incriminated in the pathogenesis of a number of neurologic disorders. It is estimated that leukemia develops in 3%–5% of people infected with HTLV-I and then only after a latency period of 30–50 years. A closely related virus, HTLV-II, has been associated with only a few cases of lymphoproliferative disorders.

The HTLV-I genome contains no known oncogene and does not integrate at specific sites in the host DNA. Viral oncogenicity appears to be mediated mainly by the viral transcriptional activator Tax. This protein not only drives transcription of the viral genome but also promotes the activity of other genes involved in cell proliferation, such as NFκB and IL-2 receptor. Tax also downregulates the cell cycle control protein, $p16^{INK4a}$ and p53. Lymphocyte transformation in vitro by HTLV-I is initially polyclonal and only later monoclonal. Tax therefore probably initiates transformation, but additional genetic events are required for the complete malignant phenotype.

Hepatitis B and C Viruses Are Responsible for Liver Carcinomas

Epidemiologic studies have established a strong link between primary hepatocellular carcinoma and chronic infection with HBV, a DNA virus, and HCV, an RNA virus (see Chapter 20). Two mechanisms have been invoked to explain the mechanism of carcinogenesis in virus-related liver cancer. One theory holds that the inability of some people to clear these infections leads to continued hepatocyte

proliferation owing to ongoing liver injury, and eventually causes malignant transformation. However, a small subset of patients with HBV infection develop hepatocellular carcinomas in noncirrhotic livers. A second theory implicates a virally encoded protein in the pathogenesis of HBV-induced liver cancer. Transgenic mice expressing HBx, a small viral regulatory protein, also develop liver cancer, but without evident preexisting liver cell injury and inflammation. The *HBx* gene product upregulates a number of cellular genes. It also binds to and inactivates p53. The underlying mechanisms in HBV-induced carcinogenesis are still controversial and require further investigation.

It has not been shown that HCV is directly oncogenic. Tumors, when they develop in HCV-infected patients, tend to do so 20 or more years after primary infection, and then usually in the context of cirrhosis and chronic liver injury. However, some data suggest that expression of HCV core protein may contribute to the pathogenesis of hepatocellular carcinoma, and one of the HCV nonstructural proteins activates NFκB.

DNA Viruses Encode Proteins That Bind Regulatory Proteins

Four DNA viruses (HPV, EBV, HBV, HHV8) are incriminated in human cancers. The transforming genes of oncogenic DNA viruses exhibit virtually no homology with cellular genes, but those of animal RNA retroviruses (oncogenes) are derived from, and are homologous with, their cellular counterparts (proto-oncogenes). As discussed above, oncogenic DNA viruses have genes that encode protein products that bind to, and inactivate, the products of tumor suppressor genes (e.g., *Rb, p53*).

Human Papilloma Virus

HPVs induce lesions in humans that progress to squamous cell carcinoma. They manifest a pronounced tropism for epithelial tissues, and their full productive life cycle occurs only in squamous cells. More than 140 distinct HPVs have been identified, and most are associated with benign lesions of squamous epithelium, including warts, laryngeal papillomas and condylomata acuminata (genital warts) of the vulva, penis and perianal region. Occasionally, condylomata acuminata and laryngeal papillomas undergo malignant transformation to squamous cell carcinoma. Although warts of the skin invariably remain benign, in a rare hereditary disease called **epidermodysplasia verruciformis,** HPV produces benign flat warts that commonly progress to squamous carcinoma. At least 20 HPV types are associated with cancer of the uterine cervix, especially HPV types 16 and 18 (see Chapter 18). This association holds for both ectocervical squamous carcinoma and endocervical adenocarcinoma. A newly available vaccine protects against infection with most oncogenic HPV types and is expected to reduce the incidence of cervical cancer.

In recent years, HPV, especially HPV-16, has been identified in many head and neck squamous cell carcinomas, especially those of the tonsils and oropharynx (see Chapter 29). Similar colocalization has been reported for non–small cell lung carcinomas. Some of these tumor types are also associated with cigarette smoking, and tumors that are HPV positive may also occur in smokers. In addition, high-risk strains of HPV are involved in about 6% of lung cancers that arise in smokers.

The major oncoproteins encoded by HPV are E5, E6 and E7. E6 binds to p53 and targets it for degradation. It also activates telomerase expression and promotes tumor development via other mechanisms that are independent of p53. E7 binds to Rb, thus releasing its inhibitory effect on E2F transcriptional activity and allowing cell cycle progression. E6 and E7 of non-cancer-causing strains of HPV do not have these activities. E5 has been shown to activate the epidermal growth factor receptor. During the last half century, a cell line derived from cervical cancer, *HeLa cells,* has maintained worldwide popularity in the study of cancer. Interestingly, these cells have been found to express HPV-18 E6 and E7, and inactivation of these oncoproteins results in growth arrest. Thus, after many years growing in vitro in innumerable laboratories, these cancer cells remain dependent on the expression of HPV proteins.

Epstein-Barr Virus

EBV is a human herpesvirus that is so widely disseminated that 95% of adults in the world have antibodies to it. EBV infects B lymphocytes, transforming them into lymphoblasts. In a small proportion of primary infections with EBV, this lymphoblastoid transformation is manifested as infectious mononucleosis (see Chapter 9), a short-lived benign lymphoproliferative disease. However, EBV is also intimately associated with the development of certain human cancers. A number of EBV genes are implicated in lymphocyte immortalization, including Epstein-Barr nuclear antigens (EBNAs); certain untranslated nuclear EBV RNAs, called EBER1 and EBER2; and latency-associated membrane proteins (LMPs). As well, about 40 miRNAs are encoded by EBV, some of which activate or repress specific cellular genes. LMP1 interacts with cellular proteins that normally transduce signals from the tumor necrosis factor (TNF) receptor, but it does not trigger apoptosis. Rather, it activates NFκB and other cell division–associated signaling molecules. Generally, EBV-related tumors are ascribed to the activities of the virus's latency-associated genes.

EBV-induced tumors tend to reflect the establishment of patterns of gene expression associated with viral latency. This may happen even in acute infection. EBV, in fact, is unusual in that virus-related lymphomas (see below) can occur during primary exposure. The known three different patterns of EBV latency (called latency I, II and III) have different associations with human malignancies. However, the human tumors that develop as a result all appear to entail viral orchestration of the same types of cancer hallmark traits (see above) that characterize sporadic cancers that occur independently of such infections.

BURKITT LYMPHOMA: EBV was the first virus to be unequivocally linked to the development of a human tumor. In 1958, Denis Burkitt described a form of childhood lymphoma in a geographical belt across equatorial Africa, which he suggested might have a viral etiology. A few years later, Epstein and Barr discovered viral particles in cell lines cultured from patients with Burkitt lymphoma (BL).

African BL is a B-cell tumor, in which the neoplastic lymphocytes invariably contain EBV and manifest EBV-related antigens (see Chapter 26). The tumor has also been recognized in non-African populations, but in those cases only about 20% carry EBV genomes. The localization of BL to equatorial Africa is not understood, but prolonged stimulation of the immune system by endemic malaria may be

important. Normally, EBV-stimulated B-cell proliferation is controlled by suppressor T cells. The lack of an adequate T-cell response often reported in chronic malarial infections might result in uncontrolled B-cell proliferation, thus providing a context for further genetic changes that may lead to the development of lymphoma. One of these is a translocation in which c-*myc* is being brought into proximity to an immunoglobulin promoter. In addition, EBV proteins inhibit apoptosis and activate signaling pathways involved in cell proliferation. Therefore, the multistep pathogenesis of African BL may be viewed as follows:

1. Infection and polyclonal lymphoblastoid transformation of B cells by EBV
2. Proliferation of B cells and inhibition of suppressor T cells induced by malaria
3. Deregulation of c-*myc* by translocation in a single transformed B cell, with effects on other signaling pathways
4. Uncontrolled proliferation of a malignant clone of B lymphocytes

NASOPHARYNGEAL CARCINOMA: Nasopharyngeal carcinoma is a variant of squamous cell carcinoma that is particularly common in certain parts of Asia. EBV DNA and EBNA are present in virtually all of these cancers. Epithelial cells may be exposed to EBV via infected lymphocytes traveling through lymphoid-rich epithelium. One of the EBV proteins in this tumor has been shown to activate the EGFR signaling. Fortunately, 70% of patients with this disease are cured by radiation therapy alone.

OTHER EBV-ASSOCIATED TUMORS: EBV markers have been identified in about half of cases of classical Hodgkin lymphoma, in which the virus infects Reed-Sternberg cells. A number of T-cell and NK lymphomas have also been found to harbor EBV, as well as 5% of gastric carcinomas.

POLYCLONAL LYMPHOPROLIFERATION IN IMMUNODEFICIENT STATES: Congenital or acquired immunodeficiency states can be complicated by the development of EBV-induced B-cell proliferative disorders. These lesions are clinically and pathologically indistinguishable from true malignant lymphomas, but most of them are polyclonal. Lymphoid neoplasia occurs in immunosuppressed renal transplant recipients 30–50 times more often than in the general population. Almost all congenital or acquired immunodeficiencies (especially AIDS) and lymphoproliferative diseases associated with organ transplantation involve EBV. Occasionally, a true monoclonal lymphoma may develop in the background of an EBV-induced lymphoproliferative disorder.

Human Herpesvirus 8

Kaposi sarcoma (KS) is a vascular tumor that was originally described in elderly eastern European men and later observed in sub-Saharan Africa (see Chapter 16). Kaposi sarcoma is today the most common neoplasm associated with AIDS. The neoplastic cells contain sequences of a novel herpesvirus, HHV8, also known as KS-associated herpesvirus (KSHV). HHV8 is present in virtually all specimens of Kaposi sarcoma, whether from HIV-positive or HIV-negative patients, and appears to be necessary—but not sufficient—for development of KS.

Other, unidentified, factors contribute. Many more people are HHV8 positive than ever develop KS. In the United States, about 6% of the population carries HHV8, and 60%–80% of the black population in sub-Saharan Africa is seropositive for HHV 8, but the risk of developing KS is miniscule compared to these percentages. Furthermore, among HIV-1–positive people, the risk of KS is greatest when HIV-1 infection was acquired via sexual transmission, rather than by transfusion or by a baby from an infected mother.

In addition to infecting the spindle cells of Kaposi sarcoma, HHV8 is lymphotropic and has been implicated in two uncommon B-cell lymphoid malignancies, namely, **primary effusion lymphoma** and **multicentric Castleman disease** (see Chapter 26).

Like other DNA viruses, the HHV8 viral genome encodes proteins that interfere with the p53 and Rb tumor suppressor pathways. Some viral proteins also inhibit apoptosis and act in multiple ways to accelerate cell cycle transit. HHV8 encodes an inhibitor of the normal regulator of NFκB (i.e., IκB). As a result, HHV8 infection is associated with unrestrained activation of NFκB. Development and progression of KS seems to entail interdependence between lytic HHV8 infection and latently infected cells. Thus, antiviral drugs that inhibit HHV8 lytic infection provide strong protection from the development of KS.

Other DNA Viruses

There have been intriguing claims that a recently discovered virus, **Merkel cell polyoma virus** (MCV), causes a very uncommon skin tumor, Merkel cell carcinoma. MCV genomes integrated into cellular DNA have been identified in 70% of these tumors. However, serologic evidence indicates that MCV infection is widespread in the general population, so the nature of the association of the virus with the rare tumor that gives MCV its name remains uncertain.

Other viruses have been claimed to be associated with human cancers over the years, but with little or no verifiable data to substantiate those assertions. SV40, which does cause tumors in some rodents, is a case in point. However, after extensive study, there are no reproducible experimental or epidemiologic data to support the contention that SV40 is oncogenic for humans.

Enormous interspecies differences in susceptibility to oncogenicity, and past experience, reinforce concern as to the dangers of falling prey to excessive gullibility and accepting seeming reasonableness as a substitute for hard data. One should be skeptical about such contentions and demand careful studies and independent verification before inculpating any agent as a cause of human cancer.

CHEMICAL CARCINOGENESIS

The field of chemical carcinogenesis originated some two centuries ago in descriptions of an occupational disease (this was not the first recognition of an occupation-related cancer, since a specific predisposition of nuns to breast cancer was appreciated even earlier). The English physician Sir Percival Pott gets credit for relating cancer of the scrotum in chimney sweeps to a specific chemical exposure, namely, soot. Today we realize that other products of the combustion of organic materials are responsible for a man-made epidemic of cancer, namely, lung cancer in cigarette smokers.

The experimental production of cancer by chemicals dates to 1915, when Japanese investigators produced skin cancers in rabbits with coal tar. Since that time, the list of

organic and inorganic carcinogens has grown exponentially. Yet a curious paradox existed for many years. Many compounds known to be potent carcinogens are relatively inert in terms of chemical reactivity. *The solution to this riddle became apparent in the early 1960s, when it was shown that most, although not all, chemical carcinogens require metabolic activation before they can react with cell constituents.* On the basis of those observations and the close correlation between mutagenicity and carcinogenicity, an in vitro assay using *Salmonella* organisms for screening potential chemical carcinogens—the Ames test—was developed a decade later. Subsequently, a variety of genotoxicity assays have been developed and are still used to screen chemicals and new drugs for potential carcinogenicity.

Chemical Carcinogens Are Mostly Mutagens

Associations between exposure to a specific chemical and human cancers have historically been established on the basis of epidemiologic investigations. These studies have numerous inherent disadvantages, including uncertainties in estimated doses, variability of the population, long and variable latency and dependence on clinical and public health records of questionable accuracy. As an alternative to epidemiologic studies, investigators turned to the use of studies involving animals. Indeed, such studies are legally required before the introduction of a new drug. Yet the logarithmic increase in the number of chemicals synthesized every year makes even this method prohibitively cumbersome and expensive. The search for rapid, reproducible and reliable screening assays for potential carcinogenic activity has centered on the relationship between carcinogenicity and mutagenicity.

*A **mutagen** is an agent that can permanently alter the genetic constitution of a cell.* The Ames test uses the appearance of frameshift mutations and base-pair substitutions in a culture of bacteria of a *Salmonella* sp. Mutations, unscheduled DNA synthesis and DNA strand breaks are also detected in rat hepatocytes, mouse lymphoma cells and Chinese hamster ovary cells. Cultured human cells are now used increasingly for assays of mutagenicity. About 90% of known carcinogens are mutagenic in these systems. Moreover, most, but not all, mutagens are carcinogenic. This close correlation between carcinogenicity and mutagenicity presumably occurs because both reflect damage to DNA. Although not infallible, in vitro mutagenicity assays have proved to be valuable tools in screening for the carcinogenic potential of chemicals.

Chemical Carcinogenesis Is a Multistep Process

Studies of chemical carcinogenesis in experimental animals have shed light on the distinct stages in the progression of normal cells to cancer. Long before the genetic basis of cancer was appreciated, it was demonstrated that a single application of a carcinogen to the skin of a mouse was not, by itself, sufficient to produce cancer. However, when a proliferative stimulus was then applied locally, in the form of a second, noncarcinogenic, irritating chemical (e.g., a phorbol ester), tumors appeared. The first effect was called **initiation**. The action of the second, noncarcinogenic chemical was called **promotion**. Subsequently, further experiments in rodent models of a variety of organ-specific cancers (liver, skin, lung, pancreas, colon, etc.) expanded the concept of a two-stage mechanism to our present understanding of *carcinogenesis as a multistep process that involves numerous mutations.*

From these studies, one can abstract four stages of chemical carcinogenesis:

1. **Initiation** likely represents a mutation in a single cell.
2. **Promotion** reflects the clonal expansion of the initiated cell, in which the mutation has conferred a growth advantage. During promotion, the altered cells remain dependent on the continued presence of the promoting stimulus. This stimulus may be an exogenous chemical or physical agent or may reflect an endogenous mechanism (e.g., hormonal stimulation [breast, prostate] or the effect of bile salts [colon]).
3. **Progression** is the stage in which growth becomes autonomous (i.e., independent of the carcinogen or the promoter). By this time, sufficient mutations have accumulated to immortalize cells.
4. **Cancer,** the end result of the entire sequence, is established when the cells acquire the capacity to invade and metastasize.

The morphologic changes that reflect multistep carcinogenesis in humans are best exemplified in epithelia, such as those of the skin, cervix and colon. Although initiation has no morphologic counterpart, *promotion and progression are represented by the sequence of hyperplasia, dysplasia and carcinoma in situ.*

Chemical Carcinogens Usually Undergo Metabolic Activation

The International Agency for Research in Cancer (IARC) has listed about 75 chemicals as human carcinogens. Chemicals cause cancer either directly or, more often, after metabolic activation. The direct-acting carcinogens are inherently reactive enough to bind covalently to cellular macromolecules. A number of organic compounds, such as nitrogen mustard, *bis*(chloromethyl)ether and benzyl chloride, as well as certain metals are included in this category. Most organic carcinogens, however, require conversion to an ultimate, more reactive compound. This conversion is enzymatic and, for the most part, is effected by the cellular systems involved in drug metabolism and detoxification. Many cells in the body, particularly liver cells, possess enzyme systems that can convert procarcinogens to their active forms. Yet each carcinogen has its own spectrum of target tissues, often limited to a single organ. The basis for organ specificity in chemical carcinogenesis is not well understood.

POLYCYCLIC AROMATIC HYDROCARBONS: The polycyclic aromatic hydrocarbons, originally derived from coal tar, are among the most extensively studied carcinogens. In this class are such model compounds as benzo(a)pyrene, 3-methylcholanthrene and dibenzanthracene. These compounds have a broad range of target organs and generally produce cancers at the site of application. The specific type of cancer produced varies with the route of administration and includes tumors of the skin, soft tissues and breast. Polycyclic hydrocarbons have been identified in cigarette smoke, and so it has been suggested, but not proved, that they are involved in the production of lung cancer.

Polycyclic hydrocarbons are metabolized by cytochrome P450–dependent mixed function oxidases to electrophilic epoxides, which in turn react with proteins and nucleic acids. The formation of the epoxide depends on the presence of an unsaturated carbon–carbon bond. For example,

vinyl chloride, the simple two-carbon molecule from which the widely used plastic polyvinyl chloride is synthesized, is metabolized to an epoxide, which is responsible for its carcinogenic properties. Workers exposed to the vinyl chloride monomer in the ambient atmosphere later developed hepatic angiosarcomas.

ALKYLATING AGENTS: Many chemotherapeutic drugs (e.g., cyclophosphamide, cisplatin, busulfan) are alkylating agents that transfer alkyl groups (methyl, ethyl, etc.) to macromolecules, including guanines within DNA. Although such drugs destroy cancer cells by damaging DNA, they also injure normal cells. Thus, alkylating chemotherapy carries a significant risk of solid and hematologic malignancies at a later time.

AFLATOXIN: Aflatoxin B_1 is a natural product of the fungus *Aspergillus flavus.* Like the polycyclic aromatic hydrocarbons, aflatoxin B_1 is metabolized to an epoxide, which can bind covalently to DNA. Aflatoxin B_1 is among the most potent liver carcinogens recognized, producing tumors in fish, birds, rodents and primates. Since *Aspergillus* sp. are ubiquitous, contamination of vegetable foods exposed to the warm moist conditions, particularly peanuts and grains, may result in the formation of significant amounts of aflatoxin B_1. It has been suggested that in addition to hepatitis B and C, aflatoxin-rich foods may contribute to the high incidence of cancer of the liver in parts of Africa and Asia. In rodents exposed to aflatoxin B_1, the resulting liver tumors exhibit a specific inactivating mutation in the *p53* gene (G:C→T:A transversion at codon 249). Interestingly, human liver cancers in areas of high dietary concentrations of aflatoxin carry the same *p53* mutation.

AROMATIC AMINES AND AZO DYES: Aromatic amines and azo dyes, in contrast to the polycyclic aromatic hydrocarbons, are not ordinarily carcinogenic at the point of application. However, they commonly produce bladder and liver tumors, respectively, when fed to experimental animals. Both aromatic amines and azo dyes are primarily metabolized in the liver. The activation reaction undergone by aromatic amines is N-hydroxylation to form the hydroxylamino derivatives, which are then detoxified by conjugation with glucuronic acid. In the bladder, hydrolysis of the glucuronide releases the reactive hydroxylamine. Occupational exposure to aromatic amines in the form of aniline dyes has resulted in bladder cancer.

NITROSAMINES: Carcinogenic nitrosamines are a subject of considerable study because it is suspected that they may play a role in human gastrointestinal neoplasms and possibly other cancers. The simplest nitrosamine, dimethylnitrosamine, produces kidney and liver tumors in rodents. Nitrosamines are also potent carcinogens in primates, although unambiguous evidence of cancer induction in humans is lacking. However, the extremely high incidence of esophageal carcinoma in the Hunan province of China (100 times higher than in other areas) has been correlated with the high nitrosamine content of the diet. There is concern that nitrosamines may also be implicated in other gastrointestinal cancers because nitrites, commonly added to preserve processed meats and other foods, may react with other dietary components to form nitrosamines. In addition, tobacco-specific nitrosamines have been identified, although a contribution to carcinogenesis has not been proved. Nitrosamines are activated by hydroxylation, followed by formation of a reactive alkyl carbonium ion.

METALS: A number of metals or metal compounds can induce cancer, but the carcinogenic mechanisms are unknown. Divalent metal cations, such as nickel (Ni^{2+}), lead (Pb^{2+}), cadmium (Cd^{2+}), cobalt (Co^{2+}) and beryllium (Be^{2+}), are electrophilic and can, therefore, react with macromolecules. In addition, metal ions react with guanine and phosphate groups of DNA. A metal ion such as Ni^{2+} can depolymerize polynucleotides. Some metals can bind to purine and pyrimidine bases through covalent bonds or pi electrons of the bases. These reactions all occur in vitro, and the extent to which they occur in vivo is not known. Most metal-induced cancers occur in an occupational setting (see Chapter 8).

Endogenous and Environmental Factors Influence Chemical Carcinogenesis

Chemical carcinogenesis in experimental animals involves consideration of genetic aspects (species and strain, age and sex of the animal), hormonal status, diet and the presence or absence of inducers of drug-metabolizing systems and tumor promoters. A similar role for such factors in humans has been postulated on the basis of epidemiologic studies.

METABOLISM OF CARCINOGENS: Mixed-function oxidases are enzymes whose activities are genetically determined, and a correlation has been observed between the levels of these enzymes in various strains of mice and their sensitivity to chemical carcinogens. Since most chemical carcinogens require metabolic activation, agents that enhance the activation of procarcinogens to ultimate carcinogens should lead to greater carcinogenicity, while those that augment the detoxification pathways should reduce the incidence of cancer. In general, this is the case experimentally. Since humans are exposed to many chemicals in the diet and environment, such interactions are potentially significant.

SEX AND HORMONAL STATUS: These factors are important determinants of susceptibility to chemical carcinogens but are highly variable and in many instances not readily predictable. In experimental animals, there is sex-linked susceptibility to the carcinogenicity of certain chemicals. However, the effects of sex and hormonal status on chemical carcinogenesis in humans are not clear.

DIET: The composition of the diet can affect the level of drug-metabolizing enzymes. Experimentally, a low-protein diet, which reduces the hepatic activity of mixed-function oxidases, is associated with decreased sensitivity to hepatocarcinogens. In the case of dimethylnitrosamine, the decreased incidence of liver tumors is accompanied by an increased incidence of kidney tumors, an observation that emphasizes the fact that the metabolism of carcinogens may be regulated differently in different tissues.

PHYSICAL CARCINOGENESIS

The physical agents of carcinogenesis discussed here are UV light, asbestos and foreign bodies. Radiation carcinogenesis is discussed in Chapter 8.

Ultraviolet Radiation Causes Skin Cancers

Among fair-skinned people, a glowing tan is commonly considered the mark of a successful holiday. However, this overt manifestation of the alleged healthful effects of the sun conceals underlying tissue damage. The harmful effects

of solar radiation were recognized by ladies of a bygone era, who shielded themselves from the sun with parasols to maintain a "roses-and-milk" complexion and to prevent wrinkles. The more recent fad for a tanned complexion has been accompanied not only by cosmetic deterioration of facial skin but also by an increased incidence of the major skin cancers.

Cancers attributed to sun exposure, namely, basal cell carcinoma, squamous carcinoma and melanoma, occur predominantly in people of the white race. The skin of people of the darker races is protected by the increased concentration of melanin pigment, which absorbs UV radiation. In fair-skinned people, the areas exposed to the sun are most prone to develop skin cancer. Moreover, there is a direct correlation between total exposure to sunlight and the incidence of skin cancer.

UV radiation is the short-wavelength portion of the electromagnetic spectrum adjacent to the violet region of visible light. It appears that only certain portions of the UV spectrum are associated with tissue damage, and a carcinogenic effect occurs at wavelengths between 290 and 320 nm. *The effects of UV radiation on cells include enzyme inactivation, inhibition of cell division, mutagenesis, cell death and cancer.*

The most important biochemical effect of UV radiation is the formation of **pyrimidine dimers** in DNA, a type of DNA damage that is not seen with any other carcinogen. Pyrimidine dimers may form between thymine and thymine, between thymine and cytosine or between cytosine pairs alone. Dimer formation leads to a cyclobutane ring, which distorts the phosphodiester backbone of the double helix in the region of each dimer. Unless efficiently eliminated by the nucleotide excision repair pathway, genomic injury produced by UV radiation is mutagenic and carcinogenic.

Xeroderma pigmentosum, an autosomal recessive disease, exemplifies the importance of DNA repair in protecting against the harmful effects of UV radiation. In this rare disorder, sensitivity to sunlight is accompanied by a high incidence of skin cancers, including basal cell carcinoma, squamous cell carcinoma and melanoma. Both the neoplastic and nonneoplastic disorders of the skin in xeroderma pigmentosum are attributed to an impairment in the excision of UV-damaged DNA.

Asbestos Causes Mesothelioma

Pulmonary asbestosis and asbestosis-associated neoplasms are discussed in Chapter 12. Here we review possible mechanisms of carcinogenesis attributed to asbestos. In this context, it is not conclusively established whether the cancers related to asbestos exposure should be considered examples of chemical carcinogenesis or of physically induced tumors, or both.

Asbestos, a material widely used in construction, insulation and manufacturing, is a family of related fibrous silicates, which are classed as "serpentines" or "amphiboles." Serpentines, of which chrysotile is the only example of commercial importance, occur as flexible fibers; the amphiboles, represented principally by crocidolite and amosite, are firm narrow rods.

The characteristic tumor associated with asbestos exposure is ***malignant mesothelioma*** *of the pleural and peritoneal cavities.* This cancer, which is exceedingly rare in the general population, has been reported to occur in 2%–3% (in some studies even more) of heavily exposed workers. The latent period (i.e., the interval between exposure and the appearance of a tumor) is usually about 20 years but may be twice that figure. It is reasonable to surmise that mesotheliomas of both pleura and peritoneum reflect the close contact of these membranes with asbestos fibers transported to them by lymphatic channels.

The pathogenesis of asbestos-associated mesotheliomas is obscure. Thin crocidolite fibers are associated with a considerably greater risk of mesothelioma than shorter and thicker chrysotile fibers. There is increasing evidence that the surface properties of asbestos fibers are important in their carcinogenic properties.

An association between cancer of the lung and asbestos exposure is clearly established in smokers. A slight increase in the prevalence of lung cancer has been reported in nonsmokers exposed to asbestos, but the small number of cases renders an association questionable. Claims that exposure to asbestos increases the risk of gastrointestinal cancer have not withstood statistical analysis of the collected data. In any case, the widespread adoption of strict safety standards will undoubtedly relegate the hazards of asbestos to historical interest.

Foreign Bodies Produce Experimental Cancer

The implantation of inert materials induces sarcomas in certain experimental animals. However, *humans are resistant to foreign body carcinogenesis, as evidenced by the lack of cancers following the implantation of prostheses constructed of plastics and metals.* A few reports of cancer developing in the vicinity of foreign bodies in humans probably reflect scar formation, which in some organs seems to be associated with an increased incidence of cancers. Despite numerous contrary claims in lawsuits, there is no evidence that a single traumatic injury can lead to any form of cancer.

The general mechanisms underlying the development of neoplasia are summarized in Fig. 5-62.

Dietary Influences on Cancer Development Are Highly Controversial

About a quarter of a century ago, respected epidemiologists suggested that approximately one third of cancers in the United States could be prevented by changes in diet. Numerous epidemiologic studies have attempted to identify possible relationships between dietary factors and the occurrence of a variety of cancers. Such investigations have particularly emphasized the roles of dietary fats, red meat and fiber. The results of studies comparing different ethnic groups or societies across international borders have often not been accepted as accurate and in fact have sometimes yielded misleading conclusions. Prospective, cohort studies comparing like populations are usually more reliable.

Some such cohort studies have indicated correlations between consumption of animal (but not vegetable) fat and increased risk of breast cancer. This relationship was limited to premenopausal women, and there is a suggestion that nonlipid components of food containing animal fats may be involved.

In the case of colon cancer, consumption of red meat has been associated with increased risk; total fat and animal fat intake are not correlated independently of red meat intake. At one time, it was thought that intake of dietary fiber protected from colorectal cancer and other malignancies, but these conclusions have not withstood the test of time.

An association between the risk of aggressive (but not indolent) prostate cancer and the consumption of red meat has been claimed. However, further studies of this matter are needed.

Despite claims that eating fruits and vegetables helps to prevent cancer, there is little evidence that these dietary constituents protect from tumor development. Although there is a popular notion that high intake and blood concentrations of vitamin D may be associated with a lower incidence of some cancers, a recent review indicates that this is not the case. Several epidemiologic studies have provided preliminary data suggesting that a folate-rich diet decreases the risk of colorectal cancer.

In conclusion, the beneficial effects of dietary constituents on cancer risk are at best limited and are often controversial. The consequences of a specific type of diet on longevity are largely limited to reduced cardiovascular disease.

Physical activity and obesity are closely correlated with diet, and the dissection of independent effects of these influences by epidemiologic techniques has proven to be exceedingly difficult. The best evidence that physical activity decreases the risk of developing cancer exists for breast and colon malignancies. The same is true for obesity, which adds risk for endometrial, esophageal and kidney cancer. However, it is generally agreed that the evidence for these associations is not sufficient to allow for specific recommendations for changes in lifestyle in order to decrease cancer risk.

SYSTEMIC EFFECTS OF CANCER ON THE HOST

The symptoms of cancer are, for the most part, referable to local effects of the primary tumor or its metastases. However, in a minority of patients, cancer produces remote effects that are not attributable to tumor invasion or to metastasis, and are collectively called **paraneoplastic syndromes**. Such effects are rarely lethal, but in some cases they dominate the clinical course. It is important to recognize these syndromes for several reasons. First, signs and symptoms of the paraneoplastic syndrome may be the first clinical manifestation of a malignant tumor. Second, the syndromes may be mistaken for those produced by advanced metastatic disease and may, therefore, lead to inappropriate therapy. Third, the paraneoplastic syndrome itself may be disabling, and treatment that alleviates those symptoms may have important palliative effects. Finally, certain tumor products that result in paraneoplastic syndromes provide a means of monitoring recurrence of the cancer in patients who have had surgical resections or are undergoing chemotherapy or radiation therapy.

We discuss here systemic paraneoplastic manifestations. Those mainly manifesting as involvement of one or another organ are addressed in the chapters specific for individual organs.

Fever

It is not uncommon for cancer patients to present initially with fever of unknown origin that cannot be explained by an infectious disease. Fever attributed to cancer correlates with tumor growth, disappears after treatment and reappears on recurrence. The cancers in which this most commonly occurs are Hodgkin disease, renal cell carcinoma and osteogenic sarcoma, although many other tumors are occasionally complicated by fever. Tumor cells may themselves release pyrogens or the inflammatory cells in the tumor stroma can produce IL-1.

Anorexia and Weight Loss

A paraneoplastic syndrome of anorexia, weight loss and cachexia is very common in patients with cancer, often appearing before its malignant cause becomes apparent. For example, a small asymptomatic pancreatic cancer may be suspected only on the basis of progressive and unexplained weight loss. Although cancer patients often decrease their caloric intake because of anorexia and abnormalities of taste, restricted food intake does not explain the profound wasting so common among them. The mechanisms responsible for this phenomenon are poorly understood. It is known, however, that unlike starvation, which is associated with a lowered metabolic rate, cancer is often accompanied by an elevated metabolic rate. It has been demonstrated that TNF-α and other cytokines (interferons, IL-6) can produce a wasting syndrome in experimental animals.

EPIDEMIOLOGY OF CANCER

The mere compilation of raw epidemiologic data is of little use unless they are subjected to careful analysis. In evaluating the relevance of epidemiologic observations to cancer causation, the Hill criteria are germane:

- Strength of the association
- Consistency under different circumstances
- Specificity
- Temporality (i.e., the cause must precede the effect)
- Biological gradient (i.e., there is a dose-response relationship)
- Plausibility
- Coherence (i.e., a cause-and-effect relationship does not violate basic biological principles)
- Analogy to other known associations

It is not mandatory that a valid epidemiologic study satisfy all these criteria, nor does adherence to them guarantee that the hypothesis derived from the data is necessarily true. However, as a guideline they remain useful.

Cancer accounts for one fifth of the total mortality in the United States and is the second-leading cause of death after ischemic cardiovascular diseases. For most cancers, death rates in the United States have largely remained flat for more than half a century, with some notable exceptions (Fig. 5-63). The death rate from cancer of the lung among men has risen dramatically from 1930, when it was an uncommon tumor, to the present, when it is by far the most common cause of death from cancer in men. As discussed in Chapter 8, the entire epidemic of lung cancer deaths is attributable to smoking. Among women, smoking did not become fashionable until World War II. Considering the time lag needed between starting to smoke and the development of cancer of the lung, it is not surprising that the increased death rate from lung cancer in women did not become significant until after 1965. In the United States, the death rate from lung cancer in women now exceeds that for breast cancer, and it is now, as in men, the most common fatal cancer. By contrast, for reasons difficult to fathom, cancer of the stomach, which in 1930 was by far the most common cancer in men and was more

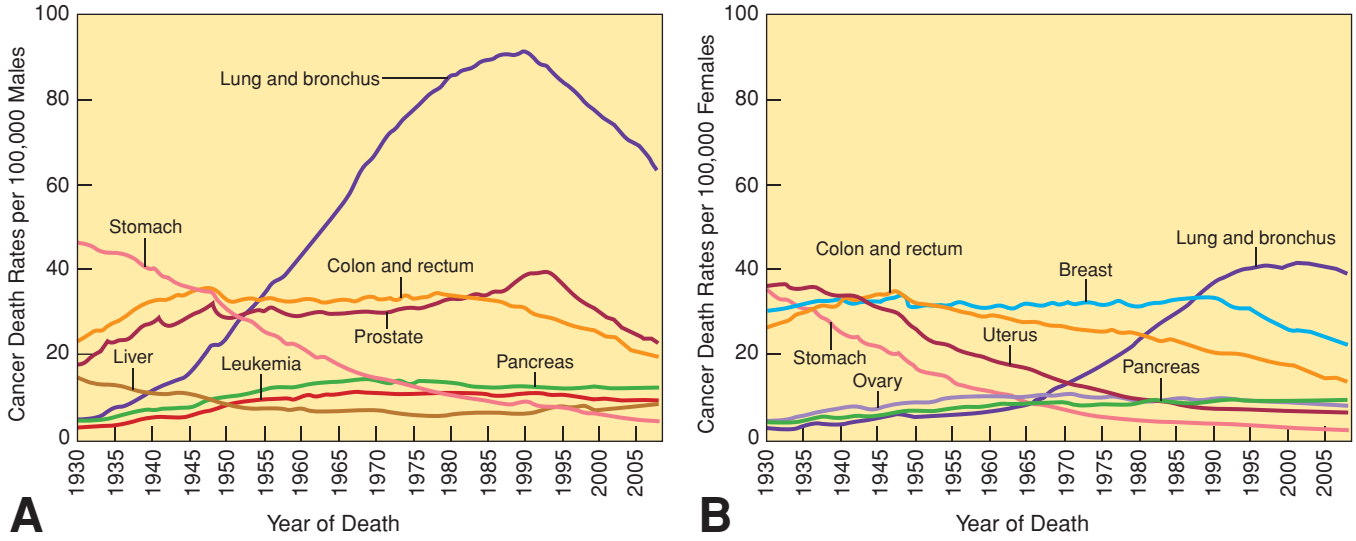

FIGURE 5-63. Cancer death rates in the United States, 1930–2009, among men (**A**) and women (**B**).

common than breast cancer in women, has shown a remarkable and sustained decline in frequency. Similarly, there has been a conspicuous decline in the death rate from cancer of the uterine corpus and cervix, possibly explained by better screening, diagnostic techniques and therapeutic methods. Overall, after decades of steady increases, the age-adjusted mortality as a result of all cancers has now reached a plateau. The ranking of the incidence of tumors in men and women in the United States is shown in Table 5-11.

Individual cancers have their own age-related profiles, but for most, increased age is associated with an increased incidence. The most striking example of the dependency on age is carcinoma of the prostate, in which the incidence increases 30-fold between men ages 50 and 85 years. Certain neoplastic diseases, such as acute lymphoblastic leukemia in children and testicular cancer in young adults, show different age-related peaks of incidence (Fig. 5-64).

TABLE 5-11
MOST COMMON TUMOR TYPES IN MEN AND WOMEN

Tumor Type	% of Cases	Tumor Type	% of Cases
Men		**Women**	
Prostate	29	Breast	29
Lung and bronchus	14	Lung and bronchus	14
Colon and rectum	9	Colon and rectum	9
Urinary bladder	7	Uterine corpus	6
Melanoma (cutaneous)	5	Thyroid	5
Kidney and renal pelvis	5	Melanoma (cutaneous)	4
Non-Hodgkin lymphoma	4	Non-Hodgkin lymphoma	4
Oral cavity	3	Kidney and renal pelvis	3
Leukemia	3	Ovary	3
Pancreas	3	Pancreas	3

Geographic and Ethnic Differences Influence Cancer Incidence

NASOPHARYNGEAL CANCER: Nasopharyngeal cancer is rare in most of the world except for certain regions of China, Hong Kong and Singapore.

ESOPHAGEAL CARCINOMA: The range in incidence of esophageal carcinoma varies from extremely low in Mormon women in Utah to a value some 300 times higher in the female population of northern Iran. Particularly high rates of esophageal cancer are noted in a so-called Asian esophageal cancer belt, which includes the great land mass stretching from Turkey to eastern China. Interestingly, throughout this region, as the incidence rises, the proportional excess in males decreases; in some of the areas of highest incidence there is even a female excess. The disease is also more common in certain regions of sub-Saharan Africa and among blacks in the United States. The causes of esophageal cancer are obscure, but it is known that it disproportionately affects the poor in many areas of the world, and the combination of alcohol abuse and smoking is associated with a particularly high risk.

STOMACH CANCER: The highest incidence of stomach cancer occurs in Japan, where the disease is almost 10 times as frequent as it is among American whites. A high incidence has also been observed in Latin American countries, particularly Chile. Stomach cancer is also common in Iceland and eastern Europe.

COLORECTAL CANCER: The highest incidence of colorectal cancer is found in the United States, where it is three or four times more common than in Japan, India, Africa and Latin America. It had been theorized that the high fiber content of the diet in low-risk areas and the high fat content in the United States are related to this difference, but this concept has been seriously questioned.

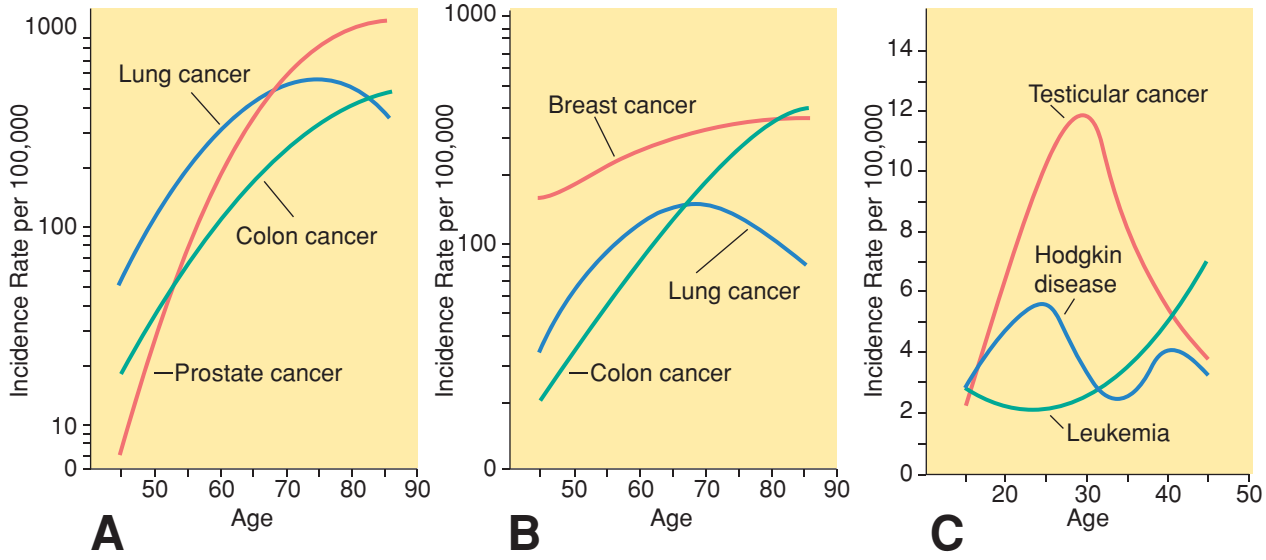

FIGURE 5-64. Incidence of specific cancers as a function of age. A. Men. **B.** Women. **C.** Testicular cancer in men and Hodgkin disease and leukemia in both sexes. The incidence of these cancers in **C** peaks at younger ages than do those in **A** and **B**.

LIVER CANCER: There is a strong correlation between the incidence of primary hepatocellular carcinoma and the prevalence of hepatitis B and C. Endemic regions for both diseases include large parts of sub-Saharan Africa and most of Asia, Indonesia and the Philippines. It must be remembered that levels of aflatoxin B_1 are high in the staple diets of many of the high-risk areas.

SKIN CANCER: As noted above, the rates for skin cancers vary with skin color and exposure to the sun. Thus, particularly high rates have been reported in northern Australia, where the population is principally of English origin and sun exposure is intense. Increased rates of skin cancer have also been noted among the white population of the American Southwest. The lowest rates are found among people with pigmented skin (e.g., Japanese, Chinese and Indians). The rates for African blacks, despite their heavily pigmented skin, are occasionally higher than those for Asians because of the higher incidence of melanomas of the soles and palms in the former population.

BREAST CANCER: Adenocarcinoma of the breast, the most common female cancer in many parts of Europe and North America, shows considerable geographic variation. The rates in African and Asian populations are only one fifth to one sixth of those prevailing in Europe and the United States. Epidemiologic studies have contributed little to our understanding of the etiology of breast cancer.

CERVICAL CARCINOMA: Striking differences in the incidence of squamous carcinoma of the cervix exist between ethnic groups and different socioeconomic levels. For instance, the very low rate in Ashkenazi Jews of Israel contrasts with a 25 times greater rate in the Hispanic population of Texas. In general, groups of low socioeconomic status have a higher incidence of cervical cancer than the more prosperous and better educated. This cancer is also directly correlated with early sexual activity and multiparity, and is rare among women who are not sexually active, such as nuns. It is also uncommon among women whose husbands are circumcised. A strong association with infection by HPVs has been demonstrated, and cervical cancer should be classed as a venereal disease.

CHORIOCARCINOMA: Choriocarcinoma, an uncommon cancer of trophoblastic differentiation, is found principally in women, following a pregnancy, although it can occur in men as a testicular tumor. The rates of this disease are particularly high in the Pacific rim of Asia (Singapore, Hong Kong, Japan and the Philippines).

PROSTATIC CANCER: Very low incidences of prostatic cancer are reported for Asian populations, particularly Japanese, while the highest rates described are in American blacks, in whom the disease occurs some 25 times more often. The incidence in American and European whites is intermediate.

TESTICULAR CANCER: An unusual aspect of testicular cancer is its universal rarity among black populations. Interestingly, although the rate in American blacks is only about one-fourth that in whites, it is still considerably higher than the rate among African blacks.

CANCER OF THE PENIS: This squamous carcinoma is virtually nonexistent among circumcised men of any race but is common in many parts of Africa and Asia. It is usually associated with HPV infection.

CANCER OF THE URINARY BLADDER: The rates for transitional cell carcinoma of the bladder are fairly uniform. Squamous carcinoma of the bladder, however, is a special case. Ordinarily far less common than transitional cell carcinoma, it has a high incidence in areas where schistosomal infestation of the bladder (bilharziasis) is endemic.

BURKITT LYMPHOMA: Burkitt lymphoma, a disease of children, was first described in Uganda, where it accounts for half of all childhood tumors. Since then, a high frequency has been observed in other African countries, particularly in hot, humid lowlands. It has been noted that these are areas where malaria is also endemic. High rates have been recorded in other tropical areas, such as Malaysia and New Guinea, but European and American cases are encountered only sporadically.

MULTIPLE MYELOMA: This malignant tumor of plasma cells is uncommon among American whites but displays a three to four times higher incidence in American and South African blacks.

CHRONIC LYMPHOCYTIC LEUKEMIA: Chronic lymphocytic leukemia is common among elderly people in Europe and North America but is considerably less common in Japan.

Studies of Migrant Populations Give Clues to Cancer Development

Although planned experiments on the etiology of human cancer are hardly feasible, certain populations have unwittingly performed such experiments by migrating from one environment to another. Initially at least, the genetic characteristics of such people remained the same, but the new environment differed in climate, diet, infectious agents, occupations and so on. *Consequently, epidemiologic studies of migrant populations have provided many intriguing clues to the factors that may influence the pathogenesis of cancer.* The United States, which has been the destination of one of the greatest population movements of all time, is the source of most of the important data in this field.

COLORECTAL, BREAST, ENDOMETRIAL, OVARIAN AND PROSTATIC CANCERS: Emigrants from low-risk areas in Europe and Japan to the United States exhibit an increased risk of colorectal cancer in the United States. Moreover, their offspring continue at higher risk and reach the incidence levels of the general American population. This rule for colorectal cancer also prevails for cancers of the breast, endometrium, ovary and prostate.

CANCER OF THE LIVER: As noted above, primary hepatocellular carcinoma is common in Asia and Africa, where it has been associated with hepatitis B and C. In American blacks and Asians, however, the neoplasm is no more common than in American whites, a situation that presumably reflects the relatively low prevalence of chronic viral hepatitis in the United States.

HODGKIN DISEASE: In general, in poorly developed countries the childhood form of Hodgkin disease is the one reported most often. In developed Western countries, by contrast, the disease is most common among young adults, except in Japan. Such a pattern is characteristic of certain viral infections. Further evidence for an environmental influence is the higher incidence of Hodgkin disease in Americans of Japanese descent than that in Japan.

GLOSSARY

The following terms are used in the text or figures of this chapter:

Allele—One of multiple forms of a physical genetic locus on a specific chromosome.

Alternative splicing—A mechanism by which variations in the assembly of a gene's exons, or coding regions, create different forms of mature messenger RNAs (mRNAs) from the same gene, leading to production of more than one related protein, or isoform.

Autosomes—Any chromosome other than a sex chromosome; autosomes normally occur in pairs in somatic cells and singly in gametes.

Base pair (bp)—The association of nucleotide bases of opposite strands of DNA within a chromosome. Adenine (A) pairs with thymine (T); cytosine (C) pairs with guanine (G) in a DNA double helix. An attached number (e.g., 12 bp) denotes the size of a sequence of DNA.

Centromere—The nonstaining primary constricted region of a chromosome, which is the point of attachment to the spindle fiber.

Codon—Three consecutive nucleotides of DNA or RNA that specify a single amino acid to be incorporated into a protein or serve as a termination signal.

Epigenetic—Regulation of the expression of gene activity without alteration of the DNA nucleotide sequence, such as methylation of regulatory sequences and histone modification.

Exon—A region of a gene that codes for mature messenger RNA, which is then translated into a protein.

Frame-shift mutation—Addition or deletion of a number of DNA bases not a multiple of 3 that disrupts boundaries of nucleotides in codons, thus shifting the reading frame of the gene. Codons downstream from the mutation are changed. The resulting protein is abnormal. Introduction of a premature stop codon or removal of a normal translational termination may alter protein size.

Gain-of-function mutation—A mutation that produces a protein that takes on a new or enhanced function.

Gene—A functional unit of heredity that occupies a specific place (locus) on a chromosome.

Genomics—The study of the functions and interactions of all the genes in the genome, including their interactions with environmental factors.

Genotype—An individual's complete genetic constitution at one or more gene loci.

Haplotype—A group of physically linked genes on one chromosome that are inherited together.

Hemizygous—Having a gene on one chromosome for which there is no counterpart on the opposite chromosome.

Heterochromatin—Chromatin that remains densely packed throughout the cell cycle. It includes satellite DNA in centromeres; acrocentric short arms; 1qh, 9qh, 16qh, and Yqh (all constitutive heterochromatin); and the inactive X chromosome (facultative heterochromatin).

Heterozygous—Having two different alleles at a specified locus.

Homozygous—Having two identical alleles at a specified locus.

Intron—A region of a gene in the intervening sequences between exons. Introns are transcribed into RNA but are spliced out of the mature mRNA that is translated into protein. Thus, introns do not contribute to the open reading frame that encodes a protein.

Linkage disequilibrium—The nonrandom occurrence of alleles at two or more loci (i.e., when two loci are not independent of each other). It implies a group of markers that are inherited coordinately.

Loss-of-function mutation—A mutation that decreases/inactivates a protein's production and/or function.

Missense mutation—A change in one DNA base that alters the amino acid encoded by a codon.

Monogenic—A trait or disease governed by the action of a single gene.

Multifactorial disease—Caused by the interaction of several genes and the environment.

Nonsense mutation—A 1-bp change resulting in the introduction of a stop codon, which causes premature truncation of a protein.

Penetrance—The likelihood of an altered phenotype in a person with a certain mutant gene.

Phenotype—The appearance or other characteristics of an individual resulting from a specific gene(s) or interactions of their genetic constitution with the environment.

Point mutation—The substitution of a single DNA base in the normal DNA sequence.

Regulatory gene—A gene that codes for an RNA or protein molecule that regulates expression of other genes.

Repeat sequence—DNA sequences present in multiple identical copies in the genome.

Silent mutation—Substitution of a single DNA base, typically in the third position of a codon, that produces no change in the amino acid sequence of the encoded protein.

Single-nucleotide polymorphism (SNP/"Snip")—A variation (substitution, deletion or insertion) in DNA sequence in which a single nucleotide alteration occurs at a site in the genome that is different among members of a species. The majority of SNPs have only two alleles.

Termination (stop) codon—One of three codons (UAG, UAA, UGA) that terminate synthesis of a polypeptide.

INTRODUCTION

Our understanding of developmental, genetic and neoplastic disorders has increased dramatically since 2003 when the Human Genome Project provided the first draft of the roughly 3 billion nucleotides in a human genome. The human genome contains about 23,000 protein-coding genes, but these constitute only less than 2% of the whole genome. Furthermore, most of the protein-coding genes in the human genome are found in genomes of other organisms including lower life forms such as yeast. It is the remaining 98% of the human genome that adds the remarkable complexity that ultimately determines the human species. This remaining 98% includes many non-protein-coding genes that are transcribed into RNA molecules such as microRNAs and long noncoding RNAs, which are increasingly being recognized to fulfill important regulatory functions.

Advances in molecular genetics and cytogenetics technologies have greatly improved clinical characterization of the genetic basis of human disease. It is also now possible to target drugs to specific genetic loci responsible for disease susceptibility and prevention. The modern field of pharmacogenomics seeks to create new classes of medicines targeting specific variants in gene and protein structure, to provide highly specific therapies with fewer side effects than occur in many of today's medicines. Gene therapies also hold great potential for treating genetic and acquired diseases.

Diseases that manifest during the perinatal period may be caused solely by factors in the fetal environment, solely by genomic abnormalities or by interactions between genetic defects and environmental influences. For example, in phenylketonuria (PKU), a genetic deficiency of phenylalanine hydroxylase causes mental retardation only if an affected infant is exposed to dietary phenylalanine.

Each year, about one quarter of a million babies in the United States are born with a birth defect. Worldwide, at least 1 in 50 newborns has a major congenital anomaly, 1 in 100 has a defect that can be attributed to a single-gene abnormality and 1 in 200 has a major chromosomal abnormality. At the same time, it has been estimated that the genomes of *healthy* individuals contain at least 400 protein-damaging sequence variants and at least 2 bona fide disease mutations. Thus, simply having a potential disease-causing mutation does not inevitably produce disease. As we will see in this chapter, disease expression ultimately depends on complex interactions among genetic, epigenetic and environmental factors.

A specific cause is not apparent in more than 2/3 of all birth defects (Fig. 6-1). No more than 6% can be attributed to uterine factors; maternal disorders such as metabolic imbalances or infections during pregnancy; or environmental exposures (drugs, chemicals, radiation). Others are caused by genomic defects (inherited traits or spontaneous mutations) and only a small number by chromosomal abnormalities. Currently about 70% have no known genetic or other cause.

Up to 50% of fetuses spontaneously aborted early in pregnancy have chromosomal abnormalities. ***The incidence of specific numerical chromosomal abnormalities in abortuses is several times higher than in term infants, indicating that most such chromosomal defects are lethal.*** Thus, only a small number of children with cytogenetic abnormalities are born alive.

In Western countries, developmental and genetic birth defects account for half of deaths in infancy and childhood. By contrast, 95% of infant mortality in less developed countries is due to environmental causes such as infectious diseases and malnutrition. Ongoing reductions in the incidence of birth anomalies will require genetic counseling, early prenatal diagnosis, identification of high-risk pregnancies, avoidance of potential teratogens and implementation of preventive measures. For example, introduction of prenatal dietary folic acid supplements has significantly reduced the incidence of congenital neural tube defects.

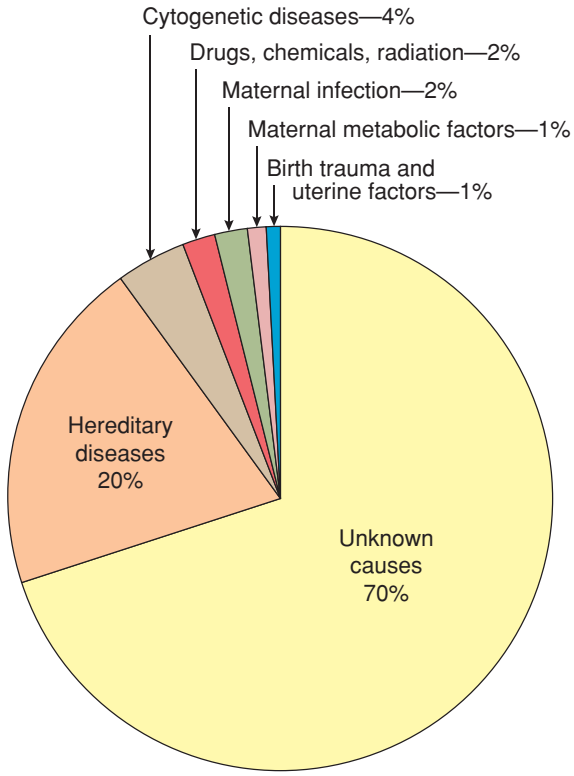

FIGURE 6-1. Causes of birth defects in humans. Most birth defects have unknown causes.

PRINCIPLES OF TERATOLOGY

Teratology is the study of developmental anomalies (Greek *teraton*, "monster"). **Teratogens** are chemical, physical and biological agents that cause developmental anomalies. Although only a relatively few teratogens have been *proven* in humans, many drugs and chemicals are teratogenic in animals and should thus be considered potentially dangerous for humans.

Malformations are morphologic defects or abnormalities of an organ, part of an organ or anatomic region due to perturbed morphogenesis. Exposure to a teratogen may result in a malformation, but not invariably. Such observations have led to the formulation of general principles of teratology:

- **Susceptibility to teratogens is variable.** Key determinants are the genotypes of the fetus and mother, but other factors play a role. For example, the fetal alcohol syndrome (FAS) affects some children of alcoholic mothers but not others. An infant of an alcoholic mother born with characteristic facial features, small size and central nervous system (CNS) damage may be diagnosed with FAS, but alcoholic mothers often abuse other substances and self-reporting of alcohol intake may be inaccurate. Thus, conclusions as to the teratogenic effects of prenatal alcohol exposure may be confounded by many variables.
- **Susceptibility to teratogens is specific for each embryologic stage.** Most agents are teratogenic only at particular times in development (Fig. 6-2). Thus, maternal rubella infection can cause congenital rubella syndrome (CRS) but only if the mother is infected within the first 20 weeks of pregnancy.
- **Mechanisms of teratogenesis are specific for each agent.** Teratogenic drugs may inhibit crucial enzymes or receptors, interfere with formation of mitotic spindles or impair energy production, thus inhibiting metabolic steps critical for normal morphogenesis. Many drugs and viruses affect specific tissues and damage some developing organs more than others.
- **Teratogenesis is dose dependent and may be idiosyncratic.** Thus, an absolutely safe dose cannot be predicted for every woman.
- **Teratogens produce death, growth retardation, malformation or functional impairment.** The outcome depends on complex interactions between a teratogen, the maternal organism and the fetal–placental unit.

Human teratogens can be identified by (1) population surveys, (2) prospective and/or retrospective studies of single malformations and (3) investigation of adverse effects of drugs or other chemicals. Proven teratogens include most cytotoxic drugs, alcohol, some antiepileptic drugs, heavy metals and thalidomide. Many drugs and chemicals have been declared safe for use during pregnancy because they were not teratogenic in laboratory animals, but the fact that a drug is not teratogenic for mice or rabbits does not necessarily mean that it is innocuous for humans. For example, thalidomide is not teratogenic in mice and rats, but it caused complex malformations when many pregnant women used it as an antiemetic during the first trimester of pregnancy. Antiviral medications to treat herpes simplex and zoster, proton pump inhibitors to treat gastroesophageal reflux and antiepileptic medications have been studied in large numbers of pregnant women with relatively reassuring results, but whether they are always safe in pregnancy is unknown. Some vaccines recommended during pregnancy to prevent infections in mothers and infants have been tested in clinical trials that specifically excluded pregnant women; thus, evaluation of their safety depends entirely on observational studies. Without adequate, well-controlled data, it is necessary to weigh the benefits of medications or vaccines with potential risks to the embryo or fetus.

Developmental and genetic disorders are classified as follows:

- **Errors of morphogenesis**
- **Chromosomal abnormalities**
- **Single-gene defects**
- **Polygenic inherited diseases**

A fetus may also be injured by **adverse transplacental influences** or deformities and injuries caused by intrauterine trauma or during parturition. After birth, acquired diseases of infancy and childhood are also important causes of morbidity and mortality.

ERRORS OF MORPHOGENESIS

Normal intrauterine and postnatal development depends on sequential activation and repression of genes. A fertilized ovum (zygote) has all the genes of an adult, but most of them are inactive. As zygotes enter cleavage stages of development, individual genes or sets of genes are specifically activated at different stages of embryogenesis. Thus, ***abnormal gene activation in early embryonic cells can cause death.***

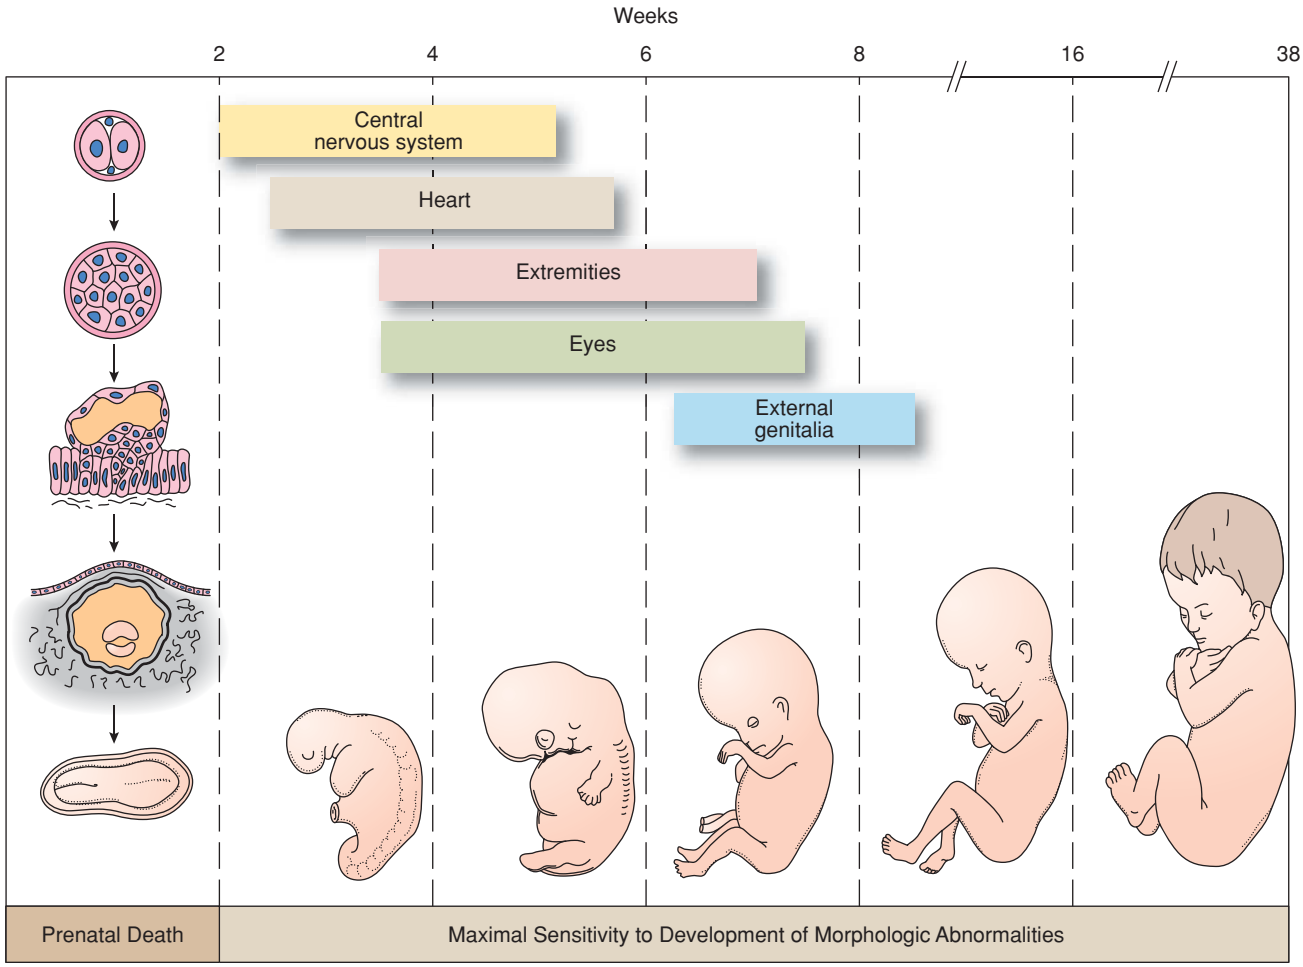

FIGURE 6-2. Sensitivity of specific organs to teratogenic agents at critical stages of human embryogenesis. Exposure to adverse influences in preimplantation and early postimplantation stages of development (*far left*) leads to prenatal death. Periods of maximal sensitivity to teratogens (*horizontal bars*) vary for different organ systems but overall are limited to the first 8 weeks of pregnancy.

Cells that form two- and four-cell embryos (blastomeres) are equipotent: each can give rise to an adult organism. If such cells separate at this stage, identical twins or quadruplets can result. Since blastomeres are equipotent and interchangeable, loss of a single blastomere at this stage does not have serious consequences. But, if one blastomere carries lethal genes, the others probably do as well. Activation of such genes is invariably fatal. Similarly, noxious exogenous agents typically affect all blastomeres and cause death. ***As a rule, exogenous toxins acting on preimplantation embryos do not produce errors of morphogenesis or malformations*** (Fig. 6-2). ***The most common consequence is death of the embryo, which often goes unnoticed or is perceived as heavy, delayed, menstrual bleeding.***

Injury during the first 8–10 days after fertilization may cause incomplete separation of blastomeres, to yield conjoined twins ("Siamese twins") linked at the head (craniopagus), thorax (thoracopagus) or rump (ischiopagus). Conjoined twins may be asymmetric; one is well developed and the other rudimentary or hypoplastic. The latter is always abnormal and may reside within the body of the better-developed sibling (fetus in fetu). Some congenital teratomas, especially in the sacrococcygeal area, are actually asymmetric monsters.

Complex developmental abnormalities affecting multiple organ systems are usually due to injuries during early organogenesis. This period is characterized by formation of so-called **developmental fields,** in which rapidly dividing cells interact to determine their developmental fate through irreversible differentiation of groups of cells. Complex morphologic movements form organ primordia (anlage), and organs are then interconnected in functionally active systems. ***The developmental stage of primordial organ system formation is most susceptible to teratogenesis owing to faulty gene activity or effects of exogenous toxins*** (Fig. 6-2). Impaired morphogenesis may affect (1) cells and tissues, (2) organs or organ systems and (3) anatomic regions.

- **Agenesis** is complete absence of an organ primordium. It may manifest as (1) total lack of an organ (e.g., unilateral or bilateral renal agenesis); (2) absence of part of an organ, such as agenesis of the corpus callosum of the brain; or (3) lack of specific cell types in an organ, such as absence of testicular germ cells in congenital Sertoli cell–only syndrome. This unusual syndrome is characterized by severely reduced or absent spermatogenesis despite the presence of both Sertoli and Leydig cells. Microdeletions

in the Yq11 region of the Y chromosome, known as the AZF (azoospermia factor) region, have been implicated.

- **Aplasia** is persistence of an organ anlage or rudiment, without the mature organ. In pulmonary aplasia, for example, the main bronchus ends blindly in a nondescript mass of rudimentary ducts and connective tissue.
- **Hypoplasia** is reduced size due to incomplete development of all or part of an organ, as in micrognathia (small jaw) and microcephaly (small brain and head).
- **Dysraphic anomalies** are defects caused by failure of apposed structures to fuse. In spina bifida, the spinal canal does not close completely, and overlying bone and skin do not fuse, leaving a midline defect.
- **Involution failures** denote persistence of embryonic or fetal structures that normally involute during development. Thus, a persistent thyroglossal duct results from incomplete involution of the tract that connects the base of the tongue with the developing thyroid.
- **Division failures** are caused by incomplete programmed cell death in embryonic tissues (see Chapter 1). Fingers and toes are formed at the distal ends of limb buds by loss of cells between cartilage-containing primordia. If these cells do not undergo apoptosis, fingers are conjoined or incompletely separated (syndactyly).
- **Atresia** reflects incomplete formation of a normal body orifice or tubular passage. Many hollow organs originate as cell strands and cords whose centers undergo programmed cell death to yield a central cavity or lumen. Esophageal atresia is characterized by localized absence of the lumen, which was not fully established in embryogenesis.
- **Dysplasia** is caused by abnormal histogenesis. (This context is different from "dysplasia" in precancerous epithelial lesions [see Chapters 1 and 5]). In tuberous sclerosis, for example, aggregates of normally developed cells are arranged into grossly visible "tubers."
- **Ectopia, or heterotopia,** denotes a normally formed organ outside of its normal anatomic location. Thus, heterotopic parathyroid glands may arise within the thymus in the anterior mediastinum.
- **Dystopia** is inadequate migration of an organ from its site of development to its normal location. Thus, kidneys originate in the pelvis and then move in a cephalad direction. Dystopic kidneys remain in the pelvis. Dystopic testes remain in the inguinal canal and do not enter the scrotum (cryptorchidism).

Developmental anomalies due to interference with morphogenesis are often multiple:

- A **polytopic effect** occurs when an injurious agent affects several organs at once during a critical stage of development.
- A **monotopic effect** is a single localized anomaly that results in a cascade of pathogenetic events.
- A **developmental sequence anomaly** (anomalad or complex anomaly) is a pattern of defects arising from a single anomaly or pathogenetic mechanism. In the Potter complex (Fig. 6-3), pulmonary hypoplasia, external signs of intrauterine fetal compression and morphologic changes of the amnion are all related to oligohydramnios (severely reduced amount of amniotic fluid). The features of Potter complex occur regardless of the cause of oligohydramnios.

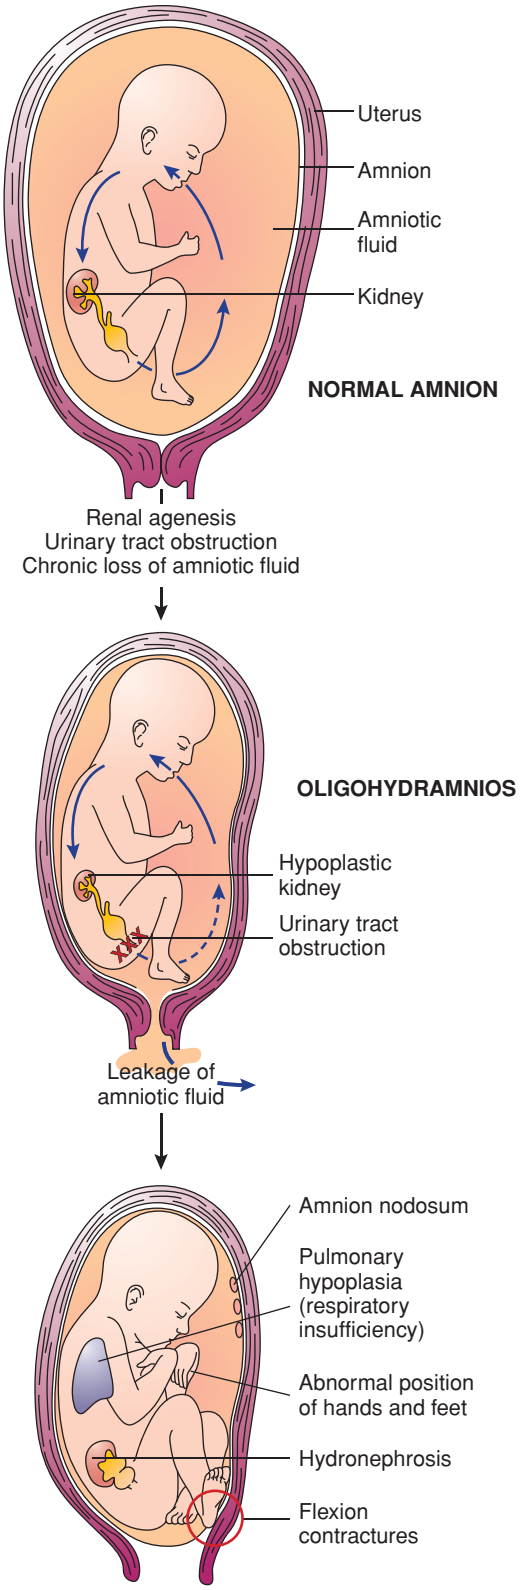

FIGURE 6-3. Potter complex. The fetus normally swallows amniotic fluid and, in turn, excretes urine, thus maintaining a normal volume of amniotic fluid. In the face of urinary tract disease (e.g., renal agenesis or urinary tract obstruction) or leakage of amniotic fluid, the volume of amniotic fluid becomes reduced, a situation called **oligohydramnios**. Oligohydramnios results in a spectrum of congenital abnormalities called **Potter sequence,** which includes pulmonary hypoplasia and contractures of the limbs. The amnion has a nodular appearance.

A **developmental syndrome** refers to multiple anomalies arising from a common pathogenic mechanism. The term **syndrome** indicates anomalies in diverse organs that have been damaged by a polytopic effect during a critical developmental period. Many such syndromes reflect chromosomal abnormalities or single-gene defects. A **developmental association,** or **syntropy,** describes multiple anomalies that arise concurrently but have different pathogeneses. Congenital anomalies in a child with multiple defects are not necessarily interrelated and do not automatically imply exposure to an exogenous teratogen or a common genetic defect. Distinguishing specific syndromes from random associations is required to accurately predict the risk of recurrence in subsequent offspring.

Teratogens rarely cause major errors of morphogenesis after the third month of pregnancy. However, functional and, to a lesser degree, structural abnormalities may occur in children exposed to exogenous teratogens during later trimesters. Although organs are formed by the end of the first trimester, most continue to restructure and mature at prescribed rates. For example, the CNS attains functional maturity several years after birth and remains susceptible to adverse exogenous influences for this interval.

A **deformation** is an abnormality of form, shape or position of a part of the body caused by mechanical forces. Most anatomic defects arising in the last two trimesters of pregnancy fall into this category. Responsible forces may be external (e.g., amniotic bands in the uterus) or intrinsic (e.g., fetal hypomobility caused by CNS injury). Thus, equinovarus foot may be caused by uterine wall compression in oligohydramnios or by spinal cord abnormalities that lead to defective innervation and movement of the foot.

FIGURE 6-4. Thalidomide-induced deformity of the arms.

All Organ Systems Are Susceptible to Malformations

Anencephaly and Other Neural Tube Defects

Anencephaly is congenital absence of the cranial vault. In this dysraphic defect of neural tube closure, cerebral hemispheres are completely missing or reduced to small masses at the base of the skull. Normally, the neural tube closes in a craniocaudad direction, so a more distal defect in this process causes abnormalities of the vertebral column. **Spina bifida** is incomplete closure of the spinal cord and/or vertebral column or both. Protrusion of the meninges through a defect in the vertebral column is called **meningocele**. In a **myelomeningocele,** a meningocele also contains herniated spinal cord. Neural tube defects are discussed in Chapter 32.

Thalidomide-Induced Malformations

Limb reduction deformities are rare congenital defects of mostly obscure origin that affect 1 in 5000 liveborn infants. They have been known for ages. A depiction of an affected infant by the 18th-century Spanish painter Goya was used in medical texts to illustrate this condition. In the 1960s, a dramatic increase in the incidence of limb reduction deformities in Germany and England was linked to maternal ingestion of a sedative, thalidomide, early in pregnancy. This derivative of glutamic acid is teratogenic between the 28th and 50th days of pregnancy. Many children born to mothers exposed to thalidomide had skeletal deformities and pleomorphic defects in other organs, mostly the ears (**microtia** and **anotia**) and heart. Typically, their arms were short and malformed (Fig. 6-4), resembling the flippers of a seal **(phocomelia),** or sometimes even completely missing **(amelia)**. The CNS was unaffected, and these children had normal intelligence. Once the link between phocomelia and thalidomide was established, the drug was banned (1962), but not before an estimated 3000 such children had been born. Thalidomide impairs limb growth by blocking angiogenesis and, perhaps, by inducing caspase-8–dependent apoptosis. The same properties make it useful in treating certain malignancies.

Fetal Hydantoin Syndrome

Ten percent of children born to mothers taking antiepileptic drugs, such as hydantoin, during pregnancy show characteristic facial features, hypoplasia of nails and digits and various congenital heart defects. This syndrome also occurs in children born to untreated epileptic mothers, raising a question about the adverse effects of the drug. Nevertheless, susceptibility to this disorder appears to correlate with fetal levels of the microsomal detoxifying enzyme epoxide hydrolase, suggesting that accumulation of reactive intermediates of hydantoin metabolism may be teratogenic.

Fetal Alcohol Syndrome

Fetal alcohol syndrome is a complex of abnormalities caused by maternal consumption of alcoholic beverages during pregnancy. It includes (1) growth retardation, (2) CNS

abnormalities and (3) characteristic facial dysmorphology. Not all children harmed by maternal alcohol abuse show the full spectrum of abnormalities. In such cases, the term **fetal alcohol effect** is used.

EPIDEMIOLOGY AND ETIOLOGIC FACTORS: Harm caused by intrauterine exposure to alcohol was noted in biblical times and was reported during the historic London gin epidemic (1720–1750). However, a specific syndrome was not defined until 1968. The incidence of fetal alcohol syndrome ranges from 0.2 to 2.0 cases per 1000 live births in the United States, but may be as high as 20–150 cases per 1000 in populations with high rates of alcoholism, such as some tribes of Native Americans. ***Mild mental deficiency and emotional disorders related to fetal alcohol effect are far more common than full-blown fetal alcohol syndrome.*** The minimum amount of alcohol that causes fetal injury is not well established. Children with the full syndrome are usually born to mothers who are chronic alcoholics. Heavy alcohol consumption during the first trimester of pregnancy is particularly dangerous. The mechanism by which alcohol damages the developing fetus is poorly understood.

PATHOLOGY AND CLINICAL FEATURES: Infants born to alcoholic mothers often show prenatal growth retardation, which continues after birth. They may also have microcephaly, epicanthal folds, short palpebral fissures, maxillary hypoplasia, thin upper lip, micrognathia and a poorly developed philtrum. One third may have cardiac septal defects, which often close spontaneously. Minor abnormalities of joints and limbs may occur.

Fetal alcohol syndrome is the most common cause of acquired but preventable mental retardation. One fifth of children with fetal alcohol syndrome have intelligence quotients (IQs) below 70, and 40% are between 70 and 85. Even with normal IQ, these children tend to have short memory spans and exhibit impulsive behavior and emotional instability (see Chapter 8).

TORCH Complex

TORCH refers to a complex of signs and symptoms produced by fetal or neonatal infection with *Toxoplasma* (T), rubella (R), cytomegalovirus (C) or herpes simplex virus (H). The "O" in TORCH represents "others" including syphilis, varicella-zoster virus (chicken pox), fifth disease (parvovirus B19) and HIV. The term reminds pediatricians that these fetal and newborn infections may be indistinguishable from one another and testing for all TORCH agents should be done in suspected cases (Fig. 6-5).

Infections with TORCH agents affect 1%–5% of all live-born infants in the United States. They are major causes of neonatal morbidity and mortality. Suspicion of congenital infection and awareness of its prominent features help facilitate early diagnosis. Severe damage due to these organisms is largely irreparable, and prevention is the best approach. The specific organisms of the TORCH complex are discussed in detail in Chapter 9.

PATHOLOGY: Clinical and pathologic findings in symptomatic newborns vary. Only a minority show the entire spectrum of abnormalities (Table 6-1).

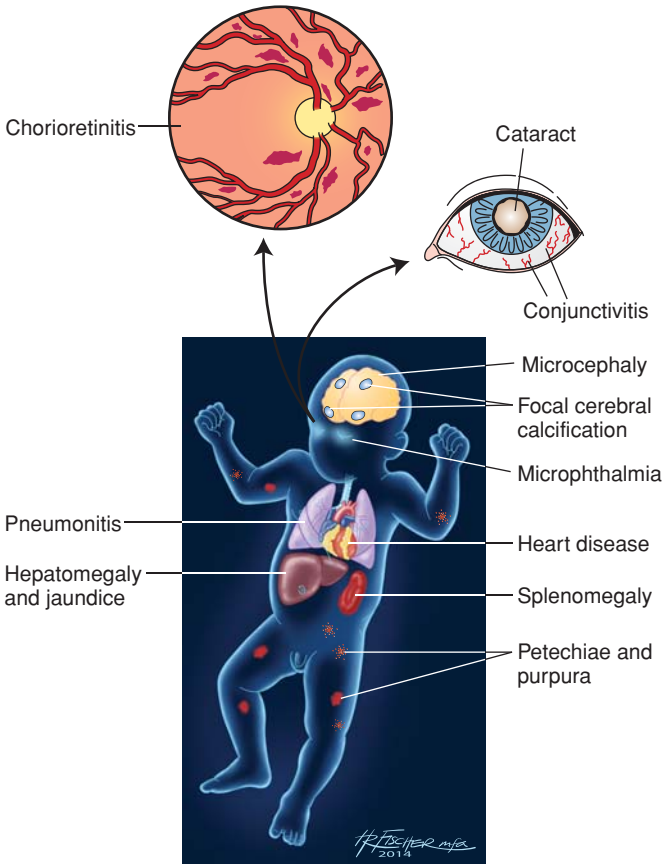

FIGURE 6-5. TORCH complex. Children infected in utero with *Toxoplasma*, rubella virus, cytomegalovirus or herpes simplex virus show remarkably similar effects.

Growth retardation and abnormalities of the brain, eyes, liver, hematopoietic system and heart are common.

CNS lesions are the most serious changes in TORCH-infected children. In acute encephalitis, foci of necrosis are initially surrounded by inflammatory cells. Later these lesions calcify, most prominently in congenital toxoplasmosis. Microcephaly, hydrocephalus and abnormally shaped gyri and sulci (microgyria) are common. Radiologically, abnormal cerebral cavities (porencephaly), missing olfactory bulbs and other major brain defects may occur. Severe CNS injury may entail psychomotor retardation, neurologic defects and seizures.

Ocular defects may also be prominent, particularly with rubella, in which over 2/3 of patients have cataracts and microphthalmia. Glaucoma and retinal malformations (coloboma) may occur. Choroidoretinitis, usually bilateral, is common with rubella, *Toxoplasma* and CMV. Keratoconjunctivitis is the most common eye lesion in neonatal herpes infection.

Cardiac anomalies occur in many children with the TORCH complex, mostly in congenital rubella, patent ductus arteriosus and septal defects. Pulmonary artery stenosis and complex cardiac anomalies are occasionally seen.

Congenital Syphilis

The organism that causes syphilis, *Treponema pallidum*, is transmitted to the fetus by a mother who had been infected

TABLE 6-1
PATHOLOGIC FINDINGS IN THE FETUS AND NEWBORN INFECTED WITH TORCH AGENTS

General	Prematurity Intrauterine growth retardation
Central nervous system	Encephalitis Microcephaly Hydrocephaly Intracranial calcifications Psychomotor retardation
Ear	Inner ear damage with hearing loss
Eye	Microphthalmia (R) Chorioretinitis (TCH) Pigmented retina (R) Keratoconjunctivitis (H) Cataracts (RH) Glaucoma (R) Visual impairment (TRCH)
Liver	Hepatomegaly Liver calcifications (R) Jaundice
Hematopoietic system	Hemolytic and other anemias Thrombocytopenia Splenomegaly
Skin and mucosae	Vesicular or ulcerative lesions (H) Petechiae and ecchymoses
Cardiopulmonary system	Pneumonitis Myocarditis Congenital heart disease
Skeleton	Various bone lesions

R = rubella virus; C = cytomegalovirus; H = herpesvirus; T = *Toxoplasma.*

during pregnancy or, potentially, within 2 years before the pregnancy. About 1 in 2000 liveborn infants in the United States have congenital syphilis. One third of pregnancies in syphilitic women end in stillbirth, and the remainder in term infants with congenital syphilis. *T. pallidum* may invade a fetus any time in pregnancy. Early infections mostly cause abortion, but 50%–80% of neonates surviving early vertical transmission show congenital infection. Grossly visible signs of congenital syphilis appear only in fetuses infected after the 16th week of pregnancy. As spirochetes grow in all fetal tissues, clinical presentations vary.

Children with congenital syphilis may appear normal at first or show changes of the TORCH complex. Early lesions teem with spirochetes. They show perivascular infiltrates of lymphocytes and plasma cells, and granuloma-like lesions, called **gummas**. Many infants are asymptomatic and only develop stigmata of congenital syphilis in the first few years of life. Late symptoms of congenital syphilis appear many years later and reflect slowly evolving tissue destruction and repair:

- **Rhinitis:** A conspicuous mucopurulent nasal discharge, "snuffles," is almost always present as an early sign of congenital syphilis. The nasal mucosa is edematous and tends to ulcerate, leading to nosebleeds. Destruction of the nasal bridge eventually results in flattening of the nose, so-called **saddle nose**.
- **Skin:** A maculopapular rash is common early in congenital syphilis. It usually affects palms and soles (as in secondary syphilis of adults), although it may cover the entire body or any part of it. Cracks and fissures **(rhagades)** occur around the mouth, anus and vulva. Flat raised plaques **(condylomata lata)** around the anus and female genitalia may develop early or after a few years.
- **Visceral organs:** A distinctive pneumonitis, with pale hypocrepitant lungs **(pneumonia alba),** may develop in the neonatal period. Hepatosplenomegaly, anemia and lymphadenopathy may also occur in early congenital syphilis.
- **Teeth:** Buds of incisors and sixth-year molars develop early in postnatal life, at a time when congenital syphilis is particularly aggressive. Thus, permanent incisors may be notched **(Hutchinson teeth)** and molars malformed **(mulberry molars).**
- **Bones:** Periosteal inflammation with new bone formation **(periostitis)** is common, especially in the anterior tibia. This causes a distinctive outward curving **(saber shins)**.
- **Eye:** Progressive corneal vascularization **(interstitial keratitis)** is an especially vexing complication of congenital syphilis, occurring as early as 4 years and as late as 20 years of age. The cornea eventually scars and becomes opaque.
- **Nervous system:** The nervous system is commonly involved, with symptoms starting in infancy or after 1 year. **Meningitis** predominates in early congenital syphilis, causing convulsions, mild hydrocephalus and mental retardation. **Meningovascular syphilis** is common later and may lead to deafness, mental retardation, paresis and other complications. **Hutchinson triad** is a combination of deafness, interstitial keratitis and notched incisor teeth.

Appropriate clinical findings, plus a history of maternal infection, suggest the diagnosis, but serologic testing to confirm active infection may not be definitive since newborns, in addition to receiving the treponeme, carry transplacentally transferred maternal immunoglobulin G (IgG). Penicillin is the drug of choice for intrauterine and postnatal syphilis. If given during intrauterine life or the first 2 years of postnatal life, prognosis can be excellent, and most symptoms of congenital syphilis are prevented.

CYTOGENETICS AND CHROMOSOMES

Cytogenetics is the study of chromosomes and their abnormalities. The current classification is the International System for Human Cytogenetic Nomenclature (ISCN, 2013). A normal human has 46 chromosomes: 2 sex chromosomes (XX or XY) plus 44 nonsex chromosomes, or autosomes.

Cytogenetic studies can be done on any cell type undergoing mitotic division. Lymphocytes are most often used as they are easily stimulated to divide. Proliferating cells are arrested in metaphase, then spread onto glass slides to

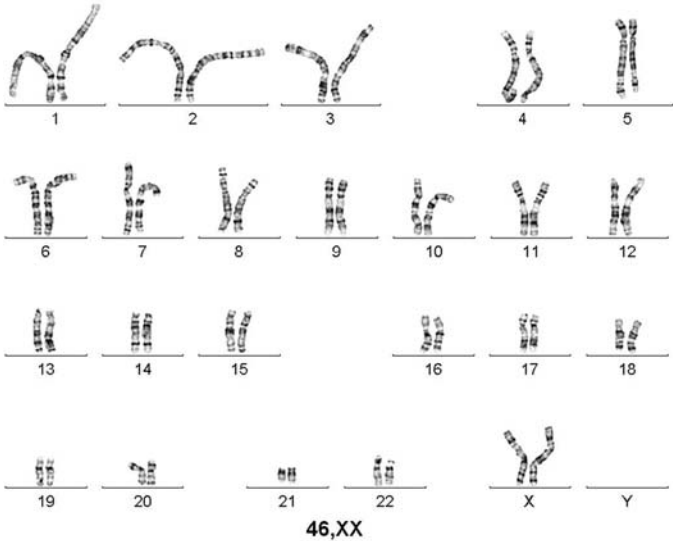

FIGURE 6-6. G-banded normal female karyotype. Chromosomes are grouped as shown: #1-3 are group A; #4, 5, group B; #6-12, group C; #13-15, group D; #16-18, group E; #19, 20, group F; #21, 22, group G.

disperse the chromosomes. Staining, usually with Giemsa trypsin, facilitates identification of chromosomes by generating distinctive band patterns (Fig. 6-6).

Chromosome Structure

Accurate detection of specific chromosome abnormalities depends on defined methods to identify normal chromosomes. Chromosomes are classified by length and centromere position—the point at which two identical strands of chromosomal DNA, the sister chromatids, attach to each other during mitosis. Centromere location identifies them as metacentric, submetacentric or acrocentric. Metacentric chromosomes (1, 3, 19, 20) have centromeres in their middle. Although these chromosomes are divided into two equal parts, the top part is defined as the p (from French, *petit*) short arm and the bottom is called q, the long arm. In submetacentric chromosomes (2, 4 through 12, 16, 17,18, X), centromeres produce two arms of unequal length, of which the q arm is longer than the upper p arm. Acrocentric chromosomes (13, 14, 15, 21, 22, Y) have very short p arms containing stalks and satellites attached to eccentrically located centromeres. In a **karyotype,** chromosomes are lined up according to their size and centromere position and classified into several groups (A to G from largest to smallest) (Fig. 6-6).

Chromosomal Banding

Special stains delineate specific bands unique to each chromosome. ***This makes it possible to recognize each chromosome, pair homologous chromosomes and identify defects on each segment of a chromosome.*** Chromosome bands are labeled as follows:

- **G bands** are highlighted using Giemsa stain (hence "G").
- **Q bands** stain with Giemsa and fluoresce when treated with quinacrine (thus, "Q").
- **R bands** are reverse (hence "R") images of G and Q bands such that dark G bands are light R bands and vice versa.
- **C banding** stains centromeres (hence "C") and other portions of chromosomes containing **constitutive heterochromatin,** highly condensed, repetitive DNA sequences that are transcriptionally silent. By contrast, **facultative heterochromatin,** which forms the inactive X chromosome (Barr body), is not repetitive but it shares the condensed structure of constitutive heterochromatin.
- **Nucleolar organizing region (NOR) staining** demonstrates secondary constrictions (stalks) of chromosomes with satellites.
- **T banding** stains chromosome termini/telomeric (hence "T") ends.

Clinical cytogenetics laboratories mostly use G banding to distinguish normal and abnormal chromosome patterns. However, each of these stains identifies DNA sequences with different structure and function along each chromosome. In centromeric DNA, most sequences are long repeats, while very short repeating units of DNA make up each chromosome's telomere region.

Fluorescence in Situ Hybridization Uses DNA Probes to Identify Specific Chromosome Regions

Fluorophore-labeled DNA probes vary in size from individual genes to small chromosome regions. They are used in fluorescence in situ hybridization (FISH) to determine if genetic material is lost, gained or rearranged. Probes with different fluorophores can identify chromosomal translocations. In multicolor FISH, or spectral karyotyping, such probes hybridize to whole chromosomes, to facilitate detection of gross abnormalities (Fig. 6-7).

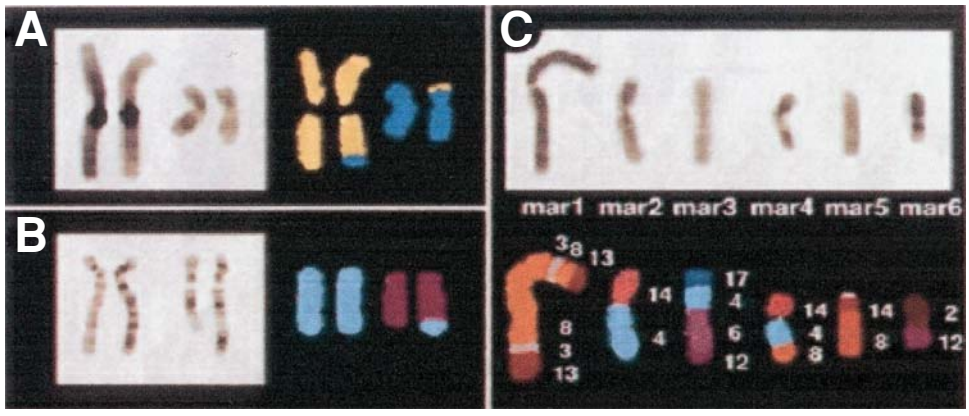

FIGURE 6-7. Translocations in human chromosomes demonstrated by spectral karyotyping. A. Balanced translocation: t(1;11). **B.** Unbalanced karyotype: derivative chromosome 12 with chromosome 4 material attached (partial trisomy for 4p and partial monosomy for 12q). **C.** Characterization of marker chromosomes from an aneuploid breast cancer showing multiple translocations.

Structural Chromosomal Abnormalities May Arise During Somatic Cell Division (Mitosis) or Gametogenesis (Meiosis)

The frequency of structural abnormalities varies considerably in different situations. Spontaneous abortions show the highest frequency, and newborns, the lowest. In part, this reflects early fetal loss, particularly in cases with significant unbalanced rearrangements. To understand how structural chromosome abnormalities arise, it is important to understand how cells undergo division. Somatic cells undergo mitosis, while gametes undergo meiosis.

Cell Division

Mitotic cell division in somatic cells results in two daughter cells identical to the original parent cell in chromosome number and genetic content. Mitosis results in a diploid (2n) number of chromosomes in the daughter cells.

Meiosis only occurs in male and female germline cells, resulting in gametes with half the diploid chromosome content (23 chromosomes, plus either an X or a Y sex chromosome). This is the haploid number (n) of chromosomes.

Mitosis

Mitosis is divided into five stages: prophase, prometaphase, metaphase, anaphase and telophase. In the resting stage, interphase, the chromosomes are in their most decondensed state and exist as long, thread-like structures in the nucleus. As mitosis approaches, chromosomes thicken and condense, allowing them to be visualized by light microscopy at prometaphase and metaphase stages. Centromeres of each chromosome attach to the spindle and are pulled to opposite poles of the dividing cell during anaphase. Chromosomes congregate at opposite ends at telophase, while the cell constricts into two daughter cells, each with the same amount of DNA as the parent cell. Colcemid, a colchicine derivative, added to a culture of dividing cells depolymerizes microtubules that form the spindle and arrests mitosis in prometaphase/metaphase.

Meiosis

Structural chromosomal abnormalities arising during gametogenesis are transmitted to all somatic cells of an individual's offspring and may cause heritable diseases. During normal meiosis, homologous chromosomes (i.e., the copies of each chromosome inherited from both parents) form pairs, called **bivalents**. Meiosis has two stages. Meiosis I results in the halving of the DNA content from diploid (2n) to haploid (n) number of chromosomes. During the first phase of meiosis, sister chromatids may engage in crossing over and so exchange genetic material. Meiosis II is similar to mitosis and gives rise to gametes haploid (n) in DNA content and with 23 chromosomes.

Structural Chromosome Alterations Occur Once in 375 Live Births

These alterations result from breakage and reunion of homologous and nonhomologous autosomal and sex chromosome segments. Chromosome breakage can occur spontaneously or result from exposure to clastogenic agents, such as viruses, radiation or various chemicals.

Chromosome Translocations

A **chromosome translocation** is an abnormal process in which *nonhomologous* chromosomes (e.g., chromosomes 11 and 22) cross over and exchange genetic material. This exchange of chromosome material can be balanced or unbalanced.

Chromosomal translocations are classified according to the International System for Human Cytogenetic Nomenclature. For example, translocation between chromosomes "11" and "22" is written as t(11;22). Sites of the translocation are further defined by Giemsa bands. Thus, t(11;22)(q23;q11) means that the region of the chromosome 11 long arm broken at band q23 translocated to the long arm of chromosome 22 at band q11, and the region from 22q11 is now part of the long arm at 11q23.

The two major types of translocations are reciprocal and robertsonian.

Reciprocal Translocations

A reciprocal translocation is exchange of chromosomal segments between different (nonhomologous) chromosomes (Fig. 6-8). Reciprocal translocations are **balanced** if there is no net loss of genetic material; each chromosomal segment is translocated in its entirety. If this occurs in gametes (sperm or ova), all somatic cells in the progeny inherit the abnormal chromosomal structure. Balanced translocations identified by cytogenetics testing are not usually associated with loss of genes or disruption of vital gene loci, so most carriers of balanced translocations are phenotypically normal. Balanced reciprocal translocations can be inherited for many generations.

Nevertheless, offspring of carriers of balanced translocations can have unbalanced karyotypes and may show severe phenotypic abnormalities (Fig. 6-9). The abnormal positions of exchanged chromosome segments may disturb meiosis and lead to abnormal segregation of chromosomes. Formation of bivalents may also be disturbed. Complete pairing of translocated segments can result in formation of a cross-like structure (quadriradial) between the two chromosomes containing the translocations and their two normal homologs. Unlike a normal bivalent, which typically resolves as each chromosome migrates to opposite poles, a quadriradial can divide along several different planes potentially yielding gametes with unbalanced chromosomes. On fertilization, the resulting zygotes may exhibit partial trisomy and monosomy for segments of the translocated chromosomes (Fig. 6-9).

Reciprocal translocations are detected in about 1 in 965 liveborn infants. Most patients with balanced translocations are asymptomatic, but 6% have an associated disorder, such as autism, decreased intellectual ability and congenital abnormalities, which are likely to result from disruption of a gene at the translocation breakpoint.

Robertsonian Translocations

Robertsonian translocations (centric fusion) result from fusion of centromere regions of two acrocentric chromosomes (Fig. 6-8). When nonhomologous chromosomes break near the centromere, the two arms combine to form one large chromosome. A small acentric chromosomal fragment is also formed and because it lacks a centromere, it is usually lost in

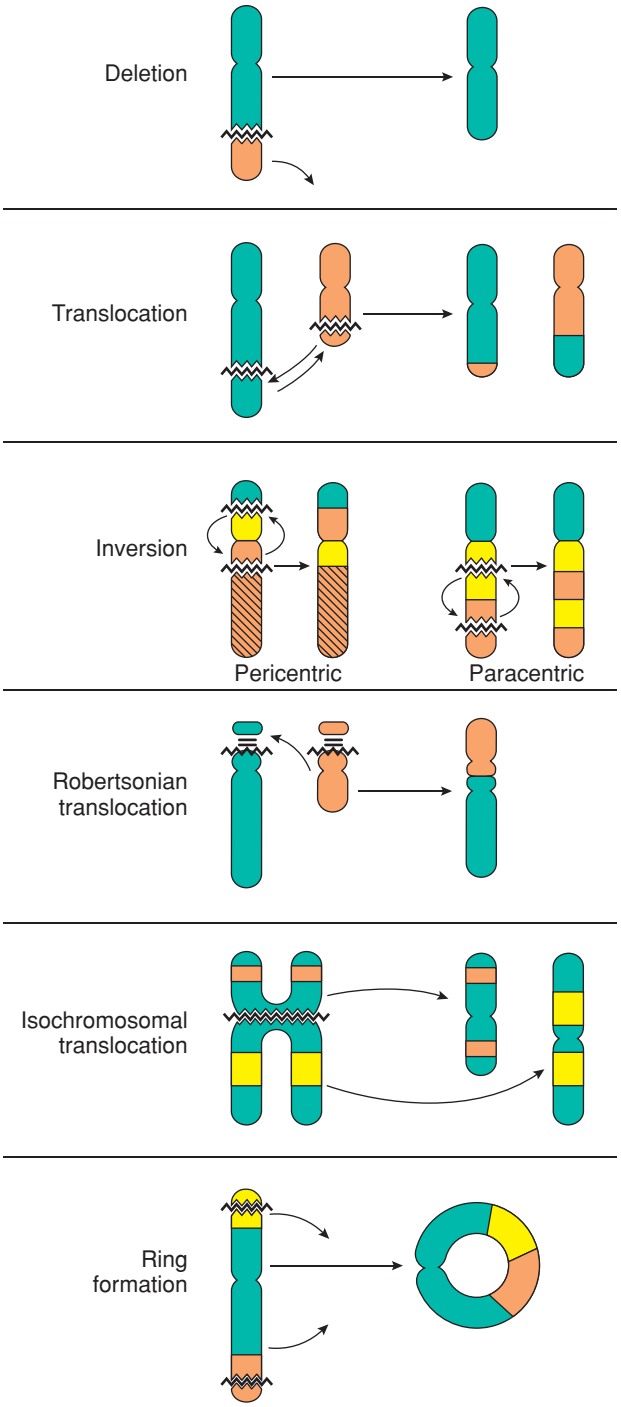

FIGURE 6-8. Structural abnormalities of human chromosomes. The **deletion** of a portion of a chromosome leads to the loss of genetic material and a shortened chromosome. A **reciprocal translocation** involves breaks on two nonhomologous chromosomes, with exchange of the acentric segments. An **inversion** requires two breaks in a single chromosome. If the breaks are on opposite sides of the centromere, the inversion is **pericentric;** it is **paracentric** if the breaks are on the same arm. A **robertsonian translocation** occurs when two nonhomologous acrocentric chromosomes break near their centromeres, after which the long arms fuse to form one large metacentric chromosome**. Isochromosomes** arise from faulty centromere division, which leads to duplication of the long arm (iso q) and deletion of the short arm, or the reverse (iso p). **Ring chromosomes** involve breaks of both telomeric portions of a chromosome, deletion of the acentric fragments and fusion of the remaining centric portion.

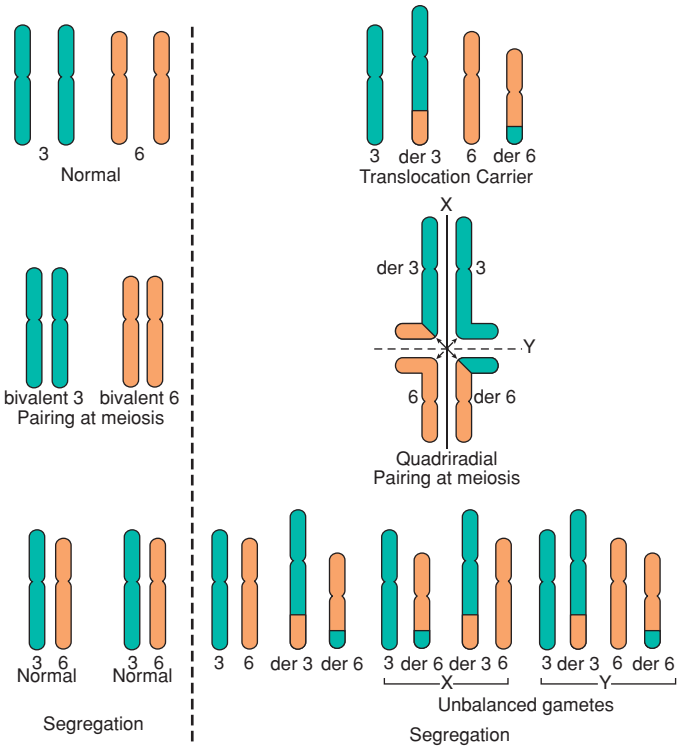

FIGURE 6-9. Meiotic segregation in a reciprocal balanced translocation involving chromosomes 3 and 6. The pairing of homologous chromosomes 3 and 6 in normal meiosis forms bivalents, which then segregate uniformly to create two gametes, each of which carries a single chromosome 3 and chromosome 6. Here the translocation carrier bears a balanced exchange of portions of the long arms of chromosomes 3 and 6. The chromosomes that carry the translocated genetic material are called **derivative chromosomes** (der3 and der6). Diploid germ cells contain pairs of homologous chromosomes 3 and 6, each of which consists of one normal chromosome and one that carries a translocation. During meiosis, instead of the normal pairing into two bivalents, a quadriradial structure, containing all four chromosomes, is formed. In this circumstance, the chromosomes can segregate along several different planes of cleavage, shown as *X* and *Y*. In addition, the chromosomes can segregate diagonally (*arrows*). As a result, six different gametes can be produced, four of which are unbalanced and can result in congenital abnormalities.

subsequent divisions. As in reciprocal translocations, a robertsonian translocation is balanced if there is no loss of genetic material. The carrier is also usually phenotypically normal but may be infertile because a robertsonian translocation can reduce the number of chromosomes, which are then asymmetrically segregated during meiosis. If a carrier is fertile, however, his or her gametes may produce unbalanced translocations, in which case offspring may have congenital malformations.

Robertsonian translocations of chromosomes 13 and 14 are most common and are seen in about 1 in 1000 newborns. A robertsonian translocation of chromosome 21 imparts a significantly greater risk of having a child with Down/trisomy 21 syndrome. In this case, maternal transmission is more common than paternal.

Chromosomal Deletions

A deletion is loss of any portion of a chromosome. By definition, such chromosome alterations are unbalanced with the loss of one or multiple genes from within the deleted chromosome segment.

TABLE 6-2
FISH ANALYSIS FOR MICRODELETION SYNDROMES

Syndrome	DNA Probes	Chromosome Location	Abnormality Detected
1p36 microdeletion	p58/LSI 1q25	1p36/1q25	1p36 deletion
Wolf Hirschhorn	WHS/CEP4	4p16.3/cen 4	4p16.3 deletion
Cri du chat	D5S23/D5S721	5p15.2	5p15.2 deletion
Williams	ELN/D7S486	7q11.23/7q31	7q11.23 deletion
Prader-Willi	SNRPN/GARB3/D15S10	15q11–13	15q11.2 deletion
Angelman	SNRPN/GARB3/D15S10	15q11–13	15q11.2 deletion
Miller Dieker	LIS1/RARA	17p13.3/17q21.1	17p13.3 deletion
Smith Magenis	SMS/RARA	17p11.2/17p21.1	17p11.2 deletion
DiGeorge/velocardiofacial	HIRA/TUPLE1/ARSA/ N25	22q11.2/22q13	22q11.2 deletion
Kallmann	KAL/DXZ1	Xp22.3/cen X	Xp22.3 deletion
X-linked ichthyosis	STS/DXZ1	Xp22.3/cen X	Xp22.3 deletion
Sex reversal/ambiguous genitalia	SRY	Yp11.3	Yp11.3 deletion

FISH = fluorescence in situ hybridization.

Chromatid breaks during mitosis in somatic cells may generate chromosomal fragments that do not recombine with any other chromosome and are lost in subsequent cell divisions. Deletions may also result from unequal crossover during meiosis. Deletions of specific genes or chromosomal regions can be detected by FISH and such higher-resolution techniques as array comparative genomic hybridization (aCGH), which detects gene copy number variations related to ploidy. aCGH can help to profile whole genomes to detect very small or cryptic deletions in unidentified regions. These minute cryptic deletions, or microdeletions, involve definitive genes in specific chromosomes (Table 6-2). Several microdeletion syndromes have been characterized using unique sequence DNA probes for the specific gene involved, such as the ELN gene (elastin). Deletion of this gene in chromosome region 7q11.2, which leads to Williams syndrome, is too small to be detected by routine chromosome analysis. It is readily detected by FISH and aCGH (Table 6-2). Prader-Willi and Angelman syndromes entail microdeletions of the long arm of chromosome 15 (see below).

Chromosome deletions play a role in the pathogenesis of cancer, including several hereditary forms. Familial **retinoblastomas** are associated with deletions in the long arm of chromosome 13 containing the RB1 gene locus at 13q14.1-q14.2.

People with chromosome 11 deletions may have **Wilms tumor aniridia syndrome** (WAGR), which includes Wilms tumor, aniridia, genitourinary malformations and mental retardation. The gene specific for WAGR syndrome, WT1, is a tumor suppressor gene in region 11p13.

Chromosomal Inversions

In chromosomal inversions, a chromosome breaks at two points and a segment inverts and then reattaches. **Pericentric inversions** result from breaks on opposite sides of the centromere and include the centromere; **paracentric inversions** involve breaks on the same arm of the chromosome and do not involve the centromere region (Fig. 6-8). During meiosis, crossing over of segments in homologous chromosomes that carry inversions does not occur as readily as in normal chromosomes, owing to formation of inversion loops. Inversions are usually benign because no genetic material is lost, but during meiosis when loops are formed, gametes with duplication or deficiency of genetic material may arise. In most cases, however, inversions are inherited with no phenotypic consequences. Up to 1% of all people have the most common inversion, a small pericentric inversion of chromosome 9 [inv(9)(p11q12)]. This classic benign inversion is considered a normal polymorphism in most families.

Ring Chromosomes

Ring chromosomes are rare. They form by breaks involving both telomeric ends of a chromosome, deletion of the acentric (without a centromere) fragments and end-to-end fusion of the remaining centric portion of the chromosome (Fig. 6-8). If the ring contains a centromere, it is usually somewhat stable. However, because of its abnormal shape, it may be lost during meiotic cell division. Any phenotype depends primarily on the amount of genetic material lost because of the break. The chromosome abnormality is often of no consequence. However, ring chromosomes have been reported in patients with epilepsy (chromosome 20); mental retardation and dysmorphic facies (chromosomes 13 and 14); mental retardation, dwarfism and microcephaly (chromosome 15); and Turner syndrome (chromosome X).

Isochromosomes

Isochromosomes are formed by faulty centromere division. Normally, centromeres divide in a plane parallel to a chromosome's long axis, to give two identical hemichromosomes.

If, instead, a centromere divides in a plane transverse to the long axis, pairs of isochromosomes result (Fig. 6-8). One pair contains the short arms bound to the upper part of the centromere and the other has the long arms with the lower part of the centromere.

The most important clinical condition involving isochromosomes is **Turner syndrome:** 15% of those affected have an isochromosome of chromosome X. Thus, a woman with a normal X chromosome and an isochromosome made of long arms of the X chromosome is monosomic for all genes on the missing short arm because the other isochromosome was lost during meiotic division. She also has 3 copies of the genes on the long arm. The absence of the genes from the short arm leads to abnormal development and Turner syndrome.

The Causes of Numerical Chromosome Abnormalities Are Obscure

Several terms help in understanding developmental defects with abnormal chromosome numbers:

- **Haploid:** A single set of each chromosome (23 in humans). Normally, only germ cells have a haploid number (n) of chromosomes.
- **Diploid:** A double set of each of the chromosomes (46 in humans). Somatic cells have a diploid number (2n) of chromosomes.
- **Euploid:** Any multiple (from n to 8n) of the haploid number of chromosomes. For example, many normal liver cells have 2 times (4n) the diploid DNA content of somatic cells and so are euploid or, more specifically, tetraploid. If the multiple is greater than 2n (i.e., greater than diploid), the karyotype is **polyploid**.
- **Aneuploid:** Karyotypes that are not exact multiples of the haploid number. Many cancer cells are aneuploid, which often corresponds to aggressive cell division (see Chapter 5).
- **Monosomy:** Absence in a somatic cell of one chromosome of a homologous pair. Thus, in Turner syndrome, there is a single X chromosome (45,X).
- **Trisomy:** Presence of an extra copy of a normally paired chromosome. For example, in Down syndrome, there are three chromosomes 21 (47,XX,+21).

Genesis of Numerical Aberrations

The causes of chromosomal aberrations are obscure. Exogenous factors, such as radiation, viruses and chemicals, can affect mitotic spindles or DNA synthesis, disturb mitosis and meiosis and cause breakage in human chromosomes, all of which increase risk of chromosome alteration. Changes in chromosome numbers arise primarily from nondisjunction, which occurs more commonly in maternal and paternal gametes of older people.

Nondisjunction

Nondisjunction is failure of paired chromosomes or chromatids to separate and move to opposite poles of the spindle at anaphase, during mitosis or meiosis. This leads to aneuploidy if only one pair of chromosomes fails to separate. It results in polyploidy if the entire set does not divide and all the chromosomes are segregated into a single daughter cell. Aneuploidy due to nondisjunction in somatic cells leads to one daughter cell with trisomy (2n + 1) and the other with monosomy (2n – 1) for the affected chromosome pair. Aneuploid germ cells have two copies of the same chromosome (n + 1) or lack the affected chromosome entirely (n – 1).

Chromosomal Aberrations at Various Stages of Pregnancy

Chromosomal abnormalities identified in liveborn infants at birth differ from those in early spontaneous abortions. At birth, the common chromosomal abnormalities are trisomies 21 (most frequent), 18, 13 and X or Y (47,XXX; 47,XXY; and 47,XYY). About 0.3% of all infants have a chromosomal abnormality. The most common chromosomal abnormalities in spontaneous abortions are, in descending order of frequency, 45,X, then trisomies 16, 21 and 22. However, trisomy of almost any chromosome occurs in spontaneous abortions. ***Up to 35% of spontaneous abortions have a chromosomal abnormality.*** The reason for these differences is presumably related to survival in utero. Very few fetuses with 45,X survive to term, and trisomy 16 is nearly always lethal in utero. A fetus with trisomy 21 has a better chance of surviving to birth.

Effects of Chromosomal Aberrations

Most major chromosomal abnormalities are incompatible with life. They are usually lethal to a developing conceptus and cause early death and spontaneous abortion. Embryos with significant loss of genetic material (e.g., autosomal monosomies) rarely survive pregnancy. Even though X chromosome monosomy (45,X) may be compatible with life, more than 95% of such embryos are lost during pregnancy. Absence of an X chromosome in male fetuses (45,Y) invariably leads to early abortion.

Autosomal trisomies lead to developmental abnormalities. Affected fetuses usually die during pregnancy or shortly after birth. Trisomy 21, which causes Down syndrome, is an exception, and people with Down syndrome survive for years. X chromosome trisomy may result in abnormal development but is not lethal.

Mitotic nondisjunction in embryonic cells early in development results in **mosaicism,** in which chromosomal aberrations are transmitted in some cell lineages but not others. ***The body thus has two or more karyotypically different cell lines.*** Mosaicism may involve autosomes or sex chromosomes, and the phenotype depends on the chromosome involved and the extent of mosaicism. Autosomal mosaicism was once thought to be rare but probably occurs fairly frequently, and mosaicism involving sex chromosomes is common. Aneuploidy and mosaicism of sex chromosomes are the most important causes of infertility and/or abnormal development. Phenotypes in patients with mosaicism depend on the ratio of abnormal to normal cells and are more severe when the proportion of abnormal cells is higher.

Nomenclature of Chromosomal Aberrations

According to the International System for Human Cytogenetic Nomenclature (Table 6-3), structural and numerical chromosomal abnormalities are classified by:

1. Total number of chromosomes
2. Designation (number) of affected chromosomes
3. Nature and location of the defect on the chromosome

TABLE 6-3
CHROMOSOMAL NOMENCLATURE

Numerical designation of autosomes	1–22
Sex chromosomes	X, Y
Addition of a whole or part of a chromosome	+
Loss of a whole or part of a chromosome	–
Numerical mosaicism (e.g., 46/47)	/
Short arm of chromosome (petite)	p
Long arm of chromosome	q
Isochromosome	i
Ring chromosome	r
Deletion	del
Insertion	ins
Translocation	t
Derivative chromosome (carrying translocation)	der
Terminal	ter
Representative Karyotypes	
Male with trisomy 21 (Down syndrome)	47,XY, +21
Female with robertsonian translocation between chromosomes 14 and 21	45,XX,t(14;21)(q10;q10)
Cri du chat syndrome (male) with deletion of a portion of the short arm of chromosome 5	46,XY, del(5p)
Male with ring chromosome 19	46,XY, r(19)
Turner syndrome with monosomy X	45,X
Mosaic Klinefelter syndrome	47,XXY/46,XY

Karyotypes are described sequentially by:

1. Total number of chromosomes
2. Sex chromosome complement
3. Any abnormality

Addition of chromosomal material, either an entire chromosome or a portion, is indicated by a plus sign (+) before the number of the affected chromosome. A minus sign (–) denotes loss of part or all of a chromosome. Deletion of part of a chromosome is designated by **del,** followed by the location of the deleted material on the affected chromosome. Translocations, deletions and duplications may all cause clinical disorders (Table 6-3).

Defining chromosome alterations in patients can be a complicated process. For example, multiple cell lines with different chromosome abnormalities may arise in patients with aggressive cancers. It is important to distinguish primary from secondary alterations to determine which genes are driving the disease and should be targeted for therapy.

TABLE 6-4
CLINICAL FEATURES OF THE AUTOSOMAL CHROMOSOMAL SYNDROMES[a]

Syndromes	Features
Trisomic Syndromes	
Chromosome 21 (Down syndrome 47,XX or XY, +21)	Epicanthic folds, speckled irides, flat nasal bridge, congenital heart disease, simian crease of palms, Hirschsprung disease, increased risk of leukemia
Chromosome 18 (47,XX or XY, +18)	Female preponderance, micrognathia, congenital heart disease, horseshoe kidney, deformed fingers
Chromosome 13 (47,XX or XY, +13)	Persistent fetal hemoglobin, microcephaly, congenital heart disease, polycystic kidneys, polydactyly, simian crease
Deletion Syndromes	
5p– syndrome (cri du chat 46,XX or XY, 5p–)	Cat-like cry, low birth weight, microcephaly, epicanthic folds, congenital heart disease, short hands and feet, simian crease
11p– syndrome (46,XX or XY, 11p–)	Aniridia, Wilms tumor, gonadoblastoma, male genital ambiguity
13q– syndrome (46,XX or XY, 13q–)	Low birth weight, microcephaly, retinoblastoma, congenital heart disease

[a]All of these syndromes are associated with mental retardation.

CHROMOSOMAL SYNDROMES

Structural alterations that may result in clinical disorders include trisomies, translocations, deletions and chromosomal breakage (Tables 6-3 and 6-4).

Trisomy 21: Down Syndrome

Trisomy 21 is the most common cause of mental retardation. Liveborn infants represent only a fraction of all conceptuses with this defect, as 2/3 abort spontaneously or die in utero. Advances in treating infections, congenital heart defects and leukemia—the leading causes of death in Down syndrome—have increased life expectancy of patients with trisomy 21.

EPIDEMIOLOGY: ***The incidence of trisomy 21 rises dramatically with increasing maternal age: older mothers are at increased risk to have children with Down syndrome*** (Fig. 6-10). Up to the mid-30s, a woman's risk of giving birth to a trisomic child is about 1 in 300–900 liveborn infants. By age 45, the incidence is 1 in 25. Nevertheless, 80% of children with Down syndrome are born to mothers under 35, perhaps because women in this age group conceive more often and are not usually screened. The risk of a second child with Down syndrome is comparable to the normal population's risk, regardless of maternal age, unless the syndrome is associated with translocation of chromosome 21.

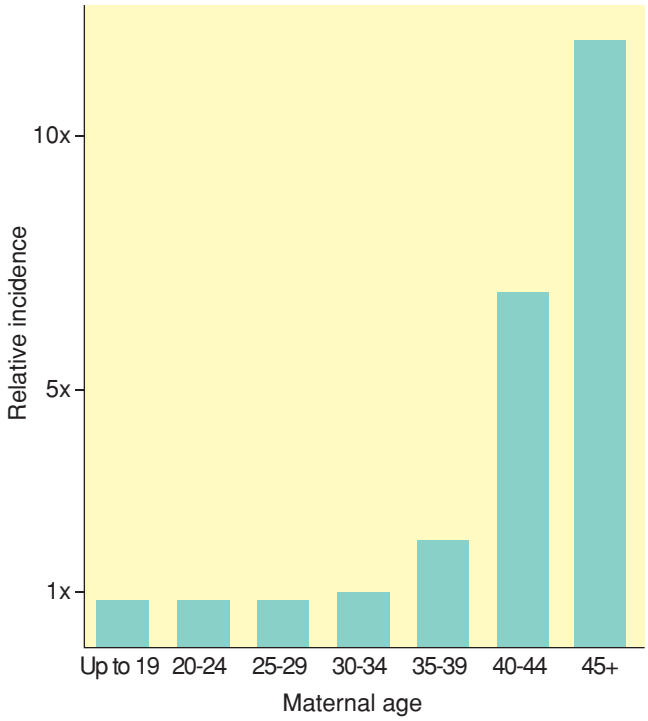

FIGURE 6-10. Incidence of Down syndrome in relation to maternal age. A conspicuous increase in the frequency of this disorder is seen beyond the age of 35 years.

MOLECULAR PATHOGENESIS: Chromosome 21 is the smallest human autosome, containing less than 2% of all human DNA. It is an acrocentric chromosome, and all known functional genes (except ribosomal RNA genes) are on the long arm (21q). It is estimated that chromosome 21 contains 200–250 genes. Studies of inherited translocations, in which only part of chromosome 21 is duplicated, suggest that the region responsible for the full Down syndrome phenotype is in band 21q22.2, a 4-Mb region of DNA, called the **Down syndrome critical region** (DSCR). Genes in DSCR implicated in Down syndrome are designated as DSCR1, DSCR2 and so forth.

Mechanisms explain how 3 copies of DSCR genes occur in somatic cells:

- **Nondisjunction** in the first meiotic division of gametogenesis (meiosis I) accounts for the majority (92%–95%) of patients with trisomy 21. The extra chromosome 21 is maternal in about 95% of such cases. Virtually all maternal nondisjunction seems to occur in meiosis I.
- **Translocation** of an extra long arm of chromosome 21 to another acrocentric chromosome accounts for 5% of cases.
- **Mosaicism** for trisomy 21 is caused by nondisjunction during mitosis of a somatic cell early in embryogenesis (2%).

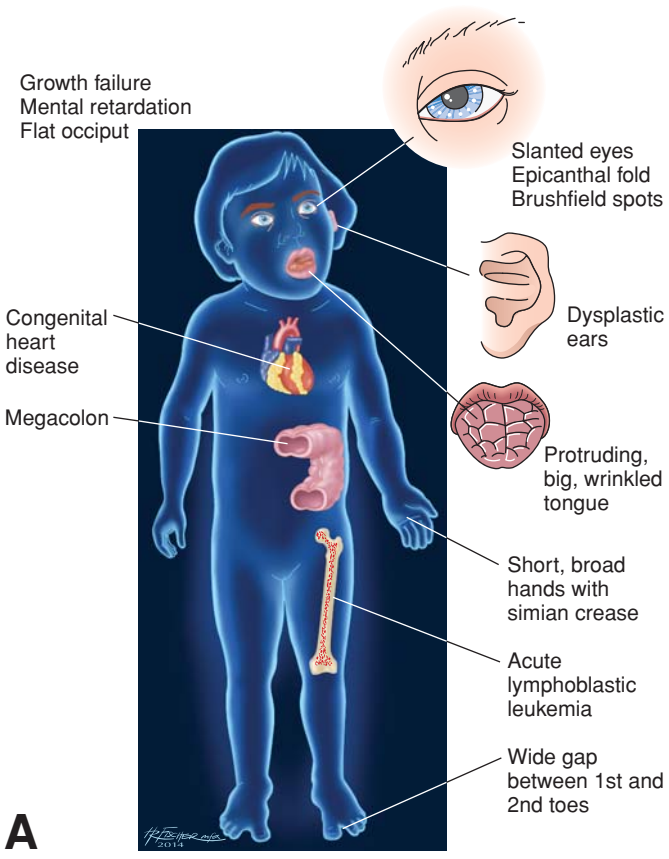
How maternal age increases the risk of bearing a child with trisomy 21 is poorly understood. The maternal age effect is related to maternal nondisjunction events, usually during maternal meiosis I. Down syndrome due to translocation or mosaicism is not related to maternal age.

Down syndrome caused by translocation of an extra portion of chromosome 21 occurs in two situations. Either parent may be a phenotypically normal carrier of a balanced translocation, or a translocation may arise de novo during gametogenesis. These translocations are typically robertsonian, tending to involve only acrocentric chromosomes, with short arms consisting of a satellite and stalk (chromosomes 13, 14, 15, 21 and 22). Translocations between these chromosomes are particularly common because they cluster during meiosis and are liable to break and recombine more than other chromosomes. The most common translocation in Down syndrome (50%) is fusion of the long arms of chromosomes 21 and 14, designated rob(14;21)(q10;q10), followed in frequency (40%) by similar fusion involving two chromosomes 21, rob(21;21)(q10;q10).

If the translocation is inherited from a parent, a balanced translocation has been converted to an unbalanced one (Fig. 6-7B shows an example of this involving chromosomes 4 and 12). Then, one would expect a 1 in 3 chance of Down syndrome among offspring of a carrier of a balanced robertsonian translocation. However, early loss of most embryos with trisomy 21 means that the actual incidence is only 10%–15% with a maternal translocation and less than 5% if the father is the carrier.

PATHOLOGY AND CLINICAL FEATURES: Down syndrome is ordinarily diagnosed at birth based on the infant's flaccid state and characteristic appearance. Diagnoses are confirmed by cytogenetics or FISH analyses. Over time, a typical constellation of abnormalities appears (Fig. 6-11).

- **Mental status:** Children with Down syndrome are invariably mentally retarded; their average IQ is usually 30–60. With stimulation programs, such children can graduate high school and work at paid jobs. Some attend postsecondary school. Still, many Down syndrome children have severe mental disability. Their cognitive skills decrease as they grow older and they are at higher risk for Alzheimer disease.
- **Craniofacial features:** Face and occiput tend to be flat, with a low-bridged nose, reduced interpupillary distance and oblique palpebral fissures. Epicanthal folds of the eyes impart an Asian appearance, which accounts for the obsolete term **mongolism**. Irides are speckled with **Brushfield spots**. Ears are enlarged, low set and malformed. A prominent tongue, typically lacking a central fissure, protrudes through an open mouth.
- **Heart:** One third of children with Down syndrome have cardiac malformations. The incidence is even higher in aborted fetuses. Anomalies include atrioventricular canal, ventricular and atrial septal defects; tetralogy of Fallot; and patent ductus arteriosus (see Chapter 17).
- **Skeleton:** These children tend to be small, owing to shorter than normal bones of the ribs, pelvis and extremities. Their hands are broad and short with a "simian crease," a single transverse crease across the palm. The middle phalanx of the fifth finger is hypoplastic and curves inward.
- **Gastrointestinal (GI) tract:** Duodenal stenosis or atresia, imperforate anus and Hirschsprung disease (megacolon) occur in 2%–3% of these children (see Chapter 19).
- **Reproductive system:** Men are invariably sterile, owing to arrested spermatogenesis. A few women with Down syndrome have given birth to children, 40% of which had trisomy 21.
- **Immune system:** Affected children are unusually susceptible to respiratory and other infections, although there is no clear pattern of immune defects.



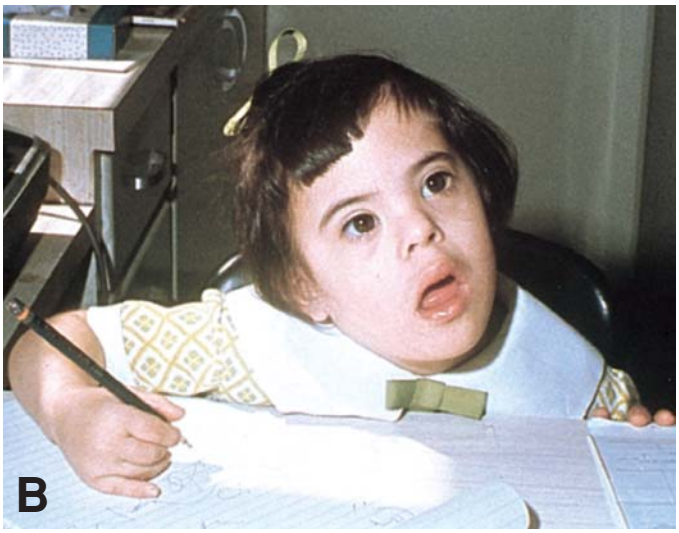


FIGURE 6-11. A. Clinical features of Down syndrome. **B.** A young girl with the facial features of Down syndrome.

- **Hematologic disorders:** Patients with Down syndrome have a particularly high risk of developing leukemia at all ages. ***The risk of leukemia in Down syndrome children under 15 years is 10–20-fold higher than normal.*** In children under 4 years of age, acute myeloid leukemia (AML) predominates. Therapy for these children is less intensive than standard AML therapy, and outcomes are generally good. Down syndrome children over 4 years of age with AML have a significantly worse prognosis and usually receive standard AML regimens. In older individuals, leukemias are usually acute lymphoblastic leukemias. The basis for the high incidence of leukemia is unknown, but leukemoid reactions (transient pronounced neutrophilia) are common in newborns with Down syndrome.
- **Neurologic disorders:** There is no clear pattern of neuropathology in Down syndrome, nor are there characteristic changes on the electroencephalogram. Nevertheless, electrophysiologic properties and other parameters are altered in cultured neurons from infants with Down syndrome. *The association of Down syndrome with Alzheimer disease* has been known for more than half a century. By age 35, characteristic Alzheimer lesions are universal in these patients, including granulovacuolar degeneration, neurofibrillary tangles, senile plaques and loss of neurons (see Chapter 32). Senile plaques and cerebral blood vessels in both Alzheimer disease and Down syndrome always contain β-amyloid protein. These similarities are mirrored in the appearance of dementia in 1/4 to 1/2 of older patients with Down syndrome and progressive loss of intellectual functions beyond that attributable to mental retardation alone. Alzheimer disease causes the sharp decline in survival in Down syndrome subjects over 45 years of age. Only about 25% live to be more than 60 years old, and most have Alzheimer disease.
- **Life expectancy:** In the first decade of life, the presence or absence of congenital heart disease largely determines survival in Down syndrome. Only 5% of those with normal hearts die before age 10, but 1/4 of those with heart disease die by then. Life expectancy in patients who reach age 10 is about 55 years, which is 20 years or more lower than that of the general population. Only 10% reach age 70.

Trisomy of Chromosomes 18 and 13

Trisomy 18, or Edwards syndrome, occurs in 1 of 3000–8000 live births and is the second most common autosomal trisomy syndrome. It causes mental retardation and affects females 3 times more often than males. Virtually all infants with trisomy 18 have severe cardiac malformations and survival of a few months is rare. Other anomalies include clenched hands with overlap of fingers, intrauterine growth retardation (IUGR), rocker bottom feet, micrognathia, prominent occiput, micro-ophthalmia, low-set ears and renal anomalies. Given the severe anomalies, about 95% abort spontaneously. About 50% of trisomy 18 patients die within 1 week, and 90% die within a year. Risk of bearing a fetus with trisomy 18 is higher in women older than 35 years. This trisomy may occur as a mosaic with more moderate phenotypic expression.

Trisomy 13, or Patau syndrome, is rare. It occurs in 1 in 20,000–25,000 births and is associated with severe mental and growth retardation. Significant malformations include cleft lip and cleft palate, plus severe nervous system and

cardiac malformations. This syndrome is also associated with increased maternal age. Trisomy 21, trisomy 18 and trisomy 13 are the only known trisomies in liveborn infants.

Chromosomal Deletion Syndromes Almost Always Involve Deletion of Parts of One or More Chromosomes

Deletion of an entire autosomal chromosome (i.e., monosomy) is usually not compatible with life. However, several syndromes arise from deletions of parts of several chromosomes (Tables 6-2 and 6-4). Most of these congenital syndromes are sporadic, but in a few instances, reciprocal translocations occur in the parents. Virtually all of these deletion syndromes have phenotypes including low birth weight, mental retardation, microcephaly and craniofacial and skeletal abnormalities. Cardiac and urogenital malformations are also common.

- **5p– syndrome (cri du chat):** This is the best-known deletion syndrome, because the high-pitched cry of the infant is like that of a kitten and calls attention to the disorder. It features intellectual disability and delayed development, microcephaly, low birth weight and hypotonia in infancy. These patients also have distinctive facial features, with widely set eyes (hypertelorism), low-set ears, a small jaw and a rounded face. Some are born with heart defects. Most cases are sporadic; reciprocal translocations occur in 10%–15% of the parents. The size of the 5p deletions varies among affected individuals; larger deletions tend to cause more severe intellectual disability and developmental delay. Loss of a specific gene, *CTNND2,* on the short arm of chromosome 5 is associated with severe intellectual disability in some people with this condition.
- **Microdeletion syndromes:** These syndromes are characterized by small deletions (<5 Mb) of a chromosomal segment spanning contiguous multiple disease genes that contribute independently to the phenotype. High-resolution karyotyping (2–5 Mb) rarely detects such microdeletions, but FISH using probes for the critical deleted interval can make the diagnosis. Selected microdeletion syndromes and their respective chromosome deletions are listed in Tables 6-2 and 6-4.
- **Deletions and rearrangements of telomeric/subtelomeric sequences:** Telomeres are specialized protein–DNA complexes at the ends of chromosomes (see Chapter 5) that prevent chromosomal degradation and end-to-end fusion. Telomeric DNA has 3–20 kb of TTAGGG repeats. *Subtelomeres,* segments of DNA adjacent to telomeric caps, are rich in genes. Deletions and rearrangements of these regions, demonstrated by FISH, are major causes of mild to severe mental retardation and dysmorphic features.

Translocation Syndromes May Cause Partial Trisomies

The prototypical translocation that causes partial trisomy is Down syndrome, but many other partial trisomies are known. The best documented is 9p trisomy, in which the short arm of chromosome 9 may be translocated to one of several autosomes. Many kindreds with this syndrome have been described. Carriers of a balanced chromosome 9 translocation are asymptomatic but may pass an unbalanced translocation to their offspring. The disorder is characterized by mental retardation, microcephaly and other craniofacial abnormalities.

A reciprocal translocation between the long arms of chromosomes 11 and 22 is the most common translocation in the general population. Offspring of carriers may have an extra chromosome with parts of both 11 and 22, and so may have partial trisomy of both chromosomes, leading to microcephaly and other anomalies.

Chromosomal Breakage Syndromes Typically Show Autosomal Recessive Inheritance

These include xeroderma pigmentosum, Bloom syndrome, ataxia telangiectasia and Fanconi anemia (constitutional aplastic pancytopenia). These disorders are characterized by defects in DNA repair or genomic instability. Affected patients show increased predisposition to cancer (see Chapters 5 and 26), and their cells exhibit elevated chromosomal breakage or instability, leading to chromosomal rearrangements. Fortunately, these breakage syndromes are relatively rare, but they occur in high rates in specific ethnic groups.

Numerical Aberrations of Sex Chromosomes Usually Cause Less Severe Clinical Syndromes Than Aberrations in Autosomes

The reasons are not entirely clear, but additional sex chromosomes (Fig. 6-12) cause less severe clinical manifestations than do extra autosomes and are less likely to disturb critical stages of development. Additional X chromosomes probably cause less severe phenotypes because of **lyonization,** a normal process in which each cell only has one active X chromosome.

The contrast between the X and Y chromosomes is striking: the X chromosome is one of the larger chromosomes, containing about 2000 genes, but the much smaller Y chromosome has only 78 genes, one of which is the testis-determining gene (*SRY*). About 95% of the human Y chromosome is unable to recombine; only the tip of the Y chromosome, called the **pseudoautosomal region,** recombines with the X chromosome. The rest of the Y chromosome is passed on to the next generation relatively intact. For this reason, the Y chromosome is used for investigating male human evolution.

The Y Chromosome

In humans, genes on the Y chromosome are key determinants of gender phenotype. Thus, people who are XXY (Klinefelter syndrome; see below) have a male phenotype, and those who are XO (Turner syndrome) are female. The intronless SRY gene near the end of the short arm of the Y chromosome at Yp11.3 encodes a transcription factor that belongs to the SOX (SRY-like box) gene family of DNA-binding proteins. It is the therian testis determining factor (TDF), also called the **sex-determining region Y protein** or **SRY protein,** that initiates male sex determination. Mutations in *SRY* lead to XY females, while translocations that add *SRY* to an X chromosome produce XX males.

A small proportion of infertile men with azoospermia or severe oligospermia have small deletions in parts of the Y chromosome. The sizes and locations of these deletions vary and do not correlate with the severity of spermatogenic failure.

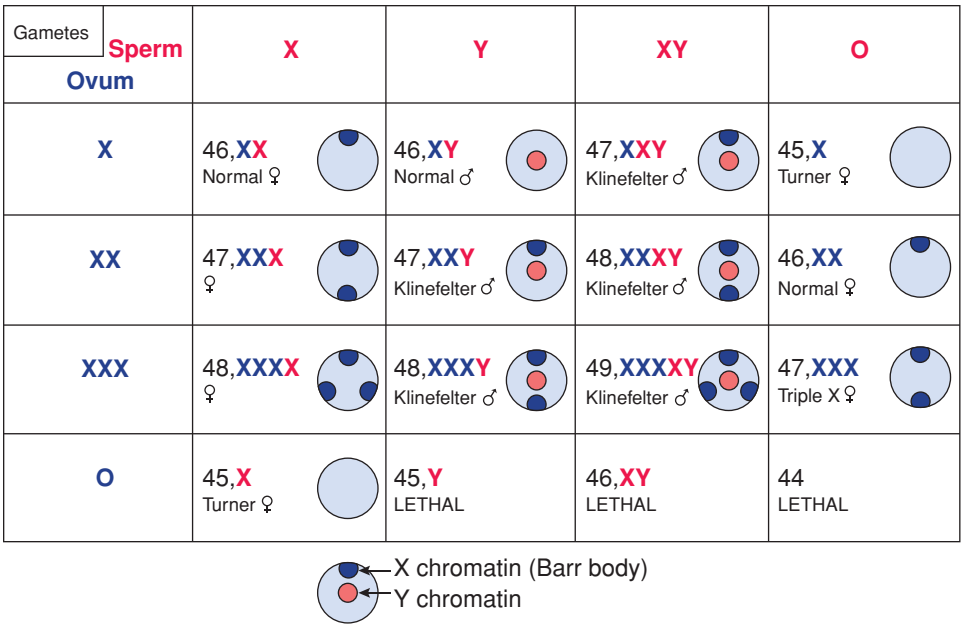

FIGURE 6-12. Numerical aberrations of sex chromosomes. Nondisjunction in either the male or female gamete is the principal cause of these abnormalities.

The X Chromosome

Males carry only one X chromosome but have the same amount of X chromosome gene products as do females. This seeming discrepancy is explained by the **Lyon effect:**

- In females, one X chromosome is irreversibly inactivated early in embryogenesis and is detectable in interphase nuclei as a clump of heterochromatin attached to the inner nuclear membrane, the **Barr body**. The inactive X chromosome is extensively methylated at gene control regions and transcriptionally repressed. Nevertheless, a significant minority of X-linked genes escape inactivation and continue to be expressed by both X chromosomes. The probability that an X chromosome is inactive seems to correlate with levels of *XIST*, an X-linked non-protein-coding RNA gene expressed only by the inactive partner.
- Either the paternal or maternal X chromosome is inactivated randomly.
- Inactivation of the X chromosome is virtually complete.
- X chromosome inactivation is permanent and transmitted to progeny cells, so paternally or maternally derived X chromosomes are propagated clonally. ***All females are thus mosaic for paternal and maternal X chromosomes.*** Mosaicism in females for glucose-6-phosphate dehydrogenase was key in demonstrating the monoclonal origin of neoplasms (see Chapter 5).

The issue is not quite so simple, however. If one X chromosome is entirely nonfunctional, individuals with XXY (Klinefelter) or XO (Turner) karyotypes should be phenotypically normal. They are not, which indicates that inactivated X chromosomes still function, at least in part. Indeed, a part of the X chromosome short arm is known to escape inactivation. This pseudoautosomal region can pair with a homologous region on the short arm of the Y chromosome and undergo meiotic recombination. Genes in this location are present in two functional copies in both males and females. Thus, patients with Turner syndrome (45,X) are haploinsufficient for these genes, and those with more than two X chromosomes (e.g., Klinefelter patients) have more than two functional copies. A gene in this region, *SHOX*, is associated with height, and its haploinsufficiency in Turner syndrome may explain the short stature of Turner patients. Extra copies of *SHOX* may explain the increased stature in other sex chromosome aneuploidy conditions such as 47,XXX; 47,XYY; 47,XXY; 48,XXYY; and so forth. Several other genes outside the pseudoautosomal region also escape X inactivation. ***Mental retardation in phenotypic boys and girls with extra X chromosomes correlates roughly with the number of X chromosomes.***

Klinefelter Syndrome (47,XXY)

In Klinefelter syndrome, males have a Y chromosome plus 2 more X chromosomes. This is the most important clinical condition involving trisomy of sex chromosomes (Fig. 6-13). It is a prominent cause of male hypogonadism and infertility.

MOLECULAR PATHOGENESIS: Most men with Klinefelter syndrome (80%) have one extra X chromosome (47,XXY). A minority are mosaics (46,XY/47,XXY) or have more than two X chromosomes (48,XXXY). ***Regardless of the number of supernumerary X chromosomes (even up to 4), the Y chromosome ensures a male phenotype.*** Additional X chromosomes correlate with more abnormal phenotypes, despite inactivation of the extra X chromosomes. Presumably, the same genes that escape inactivation in normal females are functional in Klinefelter syndrome.

Klinefelter syndrome occurs in 1 per 1000 male newborns, about the incidence of Down syndrome. Interestingly, half of all 47,XXY conceptuses are miscarried. The additional X chromosome(s) results from meiotic nondisjunction during gametogenesis. In half of cases, nondisjunction in paternal meiosis I leads to sperm with both X and Y chromosomes. Fertilization of a normal egg by such a sperm yields a 47,XXY karyotype.

PATHOLOGY: After puberty, the intrinsically abnormal testes do not respond to gonadotropin stimulation and show later regressive changes.

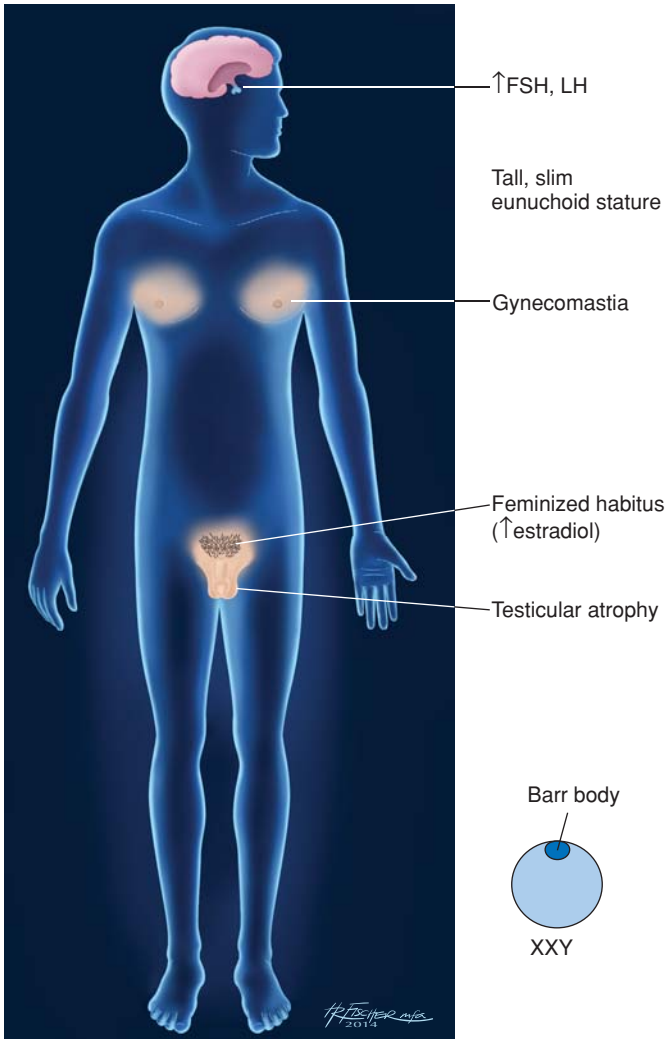

FIGURE 6-13. Clinical features of Klinefelter syndrome. *FSH* = follicle-stimulating hormone; *LH* = leuteinizing hormone.

Seminiferous tubules display atrophy, hyalinization and peritubular fibrosis. Germ cells and Sertoli cells are usually absent and the tubules become dense cords of collagen. Leydig cells are usually increased in number and are functionally impaired, as evidenced by low testosterone levels in the face of elevated luteinizing hormone (LH) levels.

CLINICAL FEATURES: The diagnosis of Klinefelter syndrome is usually made after puberty, since the main manifestations of the disorder during childhood are behavioral and psychiatric. Gross mental retardation is uncommon, but average IQ is probably somewhat reduced. As the syndrome is so common, it should be suspected in all boys with some mental deficiency and/or severe behavioral problems.

Children with Klinefelter syndrome tend to be tall and thin, with relatively long legs (eunuchoid body habitus). Normal testicular growth and masculinization do not occur at puberty, and testes and penis remain small. Feminine characteristics include a high-pitched voice, gynecomastia and a female pattern of pubic hair (female escutcheon). Azoospermia results in infertility. These changes reflect hypogonadism and a resulting lack of androgens. Serum testosterone is low to normal, but LH and FSH are quite high, indicating normal pituitary function. High circulating estradiol levels increase the estradiol-to-testosterone ratio, which determines the degree of feminization. Treatment with testosterone will virilize these patients but does not restore fertility.

The XYY Male

Interest in the XYY phenotype (1 in 1000 male newborns) comes from studies suggesting that this karyotype is significantly more prevalent in male prisoners than in the general population. However, the idea that XYY "supermales" show antisocial behavior because of an extra Y chromosome has not been substantiated and the topic remains controversial. Acknowledged features of the XYY phenotype are tall stature, a tendency toward cystic acne and some problems in motor and language development. Y chromosome aneuploidy results from meiotic nondisjunction in the father.

Turner Syndrome

Turner syndrome is the spectrum of abnormalities that derives from **complete or partial X chromosome monosomy in a phenotypic female**. It occurs in 1 in 5000 females. In 3/4 of cases, the single X chromosome is of maternal origin, suggesting that the meiotic error tends to be paternal. The incidence of Turner syndrome does not correlate with maternal age, and the risk of producing a second affected female infant is not increased.

The 45,X karyotype is one of the most common aneuploids in human conceptuses, but almost all are aborted spontaneously. As Turner patients survive normally after birth, it is unclear why the missing X chromosome is lethal during fetal development. It is believed that homologs of Y genes in the pseudoautosomal region of the X chromosome escape inactivation and are critical for survival of female embryos.

About half of Turner patients lack an entire X chromosome (monosomy X). The remainder are mosaics or have structural X chromosome aberrations, such as isochromosome of the long arm, translocations and deletions. Mosaics with a 45,X/46,XX karyotype tend to have a milder phenotype and may even be fertile. In about 5% of patients, the mosaic karyotype is 45,X/46,XY, in which case an original male zygote was subsequently modified by a mitotic nondisjunction. Such individuals have a 20% risk of developing a germ cell cancer and should have prophylactic removal of the abnormal gonads.

PATHOLOGY AND CLINICAL FEATURES: The clinical hallmarks of Turner syndrome are sexual infantilism with primary amenorrhea and sterility (Fig. 6-14). The disorder is usually discovered when absence of menarche brings the child to medical attention. Virtually all of these women are under 5 ft (152 cm) tall. Other clinical features include a short, webbed neck (pterygium coli); low posterior hairline; wide carrying angle of the arms (cubitus valgus); broad chest with widely spaced nipples; and hyperconvex fingernails. Half of patients have renal anomalies, the most common being horseshoe kidney and malrotation. Many have facial abnormalities, including a small mandible, prominent ears and epicanthal folds. Defective hearing and vision are common, and up to 20% may be mentally retarded. Pigmented nevi

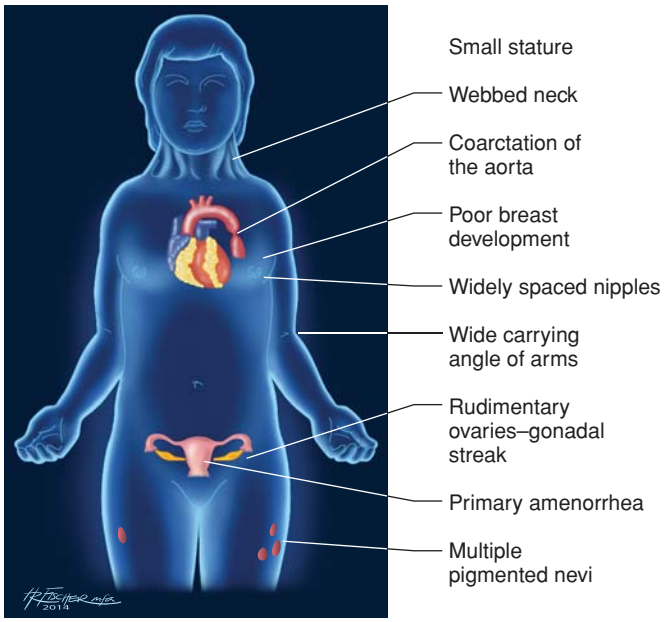

FIGURE 6-14. Clinical features of Turner syndrome.

become prominent with age. For unknown reasons, women with Turner syndrome are at a greater risk for chronic autoimmune thyroiditis and goiter.

Cardiovascular anomalies occur in almost half of Turner patients: coarctation of the aorta in 15% and a bicuspid aortic valve in up to 1/3. Essential hypertension occurs in some patients, and dissecting aneurysm of the aorta may occasionally cause death.

Ovaries of women with Turner syndrome show a curious acceleration of normal aging. Normal female fetal ovaries initially contain 7 million oocytes each, less than half of which survive until birth. Relentless loss of oocytes continues, so that by menarche only about 5% (400,000) remain. At menopause 0.1% survive. Ovaries of fetuses with Turner syndrome contain oocytes at first but lose them rapidly. None remain by 2 years of age. The ovaries become fibrous streaks, but the uterus, fallopian tubes and vagina develop normally. Thus, menopause in children with Turner syndrome may be considered to occur long before menarche.

Interestingly, there are families in which several women develop menopause prematurely and show deletions of portions of the long arm of one X chromosome. These data, with observations of Turner syndrome, further support the idea that genes controlling ovarian development and function in the inactivated X chromosome continue to be expressed in normal females.

Children with Turner syndrome are treated with growth hormone and estrogens and enjoy an excellent prognosis for a normal, albeit infertile, life.

Syndromes in Females with Multiple X Chromosomes

One extra X chromosome in a phenotypic female (i.e., a 47,XXX karyotype) is the most frequent abnormality of sex chromosomes in women. It occurs at about the same rate as Klinefelter syndrome. Most of these women are of normal intelligence but may have some difficulty in speech, learning and emotional responses. Minor physical anomalies are seen, such as epicanthal folds and clinodactyly (inward curvature of the fifth finger). These women are usually fertile, but their children are more susceptible to congenital defects.

Women with four and five X chromosomes have also been reported. Virtually all have been mentally retarded. They superficially resemble women with Down syndrome and do not mature sexually. Women with supernumerary X chromosomes have additional Barr bodies, indicating inactivation of all but one X chromosome. Clearly, some genes on inactivated X chromosomes are still expressed.

Single-Gene Abnormalities Confer Traits That Segregate Sharply within Families

The classic laws of mendelian inheritance, named in honor of Gregor Mendel, are:

- **A mendelian trait** is determined by two copies of the same gene, called alleles, situated at the same locus on two homologous chromosomes. In the case of the X and Y chromosomes in males, a trait is determined by just one allele.
- **Autosomal genes** are those located on one of the 22 autosomes.
- **Sex-linked traits** are encoded by loci on the X chromosome.
- **A dominant phenotypic trait** requires only one allele of a homologous gene pair and is expressed whether the allelic genes are homozygous or heterozygous.
- **A recessive phenotypic trait** demands that both alleles be identical (i.e., homozygous) in order for the phenotype to be expressed.
- In **codominance,** both alleles in a heterozygous gene pair are fully expressed and contribute to the phenotype (e.g., the AB blood group genes).

Mendelian traits are classified as:

1. **Autosomal dominant**
2. **Autosomal recessive**
3. **Sex-linked dominant**
4. **Sex-linked recessive**

Diseases due to sex-linked dominant genes are rare and of little practical significance.

Mutations

To make proteins, DNA is transcribed into RNA, which is processed into mRNA. This, in turn, is translated into protein by ribosomes. Changes in DNA can lead to corresponding changes in the amino acid sequence of its encoded protein or to interference with its synthesis.

A mutation is a stable heritable change in DNA. The consequences of mutations are highly variable. Some have no functional consequences, but others are lethal and so are not transmitted to the next generation. Between these extremes is a broad range of DNA changes that account for the genetic diversity of any species. ***About 1 in 1000 base pairs is polymorphic in the human genome,*** and evolution is based on the accumulation over time of such nonlethal mutations that alter the ability of a species to adapt to its environment. The genetics of human disease focuses on mutations that impair protein function detectably. The major types of mutations (Fig. 6-15) are:

- **Point mutations** occur when one base replaces another. If it is in the coding region (the part of the gene that is

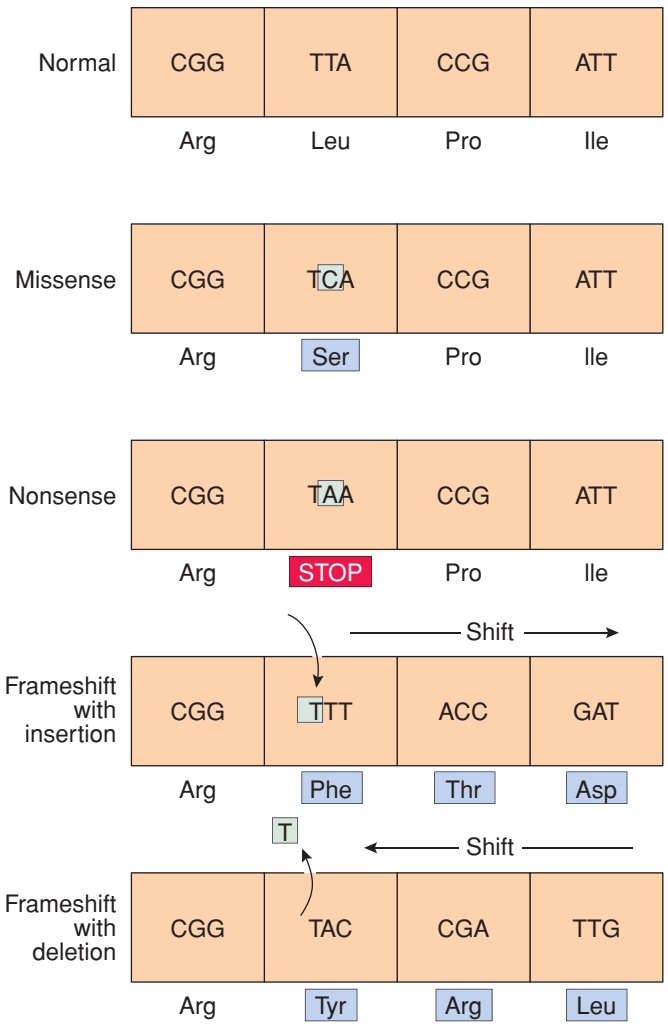

FIGURE 6-15. Point mutations that alter the reading frame of DNA. A variety of mutations in the second codon of a normal sequence of four amino acids is depicted. With a missense mutation, a change from T to C substitutes serine (Ser) for leucine (Leu). With a nonsense mutation, a change from T to A converts the leucine codon to a stop codon. A shift in the reading frame to the right results from insertion of a T, thus changing the sequence of all subsequent amino acids. Conversely, deletion of a T shifts the reading frame one base to the left and also changes the sequence of subsequent amino acids. *Arg* = arginine; *Asp* = aspartate; *Ile* = isoleucine; *Phe* = phenylalanine; *Pro* = proline; *Thr* = threonine; *Tyr* = tyrosine.

translated into a protein), a point mutation has three possible consequences:

1. A **synonymous mutation** occurs when the altered codon still encodes the same amino acid. For example, CGA and CGC both code for arginine.
2. A **missense mutation** (three fourths of base changes in the coding region) occurs when the new codon codes for a different amino acid. In sickle cell anemia, an adenine-to-thymine change in the β-globin gene replaces glutamic acid (GAG) with valine (GUG).
3. A **nonsense mutation** (4%) stops translation; that is, a codon for an amino acid is changed to a termination codon, yielding a truncated protein. For example, TAT codes for tyrosine, but TAA is a stop codon.

- **Frameshift mutations:** Amino acids are encoded by trinucleotide sequences. If the number of bases in a gene is changed by insertion or deletion, and if the number of bases added or lost is not a multiple of 3, ***the reading frame of the message is changed.*** Then, although the downstream sequence is the same, it will encode a different amino acid sequence and an unscheduled termination signal. Frameshift mutations can also alter transcription, splicing or mRNA processing.
- **Large deletions:** When a large segment of DNA is deleted, the coding region of a gene may be entirely removed, in which case the protein product is absent. A large deletion may also appose coding regions of nearby genes, giving rise to a fused gene that yields a hybrid protein in which part or all of one protein is followed by part or all of another.
- **Expansion of unstable trinucleotide repeat sequences:** The human genome contains many tandem trinucleotide repeats, some of which are associated with disease. The number of copies of some such repeats varies among individuals, representing allelic polymorphism of the genes in which they are found. As a rule, the number of repeats below a particular threshold does not change during mitosis or meiosis; but above this threshold, the number of repeats can contract or, more commonly, expand. A number of distinct trinucleotide expansions have been identified in human disease (Table 6-5).

Identification of a family of genetic diseases resulting from expansion of trinucleotide repeats has generated a new molecular category of disease. The number of these

TABLE 6-5
REPRESENTATIVE DISEASES ASSOCIATED WITH TRINUCLEOTIDE REPEATS

Disease	Location	Sequence	Normal Length	Premutation	Full Mutation
Huntington disease	4p16.3	CAG	10–30	—	40–100
Kennedy disease	Xq21	CAG	15–25	—	40–55
Spinocerebellar ataxia	6p23	CAG	20–35	—	45–80
Fragile X syndrome	Xq27.3	CGG	5–44	50–200	200–1000
Myotonic dystrophy	19q13	CTG	5–35	37–50	50–2000
Friedreich ataxia	9q13	GAA	7–30	—	120–1700

repeats increases with each successive generation, as does the severity of the disease and a younger age at onset. This mechanism is known as **genetic anticipation**. Most trinucleotide repeat diseases result from expansions of a CAG codon, which encodes glutamine, in the open reading frame of the gene, resulting in polyglutamine tracts in the protein product. All of these disorders are associated with neuronal degeneration.

Fragile X Syndrome: Loss of Protein Function

The prototypic trinucleotide repeat disease is fragile X syndrome (FXS), in which the number of trinucleotide CGG repeats is increased. It is transmitted as an X-linked dominant trait with variable penetrance and is ***the most common cause of inherited mental retardation***. Expansion of the CGG trinucleotide repeat affects the fragile X mental retardation 1 (FMR1) gene on the X chromosome, causing failure to express the fragile X mental retardation protein (FMRP) that is required for normal neural development. Depending on the length of the CGG repeat, an allele may be classified as normal (unaffected by the syndrome; 5–44 CGG repeats), a premutation (considered to be 50–200 repeats) or full mutation (affected by the syndrome, with >200 CGG repeats). A definitive diagnosis of fragile X syndrome is made through genetic testing to determine the number of CGG repeats. Testing for premutation carriers can also be performed for genetic counseling purposes.

The abnormal repeat is also associated with an inducible "fragile site" on the X chromosome, which appears as a nonstaining gap or an apparent chromosomal break at region Xq23.1 (Fig. 6-16). The phenotype includes slow intellectual development and physical abnormalities, such as an elongated face and prominent ears.

FXS occurs in about 1 in 3600 males and 1 in 4000–6000 females. Although CGG repeat expansion accounts for over 98% of cases, FXS can also occur as a result of point mutations affecting the FMR1 gene.

Huntington Disease

Huntington disease (HD) is the most common genetic cause of chorea. It is also associated with abnormalities of muscle coordination and psychomotor and cognitive functions. The disease, transmitted as an autosomal dominant trait, is caused by expansion of a CAG repeat within the HTT/IT15 gene, which encodes the protein **huntingtin**. The HTT gene is on the short arm of chromosome 4 at 4p16.3. CAG codes for glutamine and abnormal expansion of the polyglutamine tract in HD confer a toxic gain of function to huntingtin.

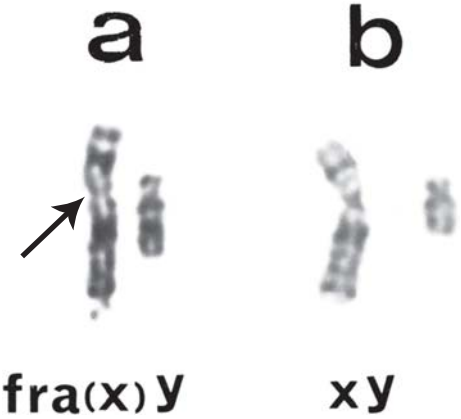

FIGURE 6-16. Fragile X chromosome. The arrow shows the nonstaining gap at Xq23.1.

Unaffected individuals have 10–26 CAG repeats, while those affected by the disease have 36 or more. In 3% of cases, a new HD mutation can occur by further expansion of CAG in offspring of individuals with a premutation between 27 and 35 repeats. In 97% of these, the HD mutation is inherited from an affected parent. The mechanism by which mutant huntingtin causes selective neuronal loss is not known, but altered protein–protein interactions have been implicated. Expanded CAG repeats determine several other neurodegenerative disorders in addition to HD (Table 6-5).

Myotonic Dystrophy

Myotonic dystrophy (DM), the most common form of autosomal muscular dystrophy (see Chapter 31), is caused by expansion of a CTG repeat in the 3′-untranslated region of the DM gene on chromosome 19q. It is inherited as an autosomal dominant trait.

Two types of myotonic dystrophy exist. Type 1 (DM1), also known as Steinert disease, has a severe congenital form and a milder childhood-onset form as well as an adult-onset form. Type 2 (DM2), also known as proximal myotonic myopathy (PROMM), is rarer than DM1 and has a milder phenotype. DM causes general weakness, usually beginning in the muscles of the hands, feet, neck or face. It slowly progresses to involve other muscle groups, including the heart. DM affects a wide variety of other organ systems as well. It occurs in 1 per 7000–8000 people worldwide, equally in males and females. In DM1, the affected gene is DMPK, which codes for myotonic dystrophy protein kinase, a protein expressed predominantly in skeletal muscle. The gene is on the long arm of chromosome 19. In DM1, there is expansion of a CTG triplet repeat in *DMPK*. Individuals with 5–37 repeats are considered normal, while those with 38–49 repeats are considered to have a premutation and are at risk of having children with further expanded repeats and thus symptomatic disease. People with more than 50 repeats are usually symptomatic. Longer repeats are associated with earlier onset and more severe disease.

DM2 is caused by a defect of the *ZNF9* gene on chromosome 3 between 3q13.3-q24. ZNF9 protein is believed to be an RNA-binding protein. The specific defect is a repeat of the CCTG tetranucleotide in the *ZNF9* gene. Thus, DM2 is not a trinucleotide repeat disorder, but rather a tetranucleotide repeat disorder. The repeat expansion for DM2 is much larger than for DM1, ranging from 75 to over 11,000 repeats. Unlike DM1, the size of the repeated DNA expansion in DM2 does not appear to make a difference in the age of onset or disease severity. In both cases, prenatal diagnosis is now available with molecular testing for the tri- and tetranucleotide repeats.

Friedreich Ataxia

Friedrich ataxia (FA) is an autosomal recessive degenerative disease associated with expansion of a GAA repeat. It affects the CNS and is also characterized by cardiomyopathy and type 2 diabetes. FA is the most common inherited ataxia, affecting 1 in 50,000 people in the United States, with males and females affected equally. The estimated carrier prevalence is 1 in 110. Because the defect is in an intron (which is removed from the mRNA transcript between transcription and translation), abnormal frataxin (FXN) protein is not

produced. Instead, it causes gene silencing and loss of function of the frataxin gene protein product (see Chapter 32). Affected individuals have 200–1700 repeats in the first intron of the FXN gene.

Functional Consequences of Mutations

A biochemical pathway represents the sequential actions of a series of enzymes, which are encoded by specific genes. A typical pathway can be represented by the conversion of a substrate (A) through intermediate metabolites (B and C) to a final product (D).

$$\underset{\text{initial substrate}}{A} \rightarrow \underset{\text{intermediary metabolites}}{B \rightarrow C} \rightarrow \underset{\text{end-products}}{D}$$

A single gene defect can have several consequences:

- **Failure to complete a metabolic pathway:** The end-product (D) is not formed since an enzyme needed to complete a metabolic sequence is missing:

  $$A \rightarrow B \rightarrow C - // \rightarrow (D)\ (\downarrow)$$

  An example of failure to complete a metabolic pathway is **albinism,** a pigment disorder caused by a deficiency of tyrosinase. Tyrosinase converts tyrosine to melanin (via intermediate formation of dihydroxyphenylalanine [DOPA]). Without tyrosinase, the melanin end-product is not formed, and an affected person (an "albino") has no pigment in all organs that normally contain it, primarily the eyes and skin.
- **Accumulation of unmetabolized substrate:** The enzyme that converts the initial substrate to the first intermediary metabolite may be missing, so the initial substrate accumulates in excess.

  $$A\ (\rightarrow)^{-} // \rightarrow (B)\ (\downarrow)\ (C)\ (\downarrow)\ (D)\ (\downarrow)$$

  Thus, in **phenylketonuria,** an inborn deficiency of phenylalanine hydroxylase causes dietary phenylalanine to accumulate and reach toxic concentrations that interfere with postnatal brain development and cause severe mental retardation.
- **Storage of an intermediary metabolite:** An intermediary metabolite, which is normally quickly processed into the final product and so is usually present only in minute amounts, accumulates in large quantities if the enzyme for its metabolism is lacking.

  $$A \rightarrow B(\rightarrow)^{-} \rightarrow // \rightarrow C\ (\downarrow)\ D\ (\downarrow)$$

  This type of genetic disorder is exemplified by glycogen storage disease type I (GSD I), a glycogen storage disease due to a deficiency of glucose-6-phosphatase. The inability to convert glucose-6-phosphate into glucose leads to its alternative conversion to glycogen.
- **Formation of an abnormal end-product:** A mutant gene encodes an abnormal protein. In sickle cell anemia, valine replaces glutamate in β-globin.

Mutation Hotspots

Certain regions of the genome mutate at a much higher rate than average. These hotspots are usually DNA sequences with inherent instability. They have an increased tendency toward unequal crossing over, or may be predisposed to single nucleotide substitutions. The best-characterized hotspot is the dinucleotide CG or CpG sites. These sites are regions of DNA where a cytosine nucleotide occurs next to a guanine in the linear sequence of bases along its length. "CpG" is shorthand for "—C—PO_4—G—" (i.e., C and G separated by a PO_4); phosphate links any two nucleosides together in DNA.

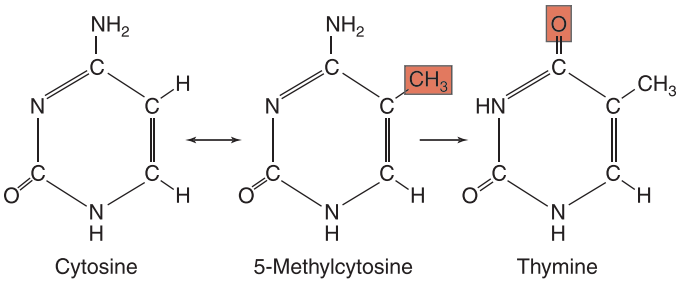

FIGURE 6-17. 5-Methylcytosine is formed from cytosine. Spontaneous deamination of 5-methylcytosine produces thymine.

The Cs in CpG dinucleotides can be methylated to 5-methylcytosine. In mammals, CpG methylation may alter the gene's transcription. Such ***epigenetic*** changes affect gene expression by mechanisms other than changes in DNA base sequence (see Chapter 5). CpG methylation commonly represses gene expression. Such 5-methylcytosines can undergo spontaneous deamination to thymine (Fig. 6-17). If this occurs in a gamete, it can become a fixed, heritable trait in the offspring.

Regions of the genome that have higher concentrations of CpGs are known as **CpG islands**. Many mammalian genes have CpG islands in their promoter regions. CpG methylation within promoters regions may, for example, silence tumor suppressor genes in malignancies (see Chapter 5). By contrast, hypomethylation of CpG sites is associated with overexpression of oncogenes in cancer cells.

Copy Number Variation

The term "copy number variation" (CNV) is a genetic change that results in an abnormal number of copies of one or more regions of DNA. It involves sequences over 1000 base pairs in length but less than 5 megabases. CNVs can arise from duplications, deletions, translocations and inversions. Roughly 12% of human genomic DNA shows CNVs.

CNVs can affect a single gene or a contiguous set of genes. They can lead to too many or too few copies of dosage-sensitive genes, which may account for significant phenotypic variability, complex behavioral traits and disease susceptibility.

There are two types of CNVs. The first category, called copy number polymorphisms (CNPs), is relatively common in the general population, with an overall frequency of greater than 1%. CNPs are typically small (most are less than 10 kilobases in length). The second class of CNVs consist of relatively rare variants that are much longer than CNPs, ranging from hundreds of thousands of base pairs to over 1 million base pairs in length. They are also called microdeletions and microduplications, and are believed to arise during gametogenesis. They have been observed disproportionately in patients with mental retardation, developmental delay, schizophrenia and autism, leading to speculation that large, rare CNVs may be more important in neurocognitive diseases than other forms of inherited mutations.

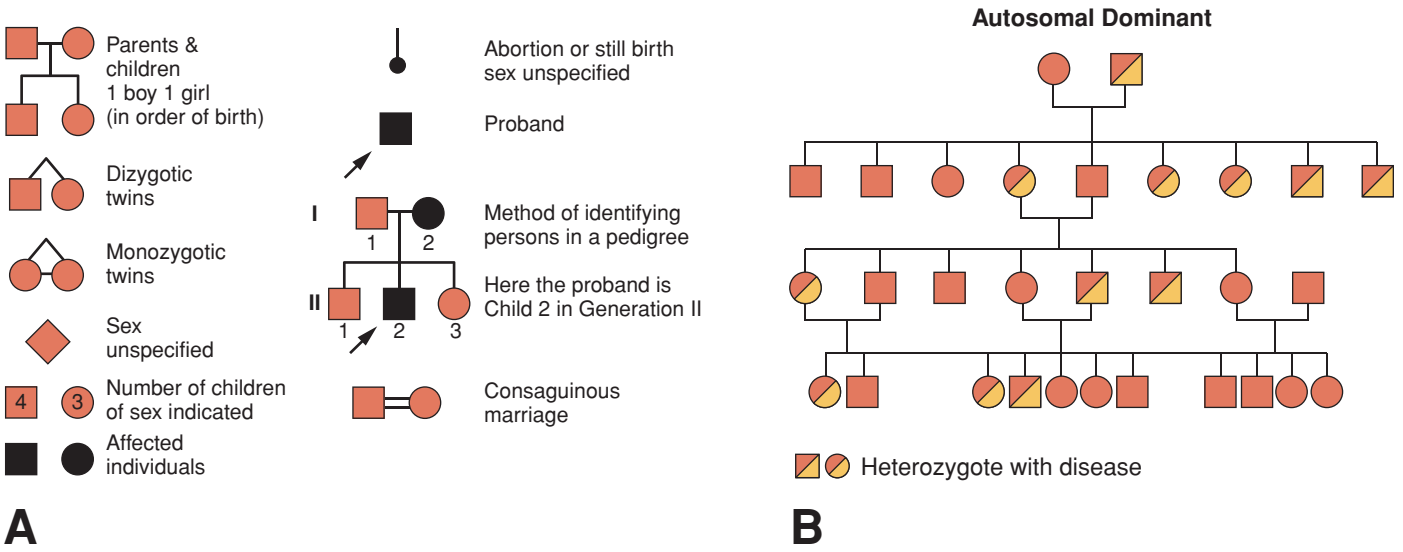

FIGURE 6-18. A. Definition of symbols in a pedigree. Males = squares; females = circles. A line drawn between a square and a circle represents a mating of that male and female. Two lines drawn between a square and a circle indicate a consanguineous mating in which the two individuals are related, usually as second cousins. Children of a mating are connected to a horizontal line, called the sibship line, by short vertical lines. The children of a sibship are always listed in order of birth, the oldest being on the left. Other conventions concerning twins and identification of probands and affected individuals are shown in the figure. **B. Autosomal dominant inheritance.** Only symptomatic individuals transmit the trait to the next generation, and heterozygotes are symptomatic. Both males and females are affected.

AUTOSOMAL DOMINANT DISORDERS ARE EXPRESSED IN HETEROZYGOTES

If only one mutated allele is sufficient to cause disease when its paired allele on the homologous autosome is normal, the mutant trait is considered to be dominant. The features of autosomal dominant traits are (Fig. 6-18):

- Males and females are affected equally, as the mutant gene is on an autosome. Thus, father-to-son transmission (which is absent in X-linked disorders) may occur.
- The trait encoded by the mutant gene can be transmitted to successive generations (unless reproductive capacity is compromised).
- Unaffected members of a family do not transmit the trait to their offspring. Unless the disease represents a new mutation, everyone with the disease has an affected parent.
- Proportions of normal and diseased offspring of patients with the disorder are about equal, since most affected people are heterozygous, and their normal mates do not carry the defective gene.

New Mutations versus Inherited Mutations

As noted above, autosomal dominant diseases may result from a new mutation rather than transmission from an affected parent. Nevertheless, offspring of patients with a new dominant mutation have a 50% risk for the disease. ***With autosomal dominant disorders, the ratio of new mutations to transmitted ones varies with the effect of the disease on fertility.*** The more a disease impairs reproduction, the greater the proportion of affected people who represent new mutations. A dominant mutation causing 100% infertility would have to be a new mutation. If reproductive capacity is only partly impaired, the proportion of new mutations is lower. Thus, in **tuberous sclerosis,** an autosomal dominant condition in which mental retardation limits reproductive potential, new mutations account for 80% of cases. If a dominant disease has little effect on fertility (e.g., familial hypercholesterolemia), virtually all affected people will have pedigrees showing classic vertical transmission of the disorder.

Biochemical Basis of Autosomal Dominant Disorders

There are several major mechanisms by which a single mutant allele may cause disease even when the other allele is normal.

- If the gene product is rate limiting in a complex metabolic network (e.g., a receptor or an enzyme), having half of the normal amount of gene product may be insufficient for a normal phenotype. This is known as **haploinsufficiency**. For example, familial hypercholesterolemia is caused by inadequate low-density lipoprotein (LDL) uptake receptors on hepatocytes.
- In some diseases, the presence of an extra copy of an allele gives rise to a phenotype. An example of this is Charcot-Marie-Tooth disease type IA, which is caused by duplication of the peripheral myelin protein-22 gene.
- A mutant protein may be insensitive to normal regulation. For example, mutations in the *RET* proto-oncogene in families with multiple endocrine neoplasia type 2 increase activity of a tyrosine kinase that stimulates cell proliferation.
- Mutations in genes for structural proteins (e.g., collagens, cytoskeletal constituents) cause abnormal molecular interactions and disrupt normal morphologic patterns. Such a situation is exemplified by osteogenesis imperfecta and hereditary spherocytosis.

More than 1000 human diseases are inherited as autosomal dominant traits, although most are rare. Examples of human autosomal dominant diseases are shown in Table 6-6.

TABLE 6-6
REPRESENTATIVE AUTOSOMAL DOMINANT DISORDERS

Disease	Frequency	Chromosome
Familial hypercholesterolemia	1/500	19p
von Willebrand disease	1/8000	12p
Hereditary spherocytosis (major forms)	1/5000	14, 8
Hereditary elliptocytosis (all forms)	1/2500	1, 1p, 2q, 14
Osteogenesis imperfecta (types I–IV)	1/10,000	17q, 7q
Ehlers-Danlos syndrome (all types)	1/5000	2q
Marfan syndrome	1/5000	15q
Neurofibromatosis type 1	1/3500	17q
Huntington chorea	1/15,000	4p
Retinoblastoma	1/14,000	13q
Wilms tumor	1/10,000	11p
Familial adenomatous polyposis	1/10,000	5q
Acute intermittent porphyria	1/15,000	11q
Hereditary amyloidosis	1/100,000	18q
Adult polycystic kidney disease	1/1000	16p

Inherited Connective Tissue Diseases Are Often Autosomal Dominant Traits

This discussion is limited to three of the most common and best-studied diseases of connective tissue: Marfan syndrome, Ehlers-Danlos syndrome and osteogenesis imperfecta. Even in these well-delineated disorders, clinical phenotypes often overlap. Thus, some patients in a family may develop the joint dislocations typical of Ehlers-Danlos syndrome, while others suffer from multiple fractures characteristic of osteogenesis imperfecta, and still others, with the same genetic defect, may have no symptoms. Thus, current classifications based on clinical criteria will eventually be replaced by references to specific gene defects, as with the hemoglobinopathies.

Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder of connective tissue affecting many organs, including the heart, aorta, skeleton, eyes and skin. Fifteen to 30% are de novo mutations occurring once in 20,000 live births. Marfan syndrome affects males and females equally and shows no ethnic or geographical bias. About 1 in 3000–5000 individuals have Marfan syndrome.

MOLECULAR PATHOGENESIS: The cause of Marfan syndrome is a missense mutation in the gene for *fibrillin-1 (FBN1)*, on the long arm of chromosome 15 (15q21.1). **Fibrillins** are a family of collagen-like connective tissue proteins. There are now about a dozen genetically distinct fibrillins, and over 100 mutations are known. They are present in many tissues, in the form of **microfibrils,** thread-like filaments that form larger fibers and are organized into rods, sheets and interlaced networks. These fibers are scaffolds for elastin deposition during embryonic development, after which they remain as a component of elastic tissues (e.g., elastin is deposited on lamellae of microfibrillar fibers in the concentric rings of elastin in the aortic wall). Abnormal microfibrillar fibers can be visualized by immunofluorescent microscopy in all tissues affected in Marfan syndrome.

Fibrillin-1 is a large, cysteine-rich glycoprotein that forms 10-nm microfibrils in the extracellular matrix of many tissues. Interestingly, the ciliary zonules that suspend the lens of the eye are devoid of elastin but consist almost exclusively of fibrillin. Dislocation of the lens is characteristic of Marfan syndrome.

Deficiencies in the amount and distribution of microfibrillar fibers occur in skin, which renders the elastic fibers incompetent to resist normal stress. Fibrillin also binds to transforming growth factor-β (TGF-β), a multifunctional protein that regulates cell proliferation and is upregulated in a variety of inflammatory diseases (see Chapters 2, 4 and 5). Patients with Marfan syndrome have increased TGF-β in their aortas, cardiac valves and lungs, possibly because of decreased fibrillin-1, which normally sequesters this cytokine. Treating fibrillin-1–deficient mice with a TGF-β antagonist decreases the severity of their "Marfan phenotype," suggesting a potential therapeutic approach in this disease that does not directly target the genetic mutation.

PATHOLOGY AND CLINICAL FEATURES: People with Marfan syndrome are usually (but not always) tall, with greater lower body length (pubis to sole) than upper body length. They are slender in habitus reflecting a paucity of subcutaneous fat and have long, thin extremities and fingers (arachnodactyly/spider fingers) (Fig. 6-19).

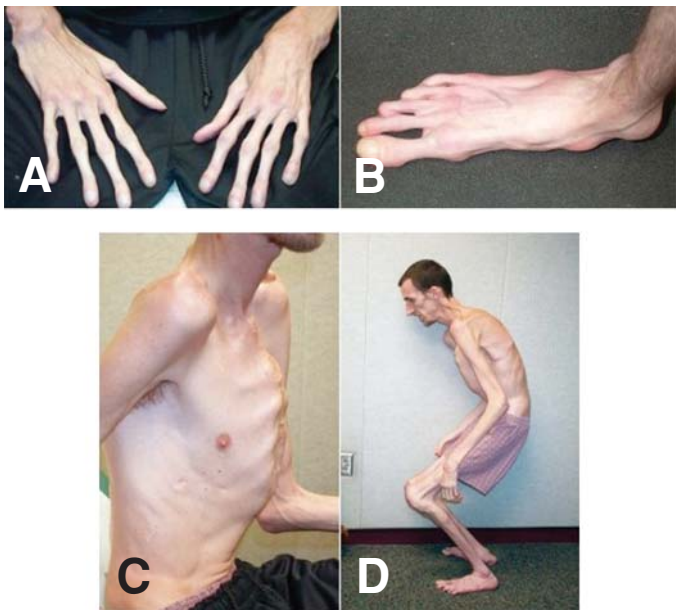

FIGURE 6-19. Features of Marfan syndrome. A, B. Long, slender digits (arachnodactyly). **C, D.** Tall slender build with disproportionately long arms, legs, fingers and toes and a breastbone that protrudes outward or dips inward.

- **Skeletal system:** The skull in Marfan syndrome is usually long (dolichocephalic), with prominent frontal eminences. Disorders of the ribs causing pectus excavatum (concave sternum) and pectus carinatum (pigeon breast) are conspicuous. Tendons, ligaments and joint capsules are weak, leading to hyperextensibility of the joints (double-jointedness), dislocations, hernias and often severe kyphoscoliosis.
- **Cardiovascular system:** ***The most important defect is in the aorta, where the tunica media is weak.*** This leads to variable dilation of the ascending aorta and a high incidence of dissecting aneurysms, usually of the ascending aorta. These may rupture into the pericardial cavity or extend down the aorta and rupture into the retroperitoneal space. Dilation of the aortic ring results in aortic regurgitation, which may be severe enough to produce angina pectoris and congestive heart failure. The mitral valve typically has redundant leaflets and chordae tendineae—leading to mitral valve prolapse syndrome (see Chapter 16). Patients most often die of cardiovascular disorders.

  The aorta shows marked fragmentation and loss of elastic fibers, with increased metachromatic mucopolysaccharide, which may accumulate in discrete pools. These features are sometimes called cystic medial necrosis of the aorta. Smooth muscle cells are enlarged and lose their orderly circumferential arrangement.
- **Eyes:** Ocular changes are common in Marfan syndrome. These include dislocation of the lens (ectopia lentis), severe myopia due to elongation of the eye and retinal detachment.

Untreated men with Marfan syndrome usually die in their 30s, and untreated women often die in their 40s. There is no cure, but life expectancy has increased significantly over the past few decades and now approaches that of the average person. Antihypertensive therapy and replacement of the ascending aorta and aortic valve with prosthetic grafts have significantly improved longevity.

Ehlers-Danlos Syndromes

Ehlers-Danlos syndromes (EDSs) are inherited disorders of connective tissue featuring remarkable hyperelasticity and fragility of the skin, joint hypermobility and often a bleeding diathesis.

EDS is clinically and genetically heterogeneous. Different forms may be inherited as autosomal dominant or recessive (autosomal or X-linked) traits depending on the specific mutation. The worldwide prevalence of all types is approximately 1 in 5000 (Table 6-6). Multiple genes on several chromosomes are associated with EDS, including the *ADAMTS2* gene at the terminal region of chromosome 5q. Procollagen cannot be processed correctly without an enzyme encoded by this gene. As a result, collagen fibrils are not assembled properly; they appear ribbon-like and disorganized. Cross-links, or chemical interactions, between collagen fibrils are also affected. ***Whatever the underlying biochemical defect, the result is deficient or defective collagen.*** Depending on the type of EDS, these molecular lesions are associated with conspicuous weakness of supporting structures of the skin, joints, arteries and viscera.

Classical EDS types 1 and 2 occur in 1 in 20,000–50,000 people. Both are autosomal dominant and affect types I and V collagen. Type 1 EDS typically presents with severe skin involvement, but in type 2 disease, the skin is only mildly to moderately affected. More than 50% of classical EDS is caused by mutations in the *COL5A1* gene at 9q34.2-q34.3 and some by mutations in *COL5A2* at 2q14-q32. Mutations in *COL1A1* on chromosome 17q21.33 are also responsible for the classic types of EDS. These gene mutations cause significant changes in the structure of connective tissue, which elicits the characteristic features of the classic types of EDS.

Hypermobility EDS type 3 affects 1 in 10,000–15,000 and can be either autosomal dominant or autosomal recessive. Joint hypermobility and chronic musculoskeletal pain are the most prominent features of EDS type 3; skin manifestations are less severe. Mutations of *TNXB* located at 6p21.3 prevent production of tenascin-X protein, which disrupts the normal organization of collagen fibrils and elastic fibers and leads to hypermobility.

Vascular EDS type 4 affects 1 in 100,000–250,000 individuals. Vascular EDS patients exhibit characteristic facial features (small chin, thin nose and lips, sunken cheeks), slight body habitus and translucent skin, through which veins appear prominently. This form of EDS is more serious than other types because autosomal dominant mutations in *COL3A1* at 2q31 produce a defect in type III collagen, resulting in fragile blood vessels that are liable to rupture. About 25% of patients with EDS type 4 experience significant complications by age 20, and more than 75% have life-threatening problems before age 40.

EDS type 6 is rare and causes severe kyphoscoliosis, blindness from retinal hemorrhage or rupture of the globe, and death from aortic rupture. Mutations in the *PLOD1* gene at 1p36.22 cause type 6 EDS. Other very rare types include EDS type 8 characterized by severe periodontal disease and loss of teeth by the third decade, and EDS type 9 with skeletal deformities and bladder diverticula during childhood, with a danger of bladder rupture.

PATHOLOGY AND CLINICAL FEATURES: All types of EDS show soft, fragile, hyperextensible skin. Patients typically can stretch their skin many centimeters and trivial injuries can lead to serious wounds. Sutures do not hold well, so surgical incisions often dehisce (burst open). Joint hypermobility allows unusual extension and flexion (e.g., as in the "human pretzel" and other contortionists), which may lead to subluxation or dislocation of joints. EDS type 4 is the most dangerous variety, owing to a tendency of the large arteries, bowel and gravid uterus to spontaneously rupture. Death from such complications is common in the third and fourth decades of life.

Many people with clinical abnormalities suggesting EDS do not match any of the documented types of this disorder. Further characterization of such cases is likely to expand the classification of EDS.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI), or brittle bone disease, is a group of inherited disorders in which a generalized abnormality of connective tissue is expressed principally as fragility of bone. OI is inherited as an autosomal dominant trait, although rare cases are transmitted as autosomal recessives.

MOLECULAR PATHOGENESIS: ***Genetic defects in the 8 types of OI are heterogeneous, but all affect type I collagen synthesis, helical structure or, rarely, other structural proteins in bone.*** The genes most commonly involved are *COL1A1* and *COL1A2,* which are required to form mature type I collagen. Point mutations may disrupt the α-helical structure of type I collagen by converting glycines that occur at every third amino acid position into bulkier amino acids. Or, alterations in the C-terminus and certain deletions can disrupt formation of mature type I collagen fibrils. Some patients have no family history and represent founders resulting from a sporadic mutation. The combined incidence of all forms is 1 in 20,000 live births in the United States.

PATHOLOGY AND CLINICAL FEATURES:

- **Type I** OI is characterized by a normal appearance at birth, but fractures of many bones occur during infancy and at the time the child learns to walk. Such patients have been described as being as "fragile as a china doll." Children with type I OI typically have blue sclerae as the deficiency in collagen fibers makes sclerae translucent so that choroidal veins are visible. Fractures and fusion of the bones of the middle ear restrict their mobility and often cause hearing loss. Type I collagen is normal, but the quantity is reduced by half (haploinsufficiency).
- **Type II** OI is usually fatal in utero or shortly after birth. Affected infants have a characteristic facies and skeletal abnormalities. Those who are born alive usually die of respiratory failure within their first month. Abnormal forms of collagen are the result of glycine substitution.
- **Type III** OI causes progressive deformities. It is ordinarily detected at birth by the baby's short stature and misshapenness caused by fractures in utero. Dental defects and hearing loss are common. Unlike other OI types, type III is often inherited as an autosomal recessive trait.
- **Type IV** OI resembles type I, but sclerae are normal and the phenotype is more variable.

Neurofibromatosis

The neurofibromatoses include two distinct autosomal dominant disorders characterized by development of multiple neurofibromas, which are benign Schwann cell tumors of peripheral nerves. These disorders involve all cells derived from the neural crest, including melanocytes in addition to Schwann cells and endoneurial fibroblasts. Thus, type 1 includes disorders of pigmentation as well as neural tumors.

Neurofibromatosis Type I (von Recklinghausen Disease)

Neurofibromatosis type I (NF1) is characterized by (1) disfiguring neurofibromas, (2) areas of dark pigmentation of the skin (café au lait spots), (3) pigmented lesions of the iris (Lisch nodules), (4) freckles in the groin or axilla, (5) optic nerve gliomas and (6) skeletal abnormalities, including thinning of the cortices of long bones (Fig. 6-20). It is one of the more common autosomal dominant disorders, occurring once in 4000 people of all races. The *NF1* gene has a very high rate of mutation, and over 500 mutations are known. Half of cases are sporadic rather than familial. NF1 was first described in 1882 by von Recklinghausen, but references to it can be found as early as the 13th century.

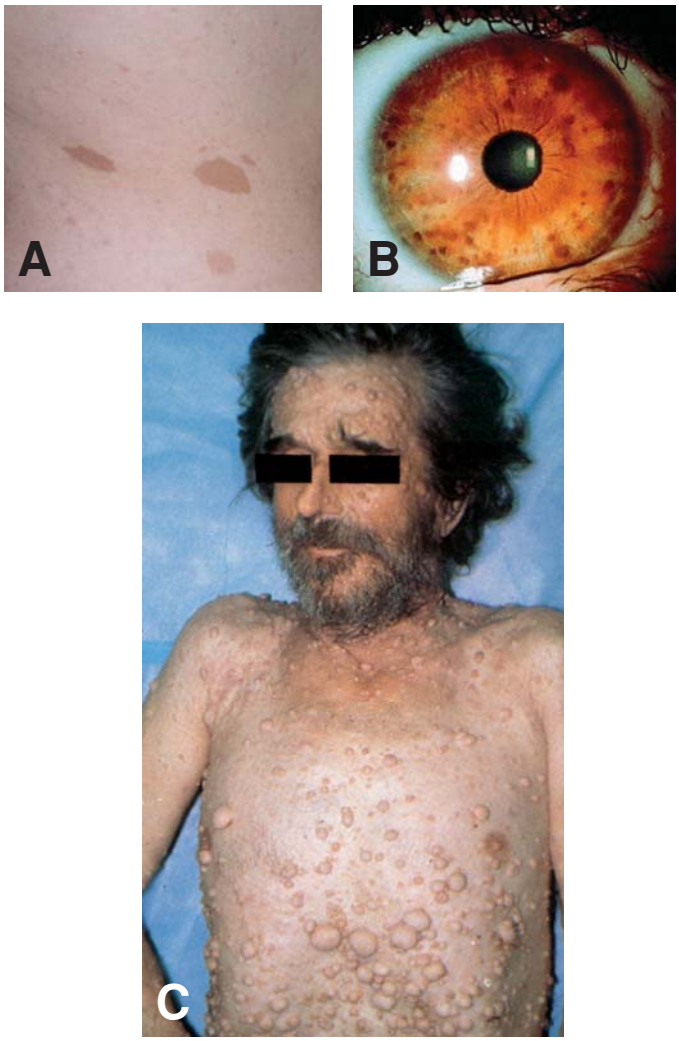

FIGURE 6-20. Features of neurofibromatosis type 1. A. Café au lait spots. **B.** Lisch nodules. **C.** Multiple cutaneous neurofibromas on the face and trunk.

MOLECULAR PATHOGENESIS: Germline mutations in the *NF1* gene, on the long arm of chromosome 17 (17q11.2), include deletions, missense mutations and nonsense mutations. The gene product, *neurofibromin,* belongs to a family of guanosine triphosphatase (GTPase)-activating proteins (GAPs), which inactivate the ras protein (see Chapter 5). In this sense, NF1 is a classic tumor suppressor. The loss of GAP activity permits uncontrolled ras activation, which greatly increases the risk of developing neoplasia in the form of neurofibromas. The high mutation rate for the *NF1* gene may reflect its large size (estimated to be 286 Kb). More than 250 mutations leading to protein truncation have been identified. The spontaneous mutation rate is 100 times greater than for many genes, and such mutations contribute to 30%–50% of neurofibromatosis cases. A more severe phenotype occurs in patients with complete gene deletion.

PATHOLOGY AND CLINICAL FEATURES: Clinical manifestations of NF1 are highly variable and include:

- **Neurofibromas:** Over 90% of patients with NF1 have cutaneous and subcutaneous neurofibromas by late childhood

or adolescence. These tumors may exceed 500 and appear as soft, pedunculated masses, usually about 1 cm (Fig. 6-20). On occasion, however, they may reach alarming proportions (up to 25 cm) and dominate a patient's physical appearance. Subcutaneous neurofibromas are soft nodules along the course of peripheral nerves. **Plexiform neurofibromas** only occur in the context of NF1 and usually involve larger peripheral nerves or occasionally cranial or intraspinal nerves. Plexiform neurofibromas are often large, infiltrative tumors that cause severe disfigurement (see Chapter 32). In 3%–5% of NF1 patients, a neurofibrosarcoma will develop in a neurofibroma, usually a larger plexiform one. Other neurogenic tumors, such as meningiomas, optic gliomas and pheochromocytomas, occur more often in NF1.

- **Café au lait spots:** Although normal people may have occasional light brown patches on the skin, greater than 95% of people with NF1 have 6 or more such lesions. These are over 5 mm before puberty and exceed 1.5 cm thereafter (Fig. 6-20). Café au lait spots tend to be ovoid, with the longer axis parallel to a cutaneous nerve. Numerous freckles, particularly in the axilla, are also common.
- **Lisch nodules:** Over 90% of patients with NF1 have pigmented nodules of the iris. These are masses of melanocytes (Fig. 6-20) and are felt to be hamartomas.
- **Skeletal lesions:** Bone lesions occur frequently in NF1. These include malformations of the sphenoid bone and thinning of the cortices of the long bones, with bowing and pseudarthrosis of the tibia, bone cysts and scoliosis.
- **Mental status:** Mild, but not severe, intellectual impairment is common in NF1.
- **Leukemia:** The risk of myeloid leukemias in children with NF1 is 200–500 times normal. In some patients, both alleles of the NF1 gene are inactivated in leukemic cells.

Neurofibromatosis Type II (Central Neurofibromatosis)

NF2 is a syndrome defined by bilateral tumors of the eighth cranial nerve (acoustic neuromas) and, commonly, by meningiomas and gliomas. NF2 is much less common than NF1, occurring in 1 in 40,000–45,000 people. Most patients have bilateral acoustic neuromas, but the condition can be diagnosed if a unilateral eighth nerve tumor occurs with two or more of the following: neurofibroma, meningioma, glioma, schwannoma or juvenile posterior lenticular opacity.

MOLECULAR PATHOGENESIS: Despite their superficial similarities, NF1 and NF2 are not variants of the same disease and have separate genetic origins. The *NF2* gene is on the long arm of chromosome 22 (22q,11.1-13.1). Unlike NF1, tumors in NF2 often show deletions or loss of heterozygous DNA markers in the affected chromosome. *NF2* encodes a tumor suppressor, **merlin** or **schwannomin,** a member of a superfamily of proteins that link the cytoskeleton to the cell membrane. This family also includes ezrin, moesin, radixin, talin and protein 4.1. Merlin is detectable in most differentiated tissues, including Schwann cells.

Achondroplastic Dwarfism

This is an autosomal dominant, hereditary disease of epiphyseal chondroblastic development that leads to inadequate enchondral bone formation (see Chapter 30). This distinctive form of dwarfism is characterized by short limbs with a normal head and trunk. Affected individuals have abnormal growth of the facial bones, which results in a small face, a bulging forehead and a deeply indented bridge of the nose. Achondroplastic dwarfism occurs once in 25,000 live births in all ethnic groups and is the most common type of short-limbed dwarfism.

MOLECULAR PATHOGENESIS: Achondroplasia reflects mutations in the basic fibroblast growth factor receptor 3 gene (*FGFR3*) with 75% arising de novo owing to advanced paternal age. This inactivating mutation removes the negative regulatory activity of this receptor on bone growth, resulting in abnormal cartilage formation and increased osteogenesis. Achondroplasia is discussed in Chapter 30.

Familial Hypercholesterolemia

Familial hypercholesterolemia is an autosomal dominant disorder characterized by high levels of LDLs in the blood and cholesterol deposition in arteries, tendons and skin. It is one of the most common autosomal dominant disorders, affecting 1 in 500 adults in the United States in its heterozygous form. Only 1 person in 1 million is homozygous for the disease. In this disease, there is a striking acceleration of atherosclerosis and its complications.

MOLECULAR PATHOGENESIS: The gene on the short arm of chromosome 19 that encodes the cell surface receptor for low-density lipoprotein (LDLR) is mutated in familial hypercholesterolemia. The LDL receptor removes LDL from the blood, a process that occurs mainly in the liver. Over 150 different mutations are known. The LDL receptor is made in the endoplasmic reticulum (ER), transferred to the Golgi and transported to the cell surface, where it resides in clathrin-coated pits. Once it binds LDL, the receptor and its ligand are internalized by receptor-mediated endocytosis and processed in lysosomes. Genetic defects in each step are known:

- **Class 1:** This, the most common defect, leads to failure to synthesize nascent LDLR protein in the ER, mostly owing to large deletions in the gene (null alleles).
- **Class 2:** These mutations impede transfer of nascent receptors from the ER to the Golgi (transport-defective alleles), preventing it from reaching the cell surface.
- **Class 3:** LDL receptors of class 3 mutations are expressed on the cell surface but are defective in the ligand-binding domain (binding-defective alleles).
- **Class 4:** These are rare mutations. LDL binds normally to its receptor, but the receptor does not cluster in coated pits. Thus, receptor internalization by endocytosis is blocked (internalization-defective alleles).
- **Class 5:** Internalized LDL–receptor complexes remain in endosomes, and receptors do not recycle to the plasma membrane (recycling-defective alleles).

Hepatocytes are the main cells that express LDLR, and roughly 70% of LDL is removed from the blood by the liver. After LDLs bind the receptor, they are internalized and processed in lysosomes, freeing cholesterol for further metabolism. If LDL receptor function is impaired, high levels of LDLs circulate and are taken up by tissue macrophages, which accumulate to form occlusive arterial plaques (atheromas), papules or nodules of lipid-laden macrophages (xanthomas; see Chapter 16).

CLINICAL FEATURES: Heterozygous and homozygous familial hypercholesterolemia are distinct clinical syndromes, reflecting a clear gene–dosage effect. In heterozygotes, total blood cholesterol (mean, 350 mg/dL; normal, <200 mg/dL in adults) is elevated at birth. Tendon xanthomas develop in half of the patients before age 30, and symptoms of coronary heart disease often occur before age 40. In homozygotes, blood cholesterol content is extremely high (600–1200 mg/dL), and virtually all patients have tendon xanthomas and generalized atherosclerosis in childhood. Untreated homozygotes typically die of myocardial infarction before age 30. Treatment of heterozygotes with statins has significantly reduced mortality and morbidity due to coronary heart disease to a level equivalent to that seen in the general population.

AUTOSOMAL RECESSIVE DISORDERS

Most genetic metabolic diseases show autosomal recessive inheritance (Fig. 6-21; Table 6-7). The fact that recessive genes are uncommon and the need for two mutant alleles to cause clinical disease determine the key characteristics of autosomal recessive inheritance. Some of the salient features of these disorders are:

- The more infrequent the mutant gene in the general population, the lower the chance that unrelated parents carry the trait. ***Rare autosomal recessive disorders often occur in offspring of consanguineous parents.***
- Both parents are usually heterozygous for the trait and are clinically normal.
- Symptoms appear in about 25% of their children. Half of all offspring are heterozygous for the trait and are asymptomatic. Thus, 2/3 of unaffected offspring are heterozygous carriers.
- Autosomal recessive traits are transmitted equally to males and females.
- Symptoms of autosomal recessive disorders tend to be more consistent than in autosomal dominant diseases. Recessive traits therefore present more commonly in childhood, while dominant disorders may initially appear in adults.

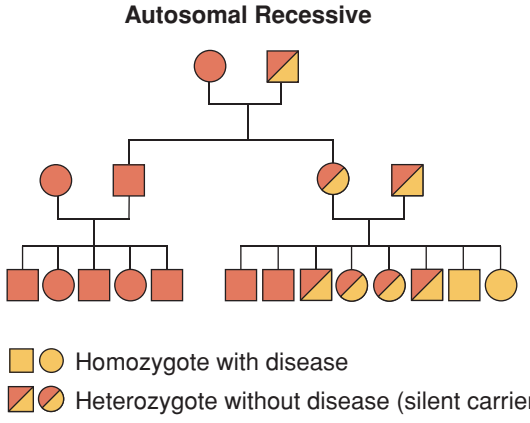

FIGURE 6-21. Autosomal recessive inheritance. Symptoms of the disease appear only in homozygotes, male or female. Heterozygotes are asymptomatic carriers. Symptomatic homozygotes result from the mating of asymptomatic heterozygotes.

TABLE 6-7
REPRESENTATIVE AUTOSOMAL RECESSIVE DISORDERS

Disease	Frequency	Chromosome
Cystic fibrosis	1/2500	7q
α-Thalassemia	High	16p
β-Thalassemia	High	11p
Sickle cell anemia	High	11p
Myeloperoxidase deficiency	1/2000	17q
Phenylketonuria	1/10,000	12q
Gaucher disease	1/50,000	1q
Tay-Sachs disease	1/300,000	15q
Hurler syndrome	1/100,000	22p
Glycogen storage disease Ia (von Gierke disease)	1/100,000	17
Wilson disease	1/50,000	13q
Hereditary hemochromatosis	1/1000	6p
α_1-Antitrypsin deficiency	1/7000	14q
Oculocutaneous albinism	1/20,000	11q
Alkaptonuria	<1/100,000	3q
Metachromatic leukodystrophy	1/100,000	22q

- Variability in clinical expression of some autosomal recessive diseases may reflect residual functionality of the affected protein. Such variability manifests in (1) different degrees of clinical severity, (2) age at onset or (3) the existence of acute and chronic forms of the specific disease.

Most mutant genes responsible for autosomal recessive disorders are rare in the general population, since those homozygous for the trait often die before reproductive age. However, a few autosomal recessive diseases, such as sickle cell anemia and cystic fibrosis (CF), are common. New mutations for recessive diseases are difficult to identify clinically because heterozygotes are asymptomatic. Nonconsanguineous mating of two such heterozygotes would occur by chance, and many generations later, if at all.

Biochemical Basis of Autosomal Recessive Disorders

Autosomal recessive diseases are usually due to deficiencies in enzymes rather than structural proteins. A mutation that inactivates an enzyme rarely causes an abnormal phenotype in heterozygotes: most cellular enzymes operate at substrate concentrations well below saturation, so an enzyme deficiency is easily corrected simply by increasing the amount of substrate. In autosomal recessive diseases caused by impaired catabolism of dietary substances (e.g., phenylketonuria, galactosemia) or cellular constituents (e.g., Tay-Sachs, Hurler),

increased substrate concentrations in heterozygotes overcome partial lack of the enzyme. By contrast, loss of both alleles in a homozygote results in complete loss of enzyme activity, which cannot be corrected by such mechanisms.

Cystic Fibrosis is the Most Common Lethal Autosomal Recessive Disorder in the Caucasian Population

CF is characterized by (1) chronic pulmonary disease; (2) deficient exocrine pancreatic function; and (3) other complications of inspissated/thickened mucus in several organs, including the small intestine, liver and reproductive tract. A defective chloride channel, the cystic fibrosis transmembrane conductance regulator (CFTR), is responsible.

EPIDEMIOLOGY: Cystic fibrosis is most common among whites. Among white Americans, about 1 in 29 people carry a mutation of the CF gene. One in 46 Hispanic Americans, 1 in 65 black Americans and 1 in 90 Asian Americans carry a CF gene mutation.

MOLECULAR PATHOGENESIS: The *CFTR* gene is on the long arm of chromosome 7 (7q31.2) (Table 6-7). It encodes a protein of 1480 amino acids that functions as a halide ion transporter in most epithelial cells. Its two adenosine triphosphate (ATP)-hydrolyzing domains drive transporter function. It also has two domains that anchor the transporter as a transmembrane spanning protein. Two R domains with phosphorylation sites for cyclic adenosine 3′,5′-monophosphate (cAMP)-dependent protein kinase A (PKA) regulate chloride channel activity.

CFTR activity is regulated by the balance between kinase and phosphatase activities (i.e., phosphorylation and dephosphorylation). Phosphorylation of the R domains, mostly by PKA, stimulates chloride channel activity. Secretion of chloride anions by mucus-secreting epithelial cells controls the parallel secretion of fluid and, thus, the viscosity of the mucus. In normal mucus-secreting epithelia, cAMP activates PKA, which phosphorylates the regulatory domains of CFTR and permits channel opening. Mutations in CFTR perturb this process. The most common mutation in the white population is loss of 3 base pairs, which deletes a phenylalanine (F) residue (ΔF_{508}), producing an abnormally folded protein that is degraded. ΔF_{508} accounts for 70% of CFTR mutations among whites. Mutations in the *CFTR* gene that disturb chloride channel function fall into several functional groupings (Fig. 6-22):

- **Failure of CFTR synthesis:** Mutations that result in premature termination signals interfere with synthesis of the full-length CFTR protein. As a result, no CFTR-mediated chloride secretion occurs in involved epithelia.
- **Failure of CFTR transport to the plasma membrane:** Some mutations prevent proper folding of the nascent protein, so it is then targeted for proteasomal degradation rather than for transport to the plasma membrane. The ΔF_{508} mutation is of this class.
- **Defective ATP binding to CFTR:** Certain mutations allow CFTR proteins to reach the plasma membrane but affect ATP-binding domains, thus interfering with channel regulation and limiting, but not abolishing, chloride secretion.
- **Defective chloride secretion by mutant CFTR:** Mutations in the channel pore inhibit chloride secretion.

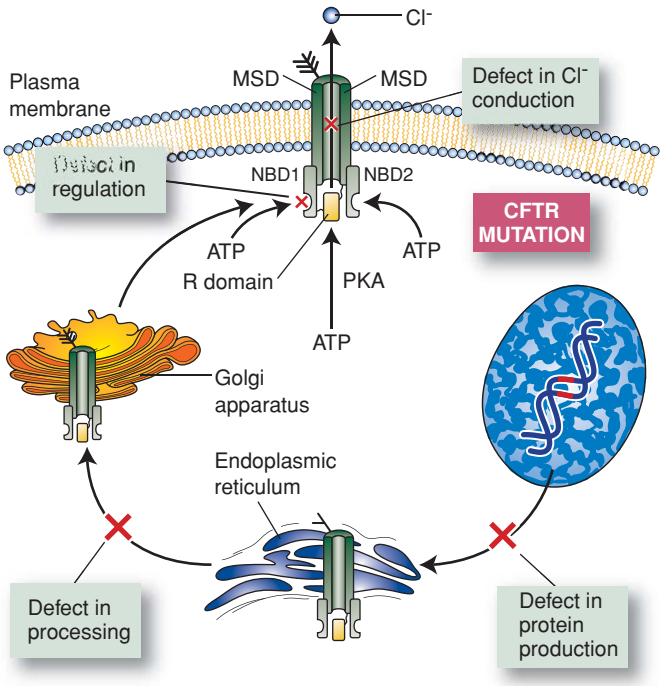

FIGURE 6-22. Cellular sites of disruption in the synthesis and function of the cystic fibrosis transmembrane conductance regulator (CFTR) in cystic fibrosis. *ATP* = adenosine triphosphate; *Cl–* = chloride ion; *MSD* = membrane-spanning domain; *NBD* = nucleotide-binding domain; *PKA* = protein kinase A.

The relationship between these genotypes (more than 1500 mutations are known) and the clinical severity of CF is complicated and not always consistent. The best correlation relates to pancreatic insufficiency. Severe symptoms are generally found in those with pancreatic insufficiency (85% of cases), while in milder cases pancreatic function is preserved. Class I and class II mutations are generally found among severely affected patients. By contrast, milder forms of CF have class III and class IV mutations.

Pathologic consequences of CF arise from abnormally thick mucus, which obstructs airway lumina, pancreatic and biliary ducts and the fetal intestine. CF was once called mucoviscidosis. Normal CFTR corrects the defect in chloride secretion in cultured cells from CF patients.

PATHOLOGY: CF affects many organs that produce exocrine secretions (Fig. 6-23).

RESPIRATORY TRACT: Lung disease causes most morbidity and mortality in CF. The earliest lesion is obstruction of bronchioles by mucus, with secondary infection and inflammation of bronchiolar walls. Recurrent cycles of obstruction and infection result in **chronic bronchiolitis** and **bronchitis,** which increase in severity as the disease progresses, and may lead to secondary pulmonary hypertension. Bronchial mucous glands undergo hypertrophy and hyperplasia, and airways are distended by thick, tenacious secretions. Widespread **bronchiectasis** is apparent by age 10 and often earlier. Late in the disease, large bronchiectatic cysts and lung abscesses are common.

PANCREAS: Most patients (85%) with CF have a form of **chronic pancreatitis,** and in long-standing cases, little or no functional exocrine pancreas remains. Inspissated secretions in central pancreatic ducts produce secondary dilation and cystic change of the distal ducts (Fig. 6-24). Recurrent pancreatitis leads to loss of acinar cells and extensive fibrosis so

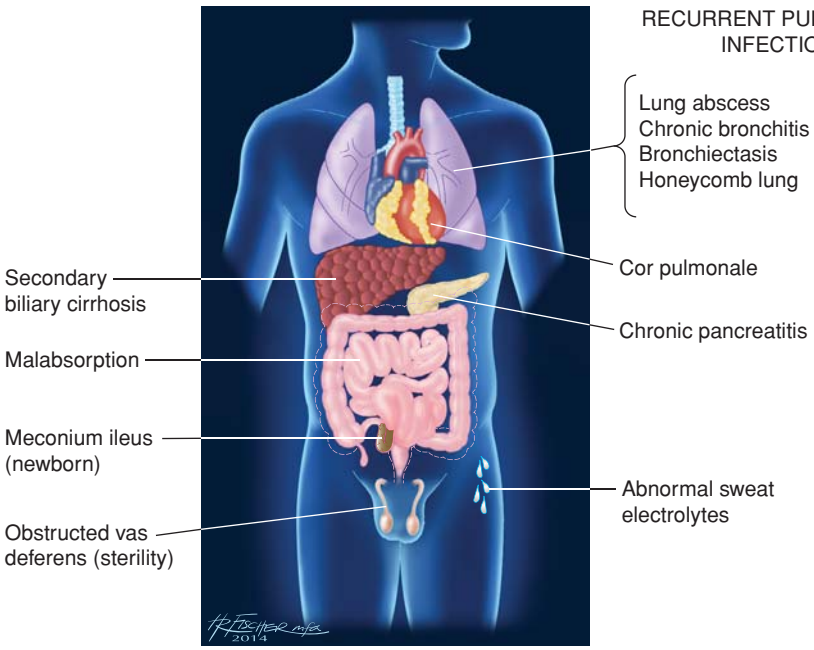

FIGURE 6-23. Clinical features of cystic fibrosis.

that the pancreas may become simply cystic fibroadipose tissue containing islets of Langerhans. The finding of pancreatic cysts and fibrosis led to the original name of cystic fibrosis.

LIVER: Inspissated mucous secretions in the intrahepatic biliary system obstruct bile flow in draining areas of the affected ducts and lead to focal **secondary biliary cirrhosis**. This is seen in 1/4 of patients at autopsy. Inspissated concretions clog bile ducts and ductules. Sometimes (<5%), hepatic lesions, which include chronic portal inflammation and septal fibrosis, are sufficiently widespread to lead to the clinical manifestations of biliary cirrhosis.

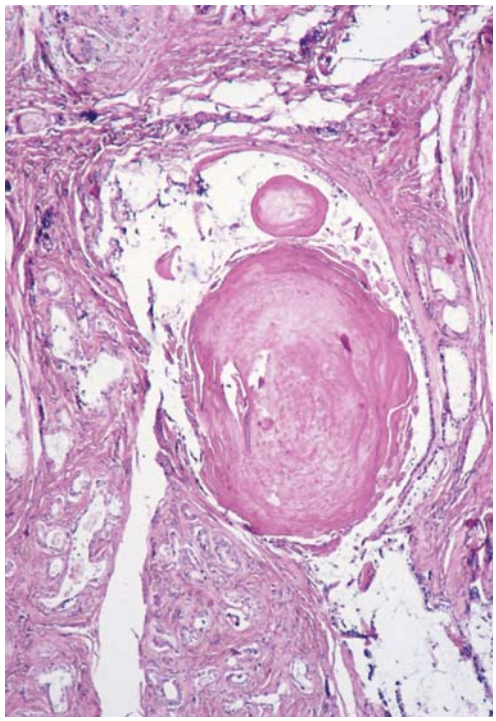

FIGURE 6-24. Intraductal concretion and acinar atrophy in the pancreas of a patient with cystic fibrosis.

GASTROINTESTINAL TRACT: Shortly after birth, a normal newborn passes the intestinal contents that have accumulated in utero (meconium). The most important lesion of the gut in CF is small bowel obstruction in newborns, **meconium ileus,** which is due to failure to pass meconium in the immediate postpartum period. This occurs in 5%–10% of newborns with CF and reflects the failure of pancreatic secretions to digest meconium, possibly augmented by the greater viscosity of small bowel secretions.

REPRODUCTIVE TRACT: Almost all boys with CF have atrophy or fibrosis of the reproductive duct system, including the vas deferens, epididymis and seminal vesicles. These lesions are due to luminal obstruction by inspissated secretions early in life and even in utero. Thus, only 2%–3% of males are fertile, with spermatozoa absent from the semen in the rest.

A minority of women with CF are fertile. Many suffer from anovulatory cycles as a result of poor nutrition and chronic infections. Moreover, the cervical mucous plug is abnormally thick and tenacious.

CLINICAL FEATURES: ***The diagnosis of CF is most reliably made by detecting increased electrolyte concentrations in the sweat and by genetic studies that show disease-causing mutations.*** Decreased chloride conductance in CF results in failure of chloride reabsorption by cells of sweat gland ducts and thus to accumulation of sodium chloride in the sweat. The skin in children with CF is salty and may even display salt crystals after vigorous sweating.

Pulmonary symptoms of CF begin with cough, which becomes productive of large amounts of tenacious and purulent sputum. Repeated bouts of infectious bronchitis and bronchopneumonia become progressively more frequent, and eventually dyspnea develops. Respiratory failure and cardiac complications of pulmonary hypertension (cor pulmonale) occur late.

The most common organisms that infect the respiratory tract in CF are *Staphylococcus* and *Pseudomonas* spp. As the disease advances, *Pseudomonas* may be the only organism cultured from the lung. ***In fact, recovery of*** Pseudomonas ***sp., particularly the mucoid variety, from the lungs of***

a child with chronic pulmonary disease is virtually diagnostic of CF. Infection with *Burkholderia cepacia* is associated with **cepacia syndrome,** a very severe pulmonary infection that is highly resistant to antibiotics and is commonly fatal.

Failure of pancreatic exocrine secretion leads to fat and protein malabsorption, causing bulky, foul-smelling stools (steatorrhea), nutritional deficiencies and growth retardation. Postural drainage of airways, antibiotic therapy and pancreatic enzyme supplementation are mainstays of treatment. Molecular prenatal diagnosis of CF is now accurate in 95% of cases.

In 1959, children with CF in the United States rarely survived for 1 year. With improved therapies, life expectancy has increased to 40 years.

Lysosomal Storage Diseases Are Enzyme Deficiencies That Cause Abnormal Accumulation of Substances within Lysosomes

Lysosomes are membrane-bound collections of hydrolytic enzymes that digest macromolecules (see Chapter 1). Lysosomal digestive enzymes are called "acid hydrolases" since their optimal activities occur at acidic pHs (pH 3.5–5.5). This environment is maintained by an ATP-dependent proton pump in the lysosomal membrane. These enzymes degrade virtually all types of biological macromolecules including lipids, glycoproteins and mucopolysaccharides. Extracellular macromolecules that are internalized by endocytosis or phagocytosis and intracellular constituents that are subjected to autophagy are digested in lysosomes to their basic components. End-products may be transported across lysosomal membranes into the cytosol, where they are reused in the synthesis of new macromolecules.

Virtually all lysosomal storage diseases result from mutations in genes for lysosomal hydrolases. Acid hydrolases may be nucleases, proteases, glycosidases, lipases, phosphatases, sulfatases and phospholipases; they make up lysosomes' 50 or so degradative enzymes. Deficiency in one of these acid hydrolases can prevent catabolism the normal macromolecular substrate of that enzyme. As a result, undigested substrates accumulate in, and engorge, lysosomes, expanding the lysosomal compartment of the cell. Resulting lysosomal distention impairs other critical cellular activities, particularly in the brain and heart, and can lead to poor cellular function or cell death.

Lysosomal storage diseases are classified by the material retained in the lysosomes. Thus, when accumulated substrates are sphingolipids, they are **sphingolipidoses**. Storage of mucopolysaccharides (glycosaminoglycans) leads to the **mucopolysaccharidoses**. Over 50 lysosomal storage diseases are known, but we limit our discussion to the more important ones.

Sphingolipidoses are lysosomal storage diseases characterized by accumulation of lipids derived from the turnover of obsolete cell membranes. Cerebrosides, gangliosides, sphingomyelin and sulfatides are all sphingolipid components of membranes of a variety of cells. These substances are degraded within lysosomes by complex pathways producing sphingosine and fatty acids (Fig. 6-25). Deficiencies of acid hydrolases that mediate specific steps in these pathways lead to accumulation of undigested intermediate substrates in lysosomes and hence a metabolic disorder.

Gaucher Disease

Gaucher disease is characterized by accumulation of glucosylceramide, mainly in macrophage lysosomes.

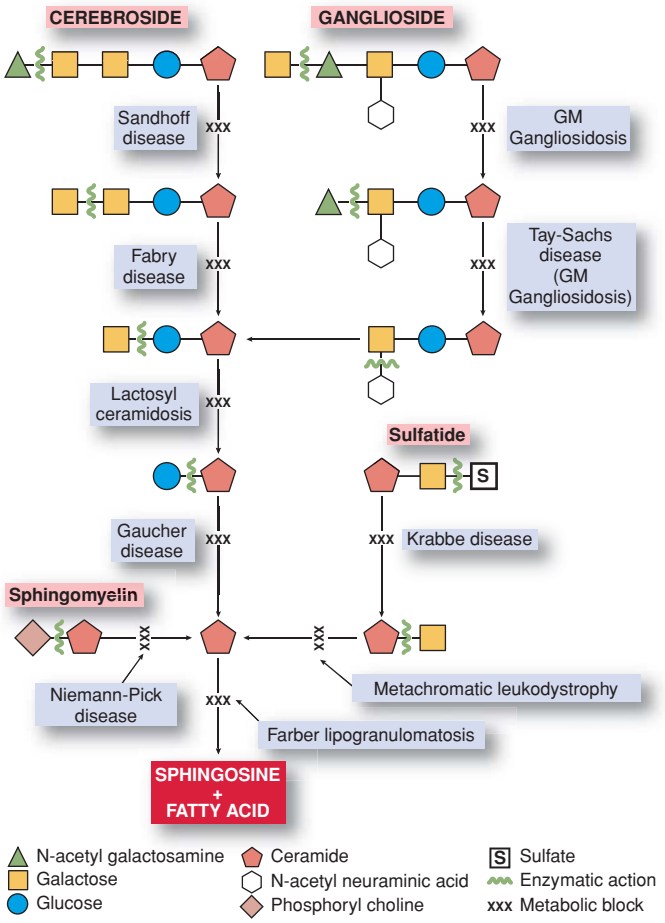

FIGURE 6-25. Disturbances of lipid metabolism in various sphingolipidoses.

MOLECULAR PATHOGENESIS: The abnormal enzyme is glucocerebrosidase, a lysosomal acid β-glucosidase. The enzyme deficiency can be traced to a variety of single base mutations in the β-glucosidase gene, on the long arm of chromosome 1 (1q21). Each of the clinical types of the disease (see below) exhibits heterogeneous mutations in this gene, although the molecular basis for the phenotypic differences remains unclear.

The glucosylceramide that accumulates in Gaucher cells of the spleen, liver, bone marrow and lymph nodes derives principally from catabolism of membranes of senescent leukocytes, which are rich in cerebrosides. When membrane degradation is blocked by a lack of glucocerebrosidase, glucosylceramide, the intermediate metabolite, accumulates. The glucosylceramide of Gaucher cells in the brain is believed to originate from turnover of plasma membrane gangliosides of cells in the CNS.

PATHOLOGY: The hallmark of this disorder is the presence of **Gaucher cells,** lipid-laden macrophages characteristically seen in the red pulp of the spleen, liver sinusoids, lymph nodes, lungs and bone marrow, although they may appear in virtually any organ. These cells are derived from resident macrophages in the respective organs (e.g., Kupffer cells in the liver and alveolar macrophages in the lung). In uncommon variants of Gaucher disease with CNS involvement, Gaucher cells originate from periadventitial cells in Virchow-Robin spaces.

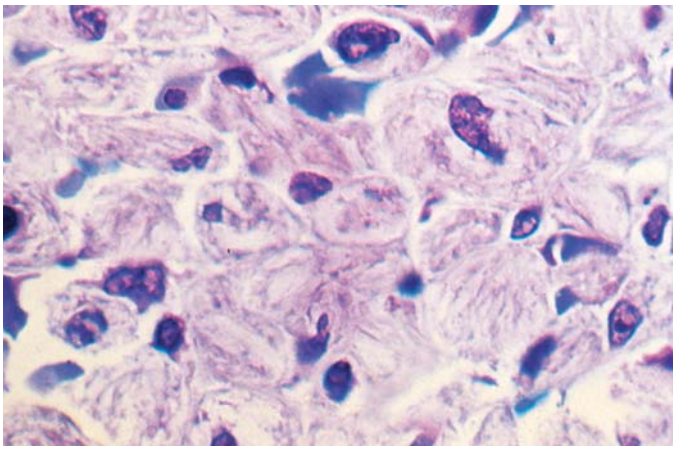

FIGURE 6-26. The spleen in Gaucher disease. Typical Gaucher cells have foamy cytoplasm and eccentrically located nuclei.

Gaucher cells are large (20–100 μm), with eccentric nuclei and clear cytoplasm (Fig. 6-26) that has a characteristic fibrillar appearance, which has been likened to "wrinkled tissue paper" and is intensely positive with periodic acid–Schiff (PAS) stain. The material is stored in enlarged lysosomes and appears as parallel layers of tubular structures.

Splenomegaly is virtually universal in Gaucher disease. In the adult form of the disorder, spleens may weigh up to 10 kg. The cut surface of the enlarged spleen is firm and pale and often contains sharply demarcated infarcts. The red pulp shows nodular and diffuse infiltrates of Gaucher cells and moderate fibrosis.

The liver is usually enlarged by Gaucher cells within sinusoids, but hepatocytes are not affected. In severe cases, hepatic fibrosis and even cirrhosis may ensue. Bone marrow involvement varies but leads to radiologic abnormalities in 50%–75% of cases.

Gaucher cells may also be found in many other organs, including lymph nodes, lungs, endocrine glands, skin, GI tract and kidneys, but symptoms referable to involvement of these organs are uncommon.

In the infantile (neuronopathic) form of the disease, Gaucher cells are also seen in the brain parenchyma, where they may stimulate gliosis and microglial nodules.

CLINICAL FEATURES: Gaucher disease is classified into three distinct forms, based on the age at onset and degree of neurologic involvement:

- **Type 1 (chronic nonneuronopathic):** This variant is the most common of the lysosomal storage diseases. It occurs in 1 in 40,000–60,000 in the general population and in 1 in 500–800 of those with Ashkenazi Jewish ancestry. Thus, the carrier rate is 1 in 12 Ashkenazi Jews. Age at onset is variable; some cases are diagnosed in infants and others at age 70. The severity of clinical manifestations also varies widely. Most cases are diagnosed as adults and present initially as painless splenomegaly and complications of hypersplenism including anemia, leukopenia and thrombocytopenia. Hepatomegaly is common, but clinical liver disease is infrequent. Bone involvement, manifesting as pain and pathologic fractures, can cause disability severe enough to confine a patient to a wheelchair.

  The life expectancy of most patients with type 1 Gaucher disease is normal. The disease is now treated by administering modified acid glucose cerebrosidase, although its high cost limits its use. Marrow transplantation is also effective but is little used because of the attendant risks. Prenatal diagnosis is based on β-glucosidase activity in amniotic fluid or chorionic villi. Prenatal DNA testing is now routinely available. As there are numerous mutations, sequencing of the affected gene is sometimes necessary to confirm the diagnosis.
- **Type 2 (acute neuronopathic):** Type 2 Gaucher disease is rare and quite different from type 1 in age at onset and clinical presentation. It usually presents by age 3 months with hepatosplenomegaly and has no ethnic predilection. Within a few months, infants show neurologic signs, with a classic triad of trismus, strabismus and backward flexion of the neck. Further neurologic deterioration rapidly ensues. Most patients die by age 3 years.
- **Type 3 (subacute neuronopathic):** This form is also rare and combines features of types 1 and 2. Neurologic deterioration starts later than in type 2 and progresses more slowly, with most living until about age 30.

Tay-Sachs Disease (GM_2 Gangliosidosis Type 1)

Tay-Sachs disease is a catastrophic infantile form of a class of lysosomal storage diseases known as the GM_2 gangliosidoses, in which this ganglioside is deposited in CNS neurons, owing to a failure of lysosomal degradation. The association of a "cherry-red spot" in the retina and profound mental and physical retardation was first pointed out in 1881 by Warren Tay, a British ophthalmologist. Fifteen years later, Bernard Sachs, an American neurologist, described the pathology of the disorder and coined the term "amaurotic (blind) family idiocy." Tay-Sachs disease is inherited as an autosomal recessive trait and is mainly seen in Ashkenazi Jews, among whom the carrier rate is about 1 in 30, with homozygotes seen in 1 in 4000 live newborns. By contrast, incidence in non–Jewish American populations is less than 1 in 100,000. Tay-Sachs disease is caused by a genetic mutation in the hexosaminidase A (HEXA) gene on (human) chromosome 15. Numerous HEXA mutations have been reported with significant frequencies in specific populations. The carrier frequency in French Canadians is similar to that in Ashkenazi Jews, but with different mutations. Interestingly, Cajuns of southern Louisiana carry the mutation seen most commonly in Ashkenazi Jews, which has been traced back to a founder couple in 18th-century France. Screening programs for heterozygous Ashkenazi Jews have reduced disease incidence by 90%. The other GM_2 gangliosidoses are very rare.

MOLECULAR PATHOGENESIS: Gangliosides are glycosphingolipids with a ceramide and an oligosaccharide chain that contains *N*-acetylneuraminic acid (Fig. 6-25). They are located in the outer leaflet of the plasma membrane of animal cells, particularly in brain neurons.

Lysosomal catabolism of ganglioside GM_2, 1 of the 12 known gangliosides in the brain, requires β-hexosaminidases (A and B), which have α- and β-subunits and need GM_2-activator protein. Deficiency in any of these components results in clinical disease.

Tay-Sachs disease (also known as hexosaminidase α-subunit deficiency) results from about 50 different mutations in the gene on chromosome 15q23–24 that codes for the α-subunit of hexosaminidase A (HEXA), with a resulting defect in the synthesis of this enzyme. An insertion of four

FIGURE 6-27. Tay-Sachs disease. A neuron contains lysosomes filled with whorled membranes.

nucleotides in exon 11 accounts for over 2/3 of the carriers among Ashkenazi Jews (i.e., about 2% of that population). The β-subunits are synthesized normally and associate to form hexosaminidase B dimers, levels of which are normal or even increased in Tay-Sachs disease.

Sandhoff disease is caused by a mutation in the gene for the β-subunit on chromosome 5 and leads to deficiencies of both hexosaminidases A and B.

A third, rare variant is the result of a defect in the synthesis of the GM_2-activator protein (chromosome 5) in the face of normal activities of the hexosaminidases.

PATHOLOGY: GM_2 ganglioside accumulates in lysosomes of all organs in Tay-Sachs disease, but it is most prominent in brain neurons and cells of the retina. The size of the brain varies with the length of survival of affected infants. Early cases are marked by brain atrophy, but the organ weight may be as much as doubled in those who survive beyond a year. Neurons are markedly distended with stored lipids. By electron microscopy, neurons are stuffed with "membranous cytoplasmic bodies," composed of concentric whorls of lamellar structures (Fig. 6-27). As disease progresses, neurons are lost and many lipid-laden macrophages are conspicuous in the cortical gray matter. Eventually, gliosis becomes prominent and myelin and axons in the white matter die. The pathologies of the other forms of GM_2 gangliosidosis are similar to those of Tay-Sachs disease, but usually less severe.

CLINICAL FEATURES: Tay-Sachs disease presents between 6 and 10 months of age with progressive weakness, hypotonia and decreased attentiveness. Motor and mental deterioration, often with generalized seizures, follow rapidly. Vision is seriously impaired. Retinal ganglion cell involvement is detected by ophthalmoscopy as a **cherry-red spot** in the macula. This feature reflects the pallor of the affected cells, which enhances the prominence of blood vessels underlying the central fovea. Most children with Tay-Sachs disease die before 4 years of age.

Niemann-Pick Disease

Niemann-Pick disease (NPD) is a form of sphingolipidosis involving dysfunctional catabolism of cell membrane sphingolipids. Macrophage lysosomes in many cells, especially in the liver and the brain, store **sphingomyelin**. There are several NPD variants; types A and B are caused by mutations in the *SMPD1* gene, which encodes the enzyme acid sphingomyelinase; type C is caused by mutations in the *NPC1* and *NPC2* genes, which encode lipid transport proteins.

Type A NPD appears in infancy, with hepatosplenomegaly and progressive neurodegeneration. Death occurs by 3 years of age. Type B NPD is more variable, with hepatosplenomegaly, minimal neurologic symptomatology and survival to adulthood. Type C NPD is biochemically, genetically and clinically distinct from types A and B NPD.

EPIDEMIOLOGY: The incidence of type A NPD is 1 in 40,000 among Ashkenazi Jews. In all other populations, both types A and B NPD occur in 1 in 250,000. For type C, incidence is 1 in 100,000. Total incidence for all types in the general population is thus 1 in 100,000.

MOLECULAR PATHOGENESIS: Sphingomyelin is a membrane phospholipid composed of phosphorylcholine, sphingosine (a long-chain amino alcohol) and a fatty acid (Fig. 6-25). It is especially abundant in myelin sheaths of nerve axons. It accounts for up to 14% of phospholipids of the liver, spleen and brain. The metabolic defect in NPD reflects 12 different mutations in the gene (11p15.1–15.4) for **sphingomyelinase,** the lysosomal enzyme that hydrolyzes sphingomyelin to ceramide and phosphorylcholine. In types A and B, this enzyme is completely or partially lacking. In type C, the protein product of the major mutated gene *NPC1* is not an enzyme but appears to function as a transporter in the endosomal-lysosomal system, which moves large water-insoluble molecules through the cell. The protein encoded by the *NPC2* gene more closely resembles an enzyme structurally but seems to cooperate with the NPC1 protein in transporting molecules in the cell. Disruption of this transport system causes cholesterol and glycolipids to accumulate in lysosomes.

PATHOLOGY: The characteristic storage cell in NPD is a foam cell, that is, an enlarged (20–90 μm) macrophage whose cytoplasm is distended by uniform vacuoles containing sphingomyelin and cholesterol. By electron microscopy, whorls of concentrically arranged lamellar structures distend lysosomes.

Foam cells are particularly abundant in the spleen, lymph nodes and bone marrow but also occur in the liver, lungs and GI tract. The spleen is enlarged, often massively, with foam cells distributed diffusely throughout the red pulp. Lymph nodes enlarged by foam cells are seen in many locations. Hematopoietic tissues in bone marrow may be displaced by aggregates of foam cells. The liver is enlarged by stored sphingomyelin and cholesterol in lysosomes of both Kupffer cells and hepatocytes.

The brain is the most important organ involved in type A NPD, and neurologic damage is the usual cause of death. Such brains are atrophied and in severe cases may be 1/2 of normal weight. Neurons are distended by vacuoles containing the same stored lipids found elsewhere in the body. In advanced cases, neuron loss is severe and may be accompanied by demyelination. Half of children with type A disease have cherry-red retinal spots, as in Tay-Sachs disease.

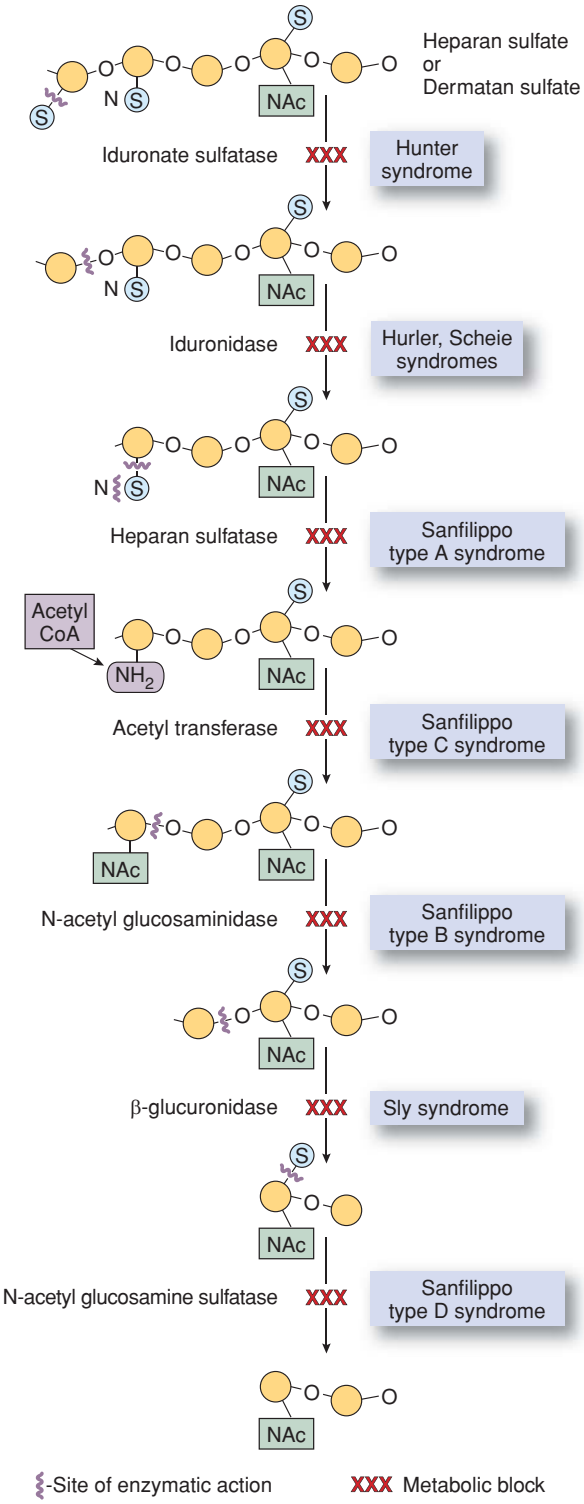

FIGURE 6-28. Metabolic blocks in various mucopolysaccharidoses that affect the degradation of heparan sulfate and dermatan sulfate with resulting syndromes. *Acetyl CoA* = acetyl coenzyme A; *Nac* = *N*-acetyl moiety.

TABLE 6-8
MUCOPOLYSACCHARIDOSES

Type	Eponym	Location of Gene	Clinical Features
I H	Hurler	4p16.3	Organomegaly, cardiac lesions, dysostosis multiplex, corneal clouding, death in childhood
I S	Scheie	4p16.3	Stiff joints, corneal clouding, normal intelligence, longevity
II	Hunter	X	Organomegaly, dysostosis multiplex, mental retardation, death earlier than 15 years of age
III	Sanfilippo	12q14	Mental retardation
IV	Morquio	16q24	Skeletal deformities, corneal clouding
V	Obsolete	—	—
VI	Maroteaux Lamy	5q13–14	Dysostosis multiplex, corneal clouding, death in second decade
VII	Sly	7q21.1–22	Hepatosplenomegaly, dysostosis multiplex

CLINICAL FEATURES: Type A NPD manifests in early infancy with conspicuous spleen and liver enlargement and psychomotor retardation. Motor and intellectual function are lost over time. Children usually die before 3 years of age. Most type B patients present in childhood with marked hepatosplenomegaly. Pulmonary infiltration with sphingomyelin-laden macrophages eventually impairs respiratory function. However, these patients have few neurologic symptoms and may survive for years. Progressive neurologic disease is the hallmark of Niemann–Pick type C disease and causes disability and early death in all cases beyond early childhood.

Mucopolysaccharidoses

Mucopolysaccharidoses (MPSs) are lysosomal diseases in which **glycosaminoglycans (mucopolysaccharides)** accumulate in many organs. All are inherited as autosomal recessive traits, except for Hunter syndrome, which is X-linked recessive. These rare diseases are caused by deficiencies in any of the 12 lysosomal enzymes that catabolize glycosaminoglycans (Fig. 6-28). Six abnormal phenotypes are described, each varying with the specific enzyme deficiency (Table 6-8).

MOLECULAR PATHOGENESIS: Glycosaminoglycans (GAGs) are large polymers of repeating disaccharide units containing *N*-acetylhexosamine and a hexose or hexuronic acid. Either disaccharide may be sulfated. The accumulated GAGs (dermatan sulfate, heparan sulfate, keratan sulfate and chondroitin sulfate) in MPSs all derive from cleavage of proteoglycans, which are important extracellular matrix constituents. GAGs are degraded stepwise by removing sulfates or sugar residues. Thus, a deficiency in any one of the glycosidases or sulfatases causes undegraded GAGs to accumulate. A special case is deficiency of an *N*-acetyltransferase, which leads to deposition of heparan sulfate in Sanfilippo C disease.

PATHOLOGY: Although the severity and location of lesions in MPSs vary with the specific enzyme deficiency, most of these syndromes share common features. Undegraded GAGs tend to accumulate in

connective tissue cells, mononuclear phagocytes (including Kupffer cells), endothelial cells, neurons and hepatocytes. Affected cells are swollen with clear cytoplasm. Stains for metachromasia confirm the presence of GAGs. Electron microscopy shows enlarged lysosomes containing granular or striped material. The most critical lesions involve the CNS, skeleton and heart, although hepatosplenomegaly and corneal clouding are common.

- Initially, the **CNS** only accumulates GAGs, but as the disease advances, extensive neurons die and gliosis occurs, leading to cortical atrophy. Communicating hydrocephalus, due to meningeal involvement, is common.
- **Skeletal deformities** result from CAG accumulation in chondrocytes, a process that eventually interferes with normal endochondral ossification. Abnormal foci of osteoid and woven bone are common in the deformed skeleton.
- **Cardiac** involvement is often severe, with thickening and distortion of valve leaflets, chordae tendineae and endocardium. Coronary arteries are frequently narrowed owing to proliferation of intimal smooth muscle cells containing GAG deposits.
- **Hepatosplenomegaly** is secondary to distention of Kupffer cells and hepatocytes and accumulation of GAG-filled macrophages in the spleen.

CLINICAL FEATURES: **Hurler syndrome** (MPS I) is the most severe clinical form of MPS and is the prototype for these syndromes. Deficiency of α-L iduronidase (IDUA) results in buildup of heparin sulfate and dermatan sulfate in various tissues (Fig. 6-28). Parents of affected children carry a mutant IDUA allele, at 4p16.3 on chromosome 4. The clinical features of other varieties of MPS are summarized in Table 6-8. The symptoms of Hurler syndrome appear at 6 months to 2 years of age. Children typically show skeletal deformities, enlarged livers and spleens, characteristic facies and joint stiffness. The combination of coarse facial features and dwarfism reminiscent of gargoyles on Gothic cathedrals accounts for the old term, **gargoylism,** for this syndrome.

Children with Hurler syndrome suffer developmental delay, hearing loss, corneal clouding and progressive mental deterioration, as well as increased intracranial pressure, due to communicating hydrocephalus. Most patients die from recurrent pulmonary infections and cardiac complications before they reach 10 years of age.

Prenatal diagnosis is possible for the MPSs and is routine in families with a history of Hurler or Hunter syndromes. Enzyme replacement therapy and bone marrow transplantation may reduce nonneurologic symptoms and pain.

Glycogenoses (Glycogen Storage Diseases)

MOLECULAR PATHOGENESIS: The glycogenoses are a group of at least 14 inherited disorders characterized by glycogen accumulation, mainly in the liver, skeletal muscle and heart. Each entity reflects a deficiency of one of the enzymes involved in glycogen metabolism (Fig. 6-29). Save for X-linked phosphorylase

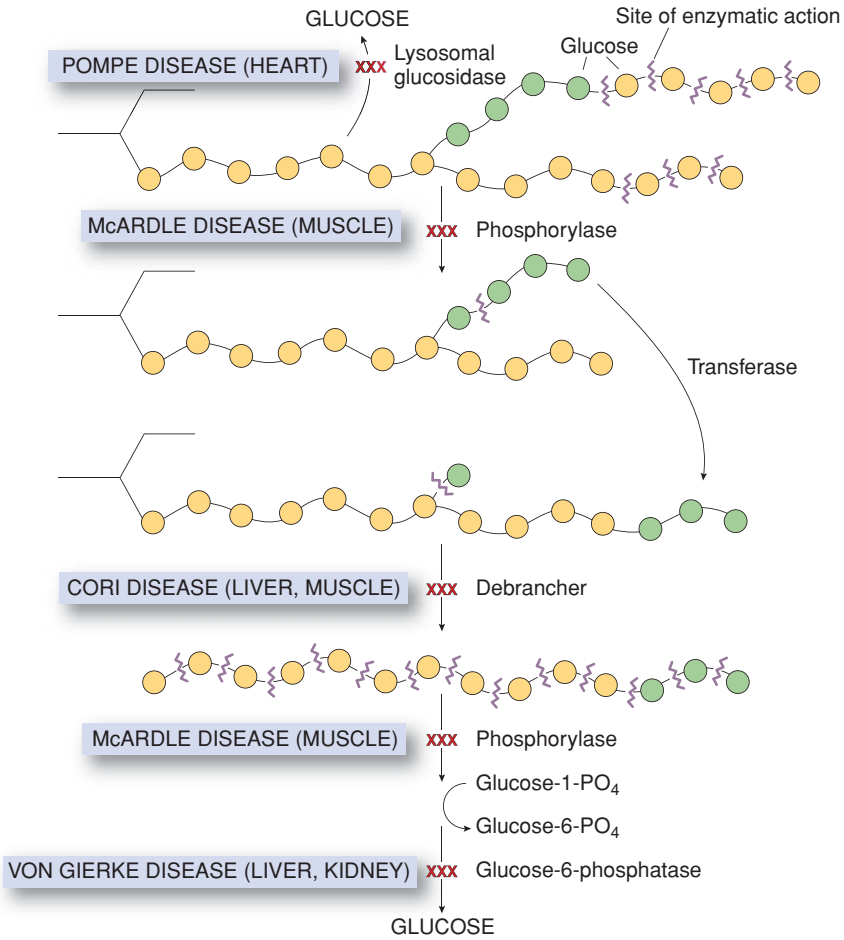

FIGURE 6-29. Sequential catabolism of glycogen and enzymes that are deficient in various glycogenoses. Glycogen is a long-chain branched polymer of glucose residues connected by α-1,4 linkages, except at branch points, where an α-1,6 linkage is present. Phosphorylase hydrolyzes α-1,4 linkages to a point three glucose residues distal to an α-1,6–linked sugar. These three glucose residues are transferred to the chain linked by α-1,4 bonds, by the bifunctional debrancher enzyme amylo-1,6-glucosidase. Subsequently, the same enzyme removes the α-1,6–linked sugar at the original branch point. This creates a linear α-1,4 chain, which is degraded by phosphorylase to glucose-1-phosphate. Following the conversion to glucose-6-phosphate, glucose is released by the action of glucose-6-phosphatase. A small proportion of glycogen is totally degraded within lysosomes by acid α-glucosidase. Red x's indicate a metabolic block and its associated glycogen storage disease.

kinase deficiency, all glycogen storage diseases are autosomal recessive traits. In the United States, they occur once in 20,000–25,000 births.

Glycogen is a large glucose polymer (20,000–30,000 glucose units per molecule) that is stored in most cells as a ready source of energy during fasting, although its function is different in each organ. Liver and muscle are particularly rich in glycogen. The liver stores glycogen not for its own use but rather to supply glucose to the blood quickly, particularly to benefit the brain. By contrast, glycogen in skeletal muscle is used as a local fuel when oxygen or glucose supplies fall. Glycogen is made and degraded by several enzymes, deficiency in any of which leads to accumulation of glycogen. Significant organ involvement varies with the specific enzyme defect. Some mainly affect the liver, while others principally cause cardiac or skeletal muscle dysfunction. Symptoms of glycogenosis may reflect accumulation of glycogen itself (Pompe disease, Andersen disease) or lack of the glucose normally derived from glycogen degradation (von Gierke disease, McArdle disease). We discuss only several representative examples of the known glycogenoses.

VON GIERKE DISEASE (TYPE IA GLYCOGENOSIS): In von Gierke disease, glucose-6-phosphatase is lacking. Glycogen accumulates in the liver, and symptoms reflect the inability of the liver to convert glycogen to glucose, leading to hepatomegaly and hypoglycemia. The disorder usually presents in infancy or early childhood. Growth is commonly stunted, but with treatment, the prognosis for normal mental development and longevity are generally good.

POMPE DISEASE (TYPE II GLYCOGENOSIS): Pompe disease is a lysosomal storage disease that involves virtually all organs and results in death from heart failure before the age of 2. Juvenile and adult variants are less common and have a better prognosis. The incidence of the disease is 1 in 140,000 for infantile GSD II and 1 in 60,000 for adult GSD II. Normally, a small proportion of cytoplasmic glycogen is degraded within lysosomes after an autophagic sequence. Type II glycogenosis is caused by a mutation in the gene for the lysosomal enzyme acid maltase/acid α-glucosidase (GAA) located on the long arm of chromosome 17 at 17q25.2-q25.3. It leads to inexorable accumulation of undegraded glycogen in lysosomes of many different cells. Patients do not develop hypoglycemia, because cytoplasmic metabolic pathways of glycogen synthesis and degradation are intact.

Without enzyme replacement therapy, the hearts of babies with infantile-onset Pompe disease progressively thicken and enlarge. These babies die before 1 year of age from cardiorespiratory failure or respiratory infection. For individuals with late-onset Pompe disease, prognosis depends on the age of onset. In general, the later the age of onset, the slower the disease progresses. Ultimately, prognosis depends on the extent of respiratory muscle involvement.

ANDERSEN DISEASE (TYPE IV GLYCOGENOSIS): Andersen disease is a very rare condition in which the branching enzyme (amyloglucantransferase; at 3p12) that creates the branch points in normal glycogen molecules is lacking. The absence of the branching enzyme leads to formation and accumulation of an abnormal, toxic form of glycogen, **amylopectin**. This starch-like material is deposited, mostly in the liver but also in the heart, skeletal muscles and nervous system. Children with this disease typically die between 2 and 4 years of age from **cirrhosis of the liver**. Liver transplantation is curative. After a liver transplant, cardiac and other extrahepatic deposits of amylopectin are greatly reduced by an unknown mechanism.

McARDLE DISEASE (TYPE V GLYCOGENOSIS): In McArdle disease, glycogen accumulates in skeletal muscles, owing to a lack of muscle phosphorylase, the enzyme that releases glucose-1-phosphate from glycogen. There are two autosomal recessive forms of this disease, childhood onset and adult onset. The gene for myophosphorylase, *PYGM* (the muscle type of the glycogen phosphorylase gene), is on chromosome 11q13. Nearly 100 different mutations, which vary among ethnic groups, have been implicated. Symptoms usually appear in adolescence or early adulthood and consist of muscle cramps and spasms during exercise, which may lead to myocytolysis and myoglobinuria. Aerobic exercise and high-protein diets have been effective therapies in some patients.

Cystinosis

Cystinosis is a lysosomal storage disease that occurs in 1 per 100,000–200,000 live births, in which crystalline cystine accumulates in lysosomes. **Cystinosin,** a transmembrane cystine transporter, is lacking. The affected gene is at chromosome 17p13. It is characterized by renal Fanconi syndrome (polydipsia, excretion of large amounts of dilute urine, dehydration, electrolyte imbalances, growth retardation and rickets) starting at 6–12 months of age. Untreated, cystinosis progresses to renal failure, often in childhood. Lung and brain function are often impaired in older patients. Cystine crystals are seen in almost all cells and organs. Renal transplantation can be used to treat the kidney disease. The use of cysteamine to decrease lysosomal cystine greatly slows disease progression and improves survival.

Inborn Errors of Amino Acid Metabolism Vary Greatly in Severity

Heritable disorders of the metabolism of many amino acids have been described (Table 6-9). Some are lethal in early childhood; others are clinically insignificant. Some of these are addressed in chapters on specific organs. This discussion

TABLE 6-9

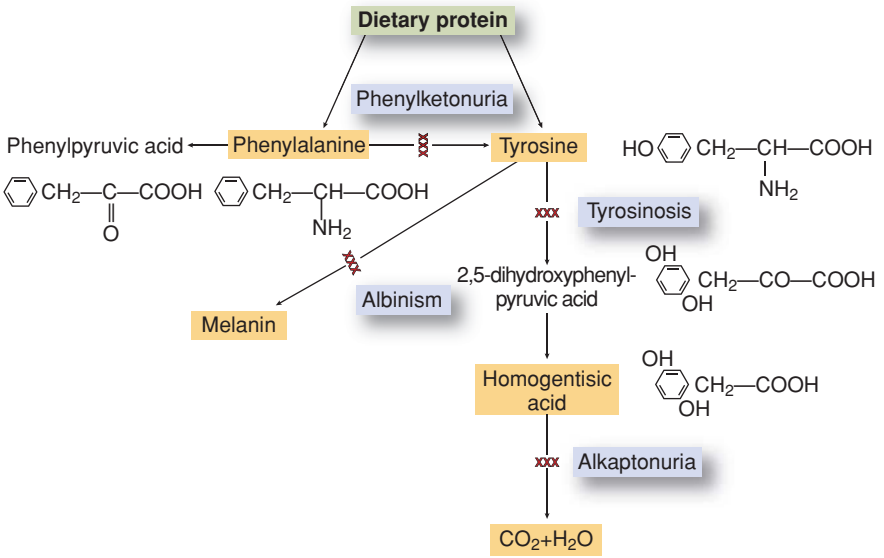

FIGURE 6-30. Diseases caused by disturbances of phenylalanine and tyrosine metabolism.

focuses on examples provided by defects in the metabolism of phenylalanine and tyrosine (Fig. 6-30).

Phenylketonuria

PKU **(hyperphenylalaninemia)** is an autosomal recessive deficiency of the hepatic enzyme phenylalanine hydroxylase. There are high circulating levels of phenylalanine, which leads to progressive mental deterioration in the first few years of life. The incidence of PKU is 1 per 10,000 in white and Asian populations, but it varies widely across different geographic areas. It is most frequent (1 in 5000) in Ireland and western Scotland and among Yemenite Jews.

MOLECULAR PATHOGENESIS: Phenylalanine is an essential amino acid derived exclusively from the diet. It is oxidized in the liver to tyrosine by phenylalanine hydroxylase (PAH). Deficiency in PAH causes hyperphenylalaninemia and formation of phenylketones by the transamination of phenylalanine. Phenylpyruvic acid and its derivatives are excreted in the urine, but phenylalanine itself, rather than its metabolites, causes the neurologic damage central to this disease. Thus, hyperphenylalaninemia is actually a more appropriate name than PKU.

Classic PKU is caused by mutations in the *PAH* gene on the long arm of chromosome 12 (12q22–24.1). Up to 400 mutations are known, most causing deficiency in PAH.

PATHOPHYSIOLOGY: The mechanism of neurotoxicity in hyperphenylalaninemia in infancy is not clear. Several processes have been implicated: competitive interference with amino acid transport systems in the brain, inhibition of neurotransmitter synthesis and disturbance of other metabolic processes. These effects presumably impair neuronal development and myelin synthesis.

PAH activity is not always totally lacking, and forms milder than classic PKU are known. In such cases, phenylpyruvic acid is not excreted in the urine. Patients with less than 1% of the normal PAH activity generally have a PKU phenotype, but those with more than 5% exhibit non-PKU hyperphenylalaninemia, do not suffer neurologic damage and develop normally. Non-PKU hyperphenylalaninemia is probably caused by mutations different from those in classic PKU.

Malignant hyperphenylalaninemia occurs in fewer than 5% of infants with the disease. In this case, dietary restriction of phenylalanine does not arrest neurologic deterioration. These patients have a deficiency in tetrahydrobiopterin (BH_4), a cofactor required for hydroxylation of phenylalanine by PAH. Sometimes this defect results from failure to regenerate BH_4, due to a lack of dihydropteridine reductase (DHPR), the enzyme that reduces dihydrobiopterin (BH_2) to the tetrahydro form (BH_4). The mutant *DHPR* gene is on the short arm of chromosome 4, and so is distinct from the *PAH* gene. Alternatively, in some cases synthesis of BH_4 is impaired. Infants with malignant hyperphenylalaninemia are phenotypically indistinguishable from those with classic PKU at first, but BH_4 deficiency also interferes with synthesis of the neurotransmitters dopamine (tyrosine hydroxylase dependent) and serotonin (tryptophan hydroxylase dependent). Thus, brain damage in malignant hyperphenylalaninemia most likely involves more than a simple elevation in phenylalanine levels.

CLINICAL FEATURES: Phenylketonuria illustrates the interaction between genetic and environmental factors in the pathogenesis of disease. It is caused by a genetic defect, but its expression requires a dietary constituent. Affected infants appear normal at birth, but mental retardation is evident within a few months. By 12 months, untreated infants have lost about 50 IQ points, which means that a child who would otherwise have normal intelligence has become severely retarded. Infants with PKU tend to have fair skin, blond hair and blue eyes, because the inability to convert phenylalanine to tyrosine leads to reduced melanin synthesis. They exude a "mousy" or "musty" odor, owing to the phenylacetic acid they make.

The main treatment for classic PKU patients is a strict phenylalanine-restricted diet supplemented by a medical formula containing amino acids and other nutrients. In the United States, the current recommendation is that the PKU diet should be maintained for life. Patients who are diagnosed early and maintain a strict diet can have a normal life span with normal mental development. However, recent studies suggest that neurocognitive and psychosocial development and growth are slightly suboptimal if the diet is not supplemented with amino acids.

In developed countries, the clinical phenotype of classical PKU is now more of historical interest than a significant concern. About 10 million newborns worldwide are screened annually for hyperphenylalaninemia by a simple blood test (Guthrie test), and new cases are promptly treated. The success of newborn PKU screening and the prompt use of a low-phenylalanine diet allow many PKU homozygotes to live normal lives and to reproduce. Expectant mothers homozygous for PKU (maternal PKU) must restrict phenylalanine intake while pregnant for the fetus to avoid complications of maternal hyperphenylalaninemia. Infants exposed to high levels of phenylalanine in utero show microcephaly, mental and growth retardation and cardiac anomalies. In other words, high levels of phenylalanine are teratogenic.

Tyrosinemia

There are three types of tyrosinemia. The most severe is type I, a rare (1 in 100,000) autosomal recessive inborn error of tyrosine catabolism caused by a shortage of the enzyme fumarylacetoacetate hydrolase (FAH). It manifests as acute liver disease in early infancy or as a more chronic disease of the liver, kidneys and brain in children.

MOLECULAR PATHOGENESIS: Blood levels of tyrosine and its metabolites are elevated. Fumarylacetoacetate hydrolase (15q23–25), the last enzyme in the catabolic pathway that converts tyrosine to fumarate and acetoacetate, is deficient in both acute and chronic forms of type I tyrosinemia. In the acute form, there is no enzyme activity, while children with chronic disease have variable residual activity. Cell injury in hereditary tyrosinemia is attributed to abnormal toxic metabolites, succinylacetone and succinylacetoacetate.

CLINICAL FEATURES: **Acute tyrosinemia** manifests in the first few months of life as hepatomegaly, edema, failure to thrive and a cabbage-like odor. Within a few months, infants die of hepatic failure.

Chronic tyrosinemia is characterized by cirrhosis of the liver, renal tubular dysfunction (Fanconi syndrome) and neurologic abnormalities. Hepatocellular carcinoma occurs in more than a third of these patients. Most children die before the age of 10. Liver transplantation corrects hepatic metabolic abnormalities and prevents the neurologic crises. Combined liver–kidney transplants have also been performed. Analysis of amniotic fluid for succinylacetone or of fetal cells for FAH establishes the diagnosis prenatally.

Alkaptonuria (Ochronosis)

This is a rare autosomal recessive disease affecting 1 in 250,000–1,000,000 people worldwide. It is more frequent in Slovakia and the Dominican Republic. Alkaptonuria has greater historical significance than clinical importance: reports of Garrod and others 100 years ago of the inheritance of alkaptonuria helped define the idea of hereditary inborn errors of metabolism.

PATHOPHYSIOLOGY: Alkaptonuria is due to a defect in the enzyme homogentisate 1,2-dioxygenase (HGD), which participates in tyrosine degradation. This deficiency prevents catabolism of homogentisic acid, an intermediate gene product in phenylalanine and tyrosine metabolism. As a result, homogentisic acid and its oxide, alkapton, accumulate in the blood and are excreted in urine in large amounts. Excessive homogentisic acid causes damage to cartilage (ochronosis, leading to osteoarthritis) and heart valves as well as precipitating as kidney stones.

PATHOLOGY AND CLINICAL FEATURES: Patients with alkaptonuria excrete urine that darkens rapidly on standing, owing to formation of a pigment on the nonenzymatic oxidation of homogentisic acid (Fig. 6-31). In long-standing alkaptonuria, a similar pigment is deposited in numerous tissues, particularly the sclerae, cartilage in many areas (ribs, larynx, trachea), tendons and synovial membranes. Although the pigment is bluish black on gross examination, it is brown under the microscope, hence the term **ochronosis** (color of ocher) coined by Virchow. A degenerative and frequently disabling **arthropathy** ("ochronotic arthritis") often develops after years of alkaptonuria. It is tempting to ascribe the joint disease to the pigment deposition, but this is not proven. Despite affecting many organs, alkaptonuria does not reduce longevity.

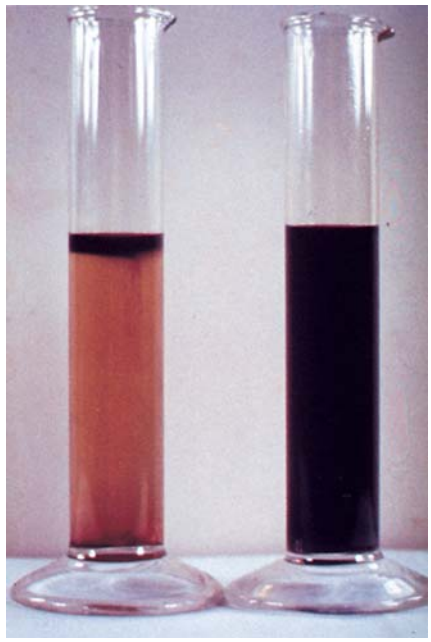

FIGURE 6-31. Urine from a patient with alkaptonuria. The specimen on the left, which has been standing for 15 minutes, shows some darkening at the surface, owing to the oxidation of homogentisic acid. After 2 hours (*right*), the urine is entirely black.

Albinism

Albinism is a heterogeneous group of at least 10 inherited disorders in which absent or reduced biosynthesis of melanin causes hypopigmentation. It is found throughout the animal kingdom (from insects to humans). Type 1 albinism is caused by defects in production of melanin pigment. Type 2 albinism is due to a defect in the "P" gene, which interferes with metabolism of tyrosine, a precursor of melanin. People with this type have slight coloring at birth.

Hermansky-Pudlak syndrome (HPS) is a form of oculocutaneous albinism caused by recessive mutations in various genes. Depending on the affected gene, it can occur with a bleeding disorder, immunodeficiency and/or lung and bowel diseases. Other complex diseases may lead to loss of coloring in only a certain area (localized albinism). These conditions include Chediak-Higashi syndrome (lack of coloring all over the skin, but not complete; see Chapter 2); tuberous sclerosis (small areas without skin coloring; see Chapter 5); Waardenburg syndrome (often a lock of hair that grows on the forehead, or no coloring in one or both irises).

The most common type is oculocutaneous albinism (OCA), a family of closely related diseases that (with one rare exception) are autosomal recessive traits. In OCA, melanin pigment is absent or reduced in the skin, hair follicles and eyes. The frequency of OCA in whites is 1 per 18,000 in the United States and 1 in 10,000 in Ireland. Blacks have the same high frequency of OCA as the Irish.

PATHOPHYSIOLOGY: Two major forms of OCA are distinguished by the presence or absence of tyrosinase, the first enzyme in the biosynthetic pathway that converts tyrosine to melanin (Fig. 6-30).

Tyrosinase-positive OCA is the most common type of albinism in whites and blacks. Patients typically begin life with complete albinism, but with age, a small amount of clinically detectable pigment accumulates. A defect in the *P* gene (15q11.2-13), which may encode a tyrosine transport protein, prevents melanin synthesis.

Tyrosinase-negative OCA is the second most common type of albinism and is characterized by complete absence of tyrosinase (11q14-21) and melanin: melanocytes are present but contain unpigmented melanosomes. Affected people have snow-white hair, pale pink skin, blue irides and prominent red pupils, owing to an absence of retinal pigment. They typically have severe ophthalmic problems, including photophobia, strabismus, nystagmus and poor visual acuity.

The skin of all types of albinos is strikingly sensitive to sunlight. Exposed skin areas require strong sunscreens. These patients have greatly increased risk for squamous cell carcinomas of sun-exposed skin. In fact, among a group of more than 500 albinos in equatorial Africa, nearly all succumbed to cancer before age 40. Interestingly, albinos seem to have a below-normal frequency of malignant melanoma.

X-LINKED DISORDERS

Expression of X-linked disorders (Fig. 6-32) is different in males and females. Females, with two X chromosomes, may be homozygous or heterozygous for a given trait. It follows that clinical expression of the trait in a female is variable, depending on whether it is dominant or recessive. Males, having one X chromosome, are hemizygous for that trait and express it regardless of whether the trait is dominant or recessive.

X-linked traits are not transmitted from father to son: a symptomatic father donates only a normal Y chromosome to his male offspring. By contrast, he always donates his abnormal X chromosome to his daughters, who are thus obligate carriers of the trait. The disease thus skips a generation in males, as female carriers transmit it to grandsons of a symptomatic male.

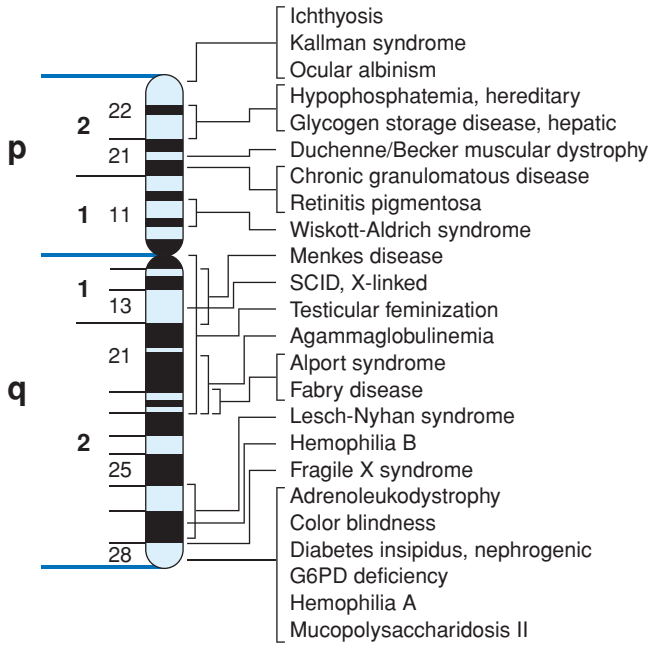

FIGURE 6-32. Localization of representative inherited diseases on the X chromosome. *G6PD* = glucose-6-phosphate dehydrogenase; *SCID* = severe combined immunodeficiency (syndrome).

X-Linked Dominant Traits

MOLECULAR PATHOGENESIS: X-linked dominance refers to expression of a trait only in females, since the hemizygous state in males precludes distinction between dominant and recessive inheritance (Fig. 6-33). The distinctive features of X-linked dominant disorders are:

- Females are affected twice as often as males.
- Heterozygous women transmit disease to half their children, both male and female.
- A man with a dominant X-linked disorder transmits it only to his daughters.
- Clinical expression of disease tends to be less severe and more variable in heterozygous females than in hemizygous males.

Only a few X-linked dominant disorders are known, including familial hypophosphatemic rickets and ornithine transcarbamylase deficiency. Phenotypic variation in these traits in females may reflect, at least in part, the Lyon effect (i.e., inactivation of one X chromosome), which produces mosaicism for the mutant allele, and inconstant expression of the trait.

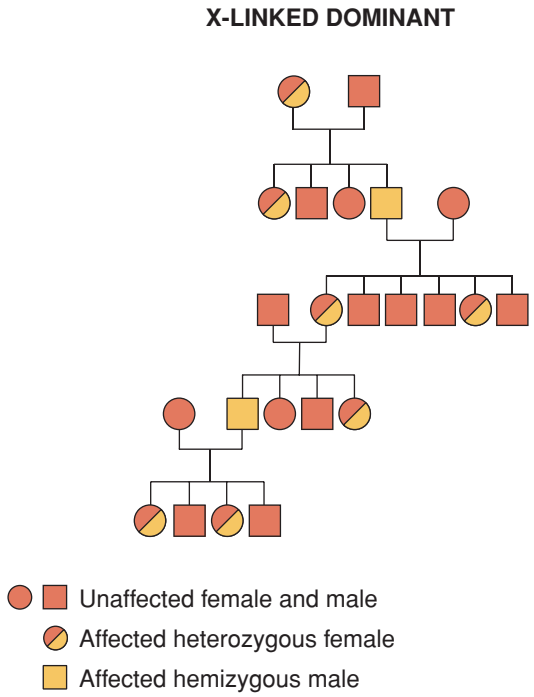

FIGURE 6-33. X-linked dominant inheritance. A heterozygous woman transmits the trait equally to males and females; men transmit the trait only to their daughters. Asymptomatic males and females do not carry the trait.

X-Linked Recessive Traits

Most X-linked traits are recessive; that is, heterozygous females do not manifest clinical disease (Fig. 6-34). The characteristics of this mode of inheritance are:

- Sons of women who are carriers have a 50% chance of inheriting the disease. Daughters are not symptomatic, but 50% of daughters will also be carriers.
- All daughters of affected men are asymptomatic carriers, but the sons of these men do not have the trait and cannot transmit it to their children.
- Symptomatic homozygous females can result from a rare mating of an affected man with an asymptomatic, heterozygous woman. Or, lyonization may preferentially inactivate the normal X chromosome, which, in extreme cases, may lead to an affected heterozygous female.
- The trait tends to occur in maternal uncles and in male cousins descended from the mother's sisters.

TABLE 6-10
REPRESENTATIVE X-LINKED RECESSIVE DISEASES

Disease	Frequency in Males
Fragile X syndrome	1/4000
Hemophilia A (factor VIII deficiency)	1/10,000
Hemophilia B (factor IX deficiency)	1/70,000
Duchenne-Becker muscular dystrophy	1/3500
Glucose-6-phosphate dehydrogenase deficiency	Up to 30%
Lesch-Nyhan syndrome (HPRT deficiency)	1/10,000
Chronic granulomatous disease	Not rare
X-linked agammaglobulinemia	Not rare
X-linked severe combined immunodeficiency	Rare
Fabry disease	1/40,000
Hunter syndrome	1/70,000
Adrenoleukodystrophy	1/100,000
Menkes disease	1/100,000

HPRT = hypoxanthine-guanine phosphoribosyltransferase.

Table 6-10 lists representative X-linked recessive disorders.

X-Linked (Duchenne and Becker) Muscular Dystrophies

The muscular dystrophies are devastating muscle diseases. Most are X-linked, although a few are autosomal recessive. The X-linked muscular dystrophies are among the most common human genetic diseases, occurring in 1 per 3500 boys, an incidence approaching that of CF. The most common X-linked recessive disorders include ***Duchenne muscular dystrophy (DMD)*** and ***Becker muscular dystrophy (BMD)***. DMD, the most common variant, is a fatal progressive degeneration of muscle that appears before the age of 4 years. It is associated with mutations in the dystrophin gene, the largest gene on the X chromosome, and characterized by rapid progression

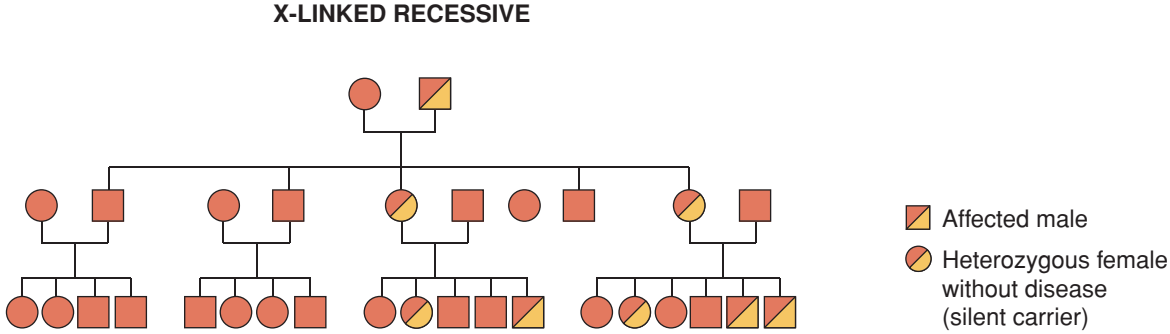

FIGURE 6-34. X-linked recessive inheritance. Only males are affected; daughters of affected men are all asymptomatic carriers. Asymptomatic men do not transmit the trait. Clinical expression of the disease skips a generation.

of muscle degeneration, with eventual loss of skeletal muscle control, respiratory failure and death. BMD is allelic with DMD but is milder and causes slowly progressive muscle weakness of the legs and pelvis (see Chapter 31).

Hemophilia A (Factor VIII Deficiency)

Hemophilia A (see Chapter 26) is an X-linked recessive disorder of blood clotting that results in spontaneous bleeding, mainly into joints, muscles and internal organs. It is caused by deficiency of factor VIII due to a mutation in the factor VIII gene.

Red-Green Color Blindness

Red-green color blindness is a very common trait in humans. Between 7% and 10% of men and 0.49% and 1% of women are affected. It is most commonly inherited as an X-linked recessive condition, but mutations involving as many as 19 chromosomes and 56 genes have been implicated in rare forms of this disorder.

Fragile X Syndrome

Fully 20% of heritable mental retardation is due to X-linked disorders, and 1/5 of these reflect an inducible fragile site on the X chromosome. A **fragile site** represents a specific locus, or band, on a chromosome that breaks easily under certain conditions. Fragile X syndrome (FXS) is second only to Down syndrome as a genetic cause of mental retardation. The prevalence of FXS in males is 1 in 3600–4000 and in females is 1 in 4000–6000.

MOLECULAR PATHOGENESIS: Mutations in the *FMR1* gene (Xq27.2) cause fragile X syndrome. This gene encodes a protein called fragile X mental retardation 1 protein, or FMRP, which helps regulate production of other proteins and plays a role in synapse development. Nearly all cases of fragile X syndrome are caused by a mutation in which DNA in the 5′ untranslated region, known as the CGG triplet repeat, is expanded within *FMR1*. In normal people, this DNA segment is repeated from 5 to 45 times. In people with FXS, however, it is repeated over 200 times. The abnormally expanded CGG silences the gene through a mechanism involving methylation of selected nucleotides. Resultant loss or deficiency of the protein disrupts nervous system functions, leading to the signs and symptoms of fragile X syndrome.

Males and females with 50–200 repeats of the CGG segment are said to have *FMR1* gene **premutation**. About 1 in 260 females and 1 in 800 males are carriers of fragile X premutation. Most people with premutation are intellectually normal, although sometimes they have lower than normal amounts of FMRP. As a result, premutation may cause mild versions of the physical features of fragile X syndrome and lead to emotional problems such as anxiety or depression. Some children with a premutation may have learning disabilities or autistic-like behavior.

Fragile sites are detected in cytogenetic preparations as a nonstaining gap or constriction (Fig. 6-16). When the cells in culture are treated to impair DNA synthesis (e.g., with methotrexate, floxuridine), fragile sites are revealed. Most people have at least 11, and possibly up to 50, fragile sites, on autosomes and on the X chromosome. However, the locus at Xq27.2 is associated with mental retardation and other clinical findings that characterize fragile X syndrome. As discussed, the fragile site at Xq27 is a distinct kind of mutation characterized by amplification of a CGG repeat.

Within fragile X families, the probability of being affected is related to position in the pedigree: later generations are more likely than earlier ones to be affected **(Sherman paradox** or **genetic anticipation).** This is due to progressive triplet repeat expansion (Fig. 6-35). Chromosomes with more than about 52 repeats can increase the number of repeats—so-called expansion. Small expansions tend to be asymptomatic but can

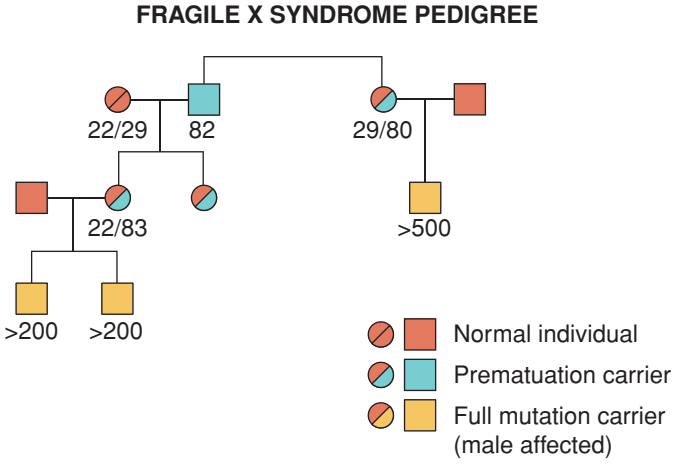

FIGURE 6-35. A. Inheritance pattern of fragile X syndrome. The number of copies of the trinucleotide repeat (CGG) in each X chromosome is shown below selected members in this pedigree. Expansion occurs primarily during meiosis in females. When the number of repeats exceeds ~200, the clinical syndrome is manifested. Individuals shaded orange carry a premutation and are asymptomatic. **B. Male diagnosed with fragile X syndrome.**

enlarge, particularly during meiosis in females, leading to larger expansions in successive generations. Expansions with over 200 repeats are associated with mental retardation and are considered full mutations of the FMR1 gene locus. Expansion of a premutation to a full mutation during gametogenesis occurs only in females (Fig. 6-35). Thus, daughters of men with premutations (carriers) are never clinically symptomatic but always harbor the premutation. However, sisters of transmitting males occasionally produce affected daughters. *The frequency of conversion of a premutation to a full mutation in such women (i.e., the probability that their sons will have fragile X syndrome) varies with the length of the expanded tract.* Premutations with more than 90 repeats are almost always converted to full mutations. Hence, the risk of the disorder increases in succeeding generations of fragile X families. As the syndrome is recessive, most daughters of carrier males transmit mental retardation to 50% of their sons.

CLINICAL FEATURES: A male newborn with FXS appears normal, but during childhood, typical features appear, including increased head circumference and elongated face, large protruding ears (Fig. 6-35B), joint hyperextensibility, enlarged testes and hypotonia. Mental retardation is profound: IQ scores vary from 20 to 60. Interestingly, a significant proportion of autistic boys have a fragile X chromosome. Among mentally handicapped female carriers, the severity of the impairment varies from a learning disability with normal IQ to serious retardation. About 80% of males with the Xq27.2 fragile site are mentally retarded; the others have expansions of less than 200 copies and are clinically normal but can transmit the trait.

A syndrome characterized by tremors, ataxia and declining cognitive abilities has been described in elderly men with fragile X premutations. This disorder has some clinical similarities to Parkinson disease and Alzheimer disease and has been called fragile X tremor ataxia syndrome (FTAXS).

Two thirds of females who carry a fragile X chromosome (obligate carriers) are intellectually normal, and the fragile site on the X chromosome cannot be demonstrated. By contrast, virtually all the 1/3 of female carriers who are mentally retarded display a fragile Xq27.2 locus. This phenotypic variability in females may relate to the pattern of X chromosome inactivation.

Molecular DNA diagnostic testing is now available to identify fragile X premutation carriers and those with the full fragile X syndrome mutation.

Fabry Disease

Fabry disease is an X-linked lysosomal storage disease. The X-linked recessive mutations cause deficiency of **α-galactosidase A,** which leads to accumulation of globotriaosylceramide and other glycosphingolipids in endothelial and smooth muscle cells throughout the vasculature, especially in coronary arteries, renal glomeruli, cardiac myocytes and components of the cardiac conduction system. A particular type of tumor, angiokeratoma, is a characteristic cutaneous manifestation of Fabry disease. Functionally affected microvasculature becomes increasingly compromised, causing progressive vascular insufficiency with cerebral, renal and cardiac infarcts. Patients die in early adulthood from complications of their vascular disease. Therapy with recombinant α-D-galactosidase A shows promise in arresting the disease.

MITOCHONDRIAL DISEASES

MOLECULAR PATHOGENESIS: Proteins in mitochondria are encoded by both nuclear and mitochondrial genes. Most mitochondrial respiratory chain proteins are encoded by nuclear genes, but 13 such proteins are products of the mitochondrial genome. The remaining 1500 or so proteins in mitochondria are nuclear encoded. A few rare, autosomal recessive (mendelian) disorders are caused by defects in nuclear-encoded mitochondrial proteins. Defects in nuclear-encoded mitochondrial proteins have also been associated with complex (i.e., polygenic rather than mendelian) disorders such as anemia, hypertension, dementia and neurodevelopmental disorder. However, most inherited defects in mitochondrial function result from mutations in the mitochondrial genome itself.

To understand these conditions, an explanation of the unique genetics of the mitochondria is needed. These features include:

- **Maternal inheritance:** All vertebrate mitochondria are inherited from the mother via the ovum, which has up to 300,000 copies of mitochondrial DNA (mtDNA).
- **Variability of mtDNA copies:** The number of mitochondria and the number of copies of mtDNA per mitochondrion vary in different tissues. Each mitochondrion has 2–10 mtDNA copies, and varying tissue needs for ATP correlate with the DNA content per mitochondrion.
- **Threshold effect:** Since any given cell has many mitochondria and thus hundreds or thousands of mtDNA copies, mutations in mtDNA lead to mixed populations of mutant and normal mitochondrial genomes, a situation called **heteroplasmy**. The phenotype of mtDNA mutations reflects the severity of the mutation, the proportion of mutant genomes and the tissue's demand for ATP. Different tissues need different amounts of ATP to sustain their metabolism; the brain, heart and skeletal muscle have particularly high energy demands.
- **High mutation rate:** The rate of mtDNA mutation is much higher than that of nuclear DNA, owing (at least in part) to less DNA repair capacity.

Diseases caused by mutations in the mitochondrial genome mainly affect the nervous system, heart and skeletal muscle. Functional deficits in all of these disorders are traced to impaired oxidative phosphorylation (OXPHOS). **OXPHOS diseases** are divided into several classes: I, nuclear mutations; II, mtDNA point mutations; III, mtDNA deletions; and IV, undefined defects.

All inherited mitochondrial diseases are rare and have variable clinical presentations for the reasons discussed above. Many diseases of aging are caused by defects in mitochondrial function. Since mitochondria process oxygen and convert constituents of foods into energy for essential cellular functions, mitochondrial dysfunction can contribute to complex diseases in adults including type 2 diabetes, Parkinson disease, atherosclerotic heart disease, stroke, Alzheimer disease and cancer. The first human mtDNA disease described was **Leber hereditary optic neuropathy,** which is characterized by progressive loss of vision. Various mitochondrial myopathies (skeletal and cardiac) and encephalomyopathies are known (see Chapter 31).

GENETIC IMPRINTING

MOLECULAR PATHOGENESIS: Phenotypes associated with some genes differ, depending on whether the allele is inherited from the mother or father. This phenomenon is called **genetic imprinting**. For imprinted genes, either the maternal or paternal allele is maintained in an inactive state. This normal physiologic process results from CpG methylation (see above) in regulatory regions of imprinted allele, such that the nonimprinted allele provides the sole biological function for that locus. If the nonimprinted allele is disrupted via mutation, the imprinted allele remains inactive and cannot compensate for the missing function. *Imprinting occurs in meiosis during gametogenesis, and the pattern of imprinting is maintained to variable degrees in different tissues. It is reset during meiosis in the next generation, so the selection of a given allele for imprinting can vary from one generation to the next.*

In extreme cases, experimental (nonhuman) embryos that obtain both sets of chromosomes exclusively from either the mother or the father never survive to term. A less severe manifestation of genetic imprinting is seen in **uniparental disomy,** in which both members of a single chromosome pair are inherited from the same parent. The pair of chromosomes may be copies of one parental chromosome (uniparental isodisomy) or may be the same pair found in one parent (uniparental heterodisomy). Uniparental disomy is rare but is implicated in unexpected inheritance patterns of genetic traits. Thus, a child with uniparental isodisomy may show a recessive disease when only one parent carries the trait, which has been observed in a few cases of cystic fibrosis and hemophilia A. Loss of a chromosome from a trisomy or duplication of a chromosome in the case of a monosomy can lead to uniparental disomy. Up to 1% of viable pregnancies carry uniparental disomy for at least one chromosome.

Genetic imprinting is illustrated by certain hereditary diseases whose phenotype is determined by the parental source of the mutant allele. Prader-Willi syndrome (PWS) and Angelman syndrome (AS) provide excellent examples of the effect of imprinting on genetic diseases. Both disorders are associated with (heterozygous) deletion in the region of 15(q11-13). In PWS, the deletion is in the paternal chromosome and critical genes in this region of the maternal chromosome are expressed but epigenetically silenced. By contrast, in AS, the same region of the maternal chromosome 15 is affected; critical genes in the paternal chromosome are expressed and epigenetically silenced.

The phenotypes of these disorders are remarkably different. PWS features hypotonia, hyperphagia with obesity, hypogonadism, mental retardation and characteristic facies. By contrast, AS patients are hyperactive, display inappropriate laughter, have different facies from that in PWS and suffer from seizures.

Prader-Willi syndrome develops because critical genes in the maternal locus are normally silenced by imprinting and the same region on the paternal chromosome is deleted, resulting in lack of expression. The converse applies in Angelman syndrome: the paternal gene is normally imprinted and silenced, and the maternal locus is inactivated by mutation or deletion. Critical genes silenced by methylation in the maternal 15q11-13 include *SNRPN* (encoding small nuclear ribonucleoprotein polypeptide), *NDN* (encoding necdin) and a cluster of small nucleolar RNAs (snoRNAs). In AS, *UBE3A*, which encodes a ubiquitin ligase, is mutated or deleted in the maternal chromosome and epigenetically silenced (in the paternal chromosome).

Each of these disorders is now routinely diagnosed by FISH or array CGH to detect the microdeletion of genes in 15q11-13 and by DNA methylation studies to detect uniparental disomy of maternal/paternal genes. This pattern is similar to loss of heterozygosity in tumor suppressor genes by aberrant methylation in some cases of cancer (see Chapter 5).

Genetic imprinting is implicated in a number of other situations relevant to human disease. In some childhood cancers, such as Wilms tumor, osteosarcoma, bilateral retinoblastoma and embryonal rhabdomyosarcoma, the maternal allele of a putative tumor suppressor gene is lost and the remaining allele is on a chromosome of paternal origin. In the case of familial glomus tumor, an adult neoplasm, both males and females may carry the trait, but it is transmitted only through the male. Thus, the responsible gene is active only when it is located on the paternal autosome. Finally, as noted above, premutation in fragile X syndrome expands to full mutation only during female gametogenesis, indicating that the trinucleotide repeat is treated differently on passage through the female than in the male.

MULTIFACTORIAL INHERITANCE

Most normal human traits reflect such complexities and are not inherited as simple dominant or recessive mendelian attributes. Many result from interplay between multiple genes and environmental, epigenetic and other factors. These reflect multifactorial inheritance. Thus, such inheritance determines height, skin color and body habitus. Similarly, most chronic disorders of adults—diabetes, atherosclerosis, many forms of cancer, arthritis and hypertension—are diseases that are understood to "run in families" but in which inheritance does not follow simple patterns. Many birth defects (e.g., cleft lip and palate, pyloric stenosis and congenital heart disease) are also transmitted via such complex mechanisms (Table 6-11).

TABLE 6-11
REPRESENTATIVE DISEASES ASSOCIATED WITH MULTIFACTORIAL INHERITANCE

Adults	Children
Hypertension	Pyloric stenosis
Atherosclerosis	Cleft lip and palate
Diabetes, type 2	Congenital heart disease
Allergic diathesis	Meningomyelocele
Psoriasis	Anencephaly
Schizophrenia	Hypospadias
Ankylosing spondylitis	Congenital hip dislocation
Gout	Hirschsprung disease

Multifactorial inheritance entails multiple genes interacting with each other and with environmental factors to produce disease in an individual. Such inheritance leads to familial aggregation that does not obey simple mendelian rules. Thus, inheritance of polygenic diseases is studied by population genetics, rather than by analysis of individual families.

The number of involved genes for any such disease is not known. Thus, in an individual case, the risk of a particular disorder cannot be quantified. The probability of disease can only be suggested from the numbers of relatives affected, the severity of their disease and statistical projections based on population analyses. While monogenic inheritance implies a specific risk of disease (e.g., 25%, 50%), the probability of symptoms in first-degree relatives of someone with a polygenic disease is usually only about 5%–10%.

The basis of polygenic inheritance is that over 1/4 of all genes in normal humans have polymorphic alleles. Such heterogeneity leads to wide variability in susceptibility to many diseases, made yet more complex by interactions with the environment.

- **Expression of symptoms is proportional to the number of mutant genes.** Close relatives of an affected person have more mutant genes than the population at large and more chance of expressing the disease. The probability of disease is highest in identical twins.
- **Environmental factors influence expression of the trait.** Thus, concordance for the disease may occur in only 1/3 of monozygotic twins.
- **Risk in first-degree relatives (parents, siblings, children) is the same (5%–10%).** The probability of disease is much lower in second-degree relatives.
- **The likelihood of a trait's expression in later offspring is influenced by its expression in earlier siblings.** If one or more children are born with a multifactorial defect, the chance it will recur in later offspring is doubled. For simple mendelian traits, by contrast, the probability is independent of the number of affected siblings.
- **The more severe the defect, the greater the risk of transmitting it to offspring.** Patients with more severe polygenic defects probably have more mutant genes. Their children thus will more likely inherit more abnormal genes than offspring of less severely affected parents.
- **Some diseases with multifactorial inheritance also show gender predilection.** Thus, pyloric stenosis is more common in males, while congenital hip dislocation is more common in females. Such differential susceptibility is thought to reflect different thresholds for expression of mutant genes in the two sexes, so that if the number of mutant genes required for pyloric stenosis in males is A, it may require 4A in the female. If so, a woman who had pyloric stenosis as an infant has more mutant genes to transmit to her children than does a similarly afflicted man. Indeed, sons of such women have a 25% chance of having pyloric stenosis, compared to a 4% risk for the son of an affected man. ***As a rule, if there is an altered sex ratio in the incidence of a polygenic defect, a member of the less commonly affected sex has a much greater probability of transmitting the defect.***

FIGURE 6-36. Cleft lip and palate in an infant.

Cleft Lip and Cleft Palate Exemplify Multifactorial Inheritance

At the 35th day of gestation, the frontal prominence fuses with the maxillary process to form the upper lip. This process is under the control of many genes, and disturbances in gene expression (hereditary or environmental) at this time interfere with proper fusion, resulting in cleft lip, with or without cleft palate (Fig. 6-36). This anomaly may also be part of a systemic malformation syndrome caused by teratogens (e.g., rubella, anticonvulsants) and often occurs in children with chromosomal abnormalities.

Incidence of cleft lip, with or without cleft palate, is 10 per 10,000 live births. The incidence of cleft palate alone is 6 per 10,000 live births. If one child is born with a cleft lip, the chances are 4% that a second child will have the same defect. If the first two children are affected, the risk of cleft lip in the third child increases to 9%. The more severe the defect, the greater the probability of transmitting cleft lip will be. While 75% of cases of cleft lip occur in boys, the sons of women with cleft lip have a 4-fold higher risk for the defect than do sons of affected fathers.

SCREENING FOR CARRIERS OF GENETIC DISORDERS

Until recently, screening for carriers of genetic diseases was not common. Among Ashkenazi Jews, screening to identify carriers of Tay-Sachs disease, an autosomal recessive disease, was done because of the relatively high frequency of the disease in that group. A number of other inherited conditions are also included in a so-called Ashkenazi screen. The goal is to identify couples in which both members are heterozygous

carriers and who thus have a 25% risk of being affected. These couples can be offered prenatal diagnosis to determine the genetic status of their fetus. In vitro fertilization combined with preimplantation genetic diagnosis is available in some centers to ensure that an implanted embryo will not have this disease.

Prenatal screening for carriers of CF has been recommended by national professional organizations for several years and represents the first large-scale adoption of testing for carriers of genetic diseases. Guidelines recommend that CF screening be offered to all white and Ashkenazi Jewish women because of the relatively high frequency of CF in these groups. The CF screening test detects 23 relatively common mutations, plus 9 other less common mutations. If a woman is a CF carrier, her partner should be tested to see if the couple is at risk of having an affected child. Because there are many CF mutations, the recommended panel detects about 88% of known CF mutations in whites, but over 94% among Ashkenazi Jews. Detection rates among other ethnic groups are lower.

PRENATAL DIAGNOSIS OF GENETIC DISORDERS

Amniocentesis and chorionic villus biopsy are the most important diagnostic tools for genetic or developmental disorders. Both procedures are safe, reliable and easily done. Indications for performing them are:

- **Age 35 years old and over:** The likelihood of having a child with Down syndrome is about 1 in 1250 for a mother age 25, compared with 1 in 100 for a 40-year-old. Risk increases even more with advanced maternal age.
- **Previous chromosomal abnormality:** The risk of Down syndrome recurring in a later child of a woman who has already had an infant with trisomy 21 is 1%.
- **Translocation carrier:** Estimates of risks to the offspring of translocation carriers are from 3% to 15%. ***Carriers of balanced translocations are more likely to produce children with unbalanced karyotypes and resulting phenotypic abnormalities.***
- **History of familial inborn error of metabolism:** Recessive inborn errors of metabolism have a 25% risk for each child if both parents are heterozygous for the trait. Newborn screening can identify disorders for which a biochemical diagnosis can be made.
- **Identified heterozygotes:** Carrier detection projects (e.g., Tay-Sachs Disease Prevention Program) identify couples in which both spouses are carriers of the same recessive gene. Each of their pregnancies has a 25% risk of an affected child and diagnosis can be made prenatally.
- **Family history of X-linked disorders:** Fetal sex determination, using amniotic cells, can be offered to women known to be carriers of X-linked disorders. Diagnosis of some of these conditions can be established biochemically by amniotic fluid analysis.

Gene-specific DNA probes have been developed for many genetic diseases, including hemophilia A and B, the hemoglobinopathies, phenylketonuria and α_1-antitrypsin deficiency. Most heterozygous carriers for Duchenne and Becker muscular dystrophies, Huntington chorea and cystic fibrosis can be identified by such techniques.

DISEASES OF INFANCY AND CHILDHOOD

The period from birth to puberty has been traditionally subdivided into several stages.

- Neonatal age (the first 4 weeks)
- Infancy (the first year)
- Early childhood (1–4 years)
- Late childhood (5–14 years)

Each of these periods has its own anatomic, physiologic and immunologic characteristics, which determine which diseases occur and how they manifest. Causes and mechanisms of morbidity and mortality in the neonatal period differ greatly from those in infancy and childhood. Infants and children are not simply "small adults," and they may be afflicted by diseases unique to their particular age group.

PREMATURITY AND INTRAUTERINE GROWTH RETARDATION

Human pregnancy normally lasts 40 ± 2 weeks, and most newborns weigh 3300 ± 600 g. The World Health Organization defines prematurity as a gestational age under 37 weeks (timed from the first day of the last menstrual period). Traditionally, prematurity signified a birth weight below 2500 g, regardless of gestational age. However, since full-term infants may weigh under 2500 g because of intrauterine growth retardation rather than prematurity, **low–birth-weight infants** (<2500 g) are either appropriate for gestational age (AGA) or small for gestational age (SGA).

The frequency of low birth weight in the United States has recently risen to 8.3% owing to increased numbers of multiple births. Two thirds of such infants are premature (AGA). By contrast, when the frequency of low–birth-weight infants exceeds 10%, as it does for blacks (>13%), most newborns suffer from IUGR and are considered SGA.

About 1% of infants born in the United States weigh under 1500 g and are classified as **very-low-birth-weight infants**. These represent half of neonatal deaths, and their survival is related to birth weight. If they are cared for in neonatal intensive care units, 90% of infants over 750 g survive. From 500 g to 750 g, 45% survive. Of these, over half develop normally.

ETIOLOGIC FACTORS: Factors that predispose to premature birth of an infant (AGA) include (1) maternal illness, (2) uterine incompetence, (3) fetal disorders and (4) placental abnormalities (see Chapter 14). If the life of a fetus is threatened by such conditions, it may be necessary to induce premature delivery to save the infant. In many AGA infants, the cause of premature birth is unknown. Intrauterine growth retardation and the resulting birth of SGA infants are associated with disorders that impair maternal health and nutrition, interfere with placental circulation or function or disturb fetal growth or development (see Chapter 14).

CLINICAL FEATURES: Complications of prematurity itself (AGA) and of IUGR (SGA) overlap. However, certain general principles apply. Prematurity is often associated with severe respiratory distress, metabolic disturbances (e.g., hypoglycemia, hypocalcemia, hyperbilirubinemia), circulatory problems (anemia,

hypothermia, hypotension) and bacterial sepsis. By contrast, SGA infants are a much more heterogeneous group, including many with congenital anomalies and infections acquired in utero. Even when these causes of intrauterine growth retardation are excluded, neonatal complications in SGA infants reflect gestational age more than birth weight. In addition to problems related to prematurity, SGA infants often suffer from perinatal asphyxia, meconium aspiration, necrotizing enterocolitis, pulmonary hemorrhage and sequelae of birth defects or inherited diseases.

Organ Immaturity Is a Cause of Neonatal Problems

The maturity of the newborn can be defined in both anatomic and physiologic terms. Organ maturation in infants born prematurely differs from that in term infants, even as total maturation of many organs may require days (lungs) to years (brain) after birth.

LUNGS: Pulmonary immaturity is a common and immediate threat to the viability of low–birth-weight infants. Fetal alveolar lining cels do not differentiate into type I and type II pneumocytes until late in pregnancy. Amniotic fluid fills fetal alveoli and drains from the lungs at birth. Sometimes respiratory movements of immature infants are sluggish and do not fully expel amniotic fluid from their lungs. Respiratory embarrassment may ensue, a syndrome called **amniotic fluid aspiration,** but that actually represents retained amniotic fluid. Air passages contain desquamated squamous cells **(squames)** and lanugo hair from the fetal skin and protein-rich amniotic fluid (Fig. 6-37; see Chapter 18).

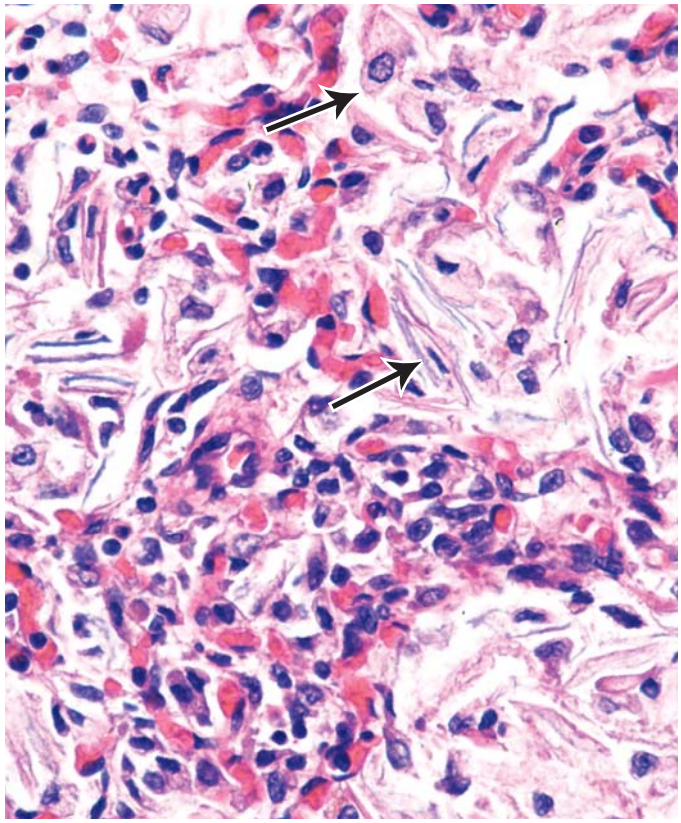

FIGURE 6-37. Retention of amniotic fluid in the lung of a premature newborn. The incompletely expanded lung contains squames (*arrows*) consisting of squamous epithelial cells shed into the amniotic fluid from the fetal skin.

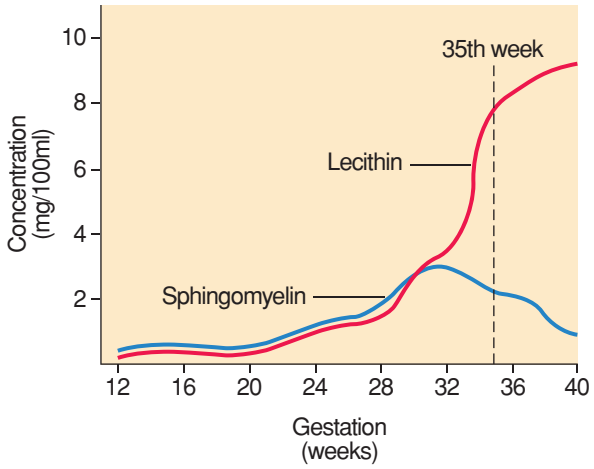

FIGURE 6-38. Changes in amniotic fluid composition during pregnancy.

The ability of alveoli to remain expanded during the respiratory cycle (i.e., not to collapse during expiration) is due largely to **pulmonary surfactant,** which reduces intra-alveolar surface tension. Surfactant, produced by type II pneumocytes, is a complex mixture of 10% proteins and 90% mixed phospholipids, the latter including 75% phosphatidylcholine (lecithin) and 10% phosphatidylglycerol. Surfactant composition changes as a fetus matures: (1) lecithin increases at the start of the third trimester and then rises rapidly to peak near term (Fig. 6-38); (2) most lecithin in the mature lung is dipalmitoyl phosphatidylcholine, but in the immature lung it is a less-surface-active α-palmitoyl, α-myristoyl species; (3) phosphatidylglycerol is not present in the lungs before the 36th week of pregnancy; and (4) before the 35th week, immature surfactant contains a higher proportion of sphingomyelin than adult surfactant.

The protein constituents of surfactant, though they make up a small proportion of its total weight, are important in facilitating the surface activity of the mixture and serve other functions as well. Two highly hydrophobic surfactant-associated proteins (SPs), SP-B and SP-C, are critical for surface activity. Two more hydrophilic proteins, SP-A and SP-D, fulfill additional functions, thought to include regulating surfactant secretion, antimicrobial protection and others.

Pulmonary surfactant is released into the amniotic fluid, which can be sampled by amniocentesis to assess fetal lung maturity. A lecithin-to-sphingomyelin ratio above 2:1 predicts extrauterine survival without respiratory distress syndrome (see below). After the 35th week, the appearance of phosphatidylglycerol in the amniotic fluid is the best proof of fetal lung maturity.

LIVER: The liver of premature infants is morphologically similar to that of adults, except for conspicuous extramedullary hematopoiesis. However, the hepatocytes tend to be functionally immature. Fetal liver is deficient in glucuronyl transferase. The liver's resulting inability to conjugate bilirubin often leads to **neonatal jaundice** (see Chapter 20). This enzyme deficiency is aggravated by the rapid destruction of fetal erythrocytes, a process that increases supply of bilirubin.

BRAIN: The brain of immature newborns differs from that of the adult, morphologically and functionally, but this difference is rarely fatal. Still, incomplete CNS development

TABLE 6-12
APGAR SCORE[a]

Sign	0	1	2
Heart rate	Not detectable	Below 100/min	Over 100/min
Respiratory effort	None	Slow, irregular	Good, crying
Muscle tone	Poor	Some flexion of extremities	Active motion
Response to catheter in nostril	No response	Grimace	Cough or sneeze
Color	Blue, pale	Body pink, extremities blue	Completely pink

[a]Sixty seconds after the completion of birth, these five objective signs are evaluated, and each is given a score of 0, 1, or 2. A maximum score of 10 is assigned to infants in the best possible condition.

often contributes to poor vasomotor control, hypothermia, feeding difficulties and recurrent apnea.

The Apgar Score

Clinical assessments of neonatal maturity in general are usually performed 1 minute and 5 minutes after delivery, and certain parameters are scored according to the criteria recommended by Virginia Apgar (Table 6-12). In general, the higher the **Apgar score,** the better the clinical condition of the infant. The score taken at 1 minute is an index of asphyxia and the need for assisted ventilation. The 5-minute score is a more accurate indication of impending death or likelihood of persistent neurologic damage. For example, newborns under 2000 g whose 5-minute Apgar scores are 9 or 10 have a 95% chance of surviving their first month. This declines to 20% if the 5-minute Apgar score is 3 or less.

Neonatal Respiratory Distress Syndrome Is Due to Deficiency of Surfactant

Neonatal respiratory distress syndrome (RDS) is the leading cause of morbidity and mortality among premature infants, accounting for half of neonatal deaths in the United States. Its incidence varies inversely with gestational age and birth weight. Over half of infants born younger than 28 weeks' gestational age develop RDS, compared with 1/5 of infants born between 32 and 36 weeks. Additional risk factors for RDS include (1) neonatal asphyxia, (2) maternal diabetes, (3) delivery by cesarean section, (4) precipitous delivery and (5) twin pregnancy.

ETIOLOGIC FACTORS: ***The pathogenesis of RDS of the newborn is intimately linked to surfactant deficiency*** (Fig. 6-39). When a newborn starts breathing, type II cells release their surfactant stores. Surfactant reduces surface tension by decreasing the affinity of alveolar surfaces for each other. This allows alveoli to remain open when the baby exhales and reduces resistance to reinflating the lungs. If surfactant function is inadequate, as it is in many premature infants with immature lungs, alveoli collapse when the baby exhales and resist expansion with the next breath. The energy required for the second breath must then overcome the stickiness within alveoli. Inspiration therefore requires considerable effort, and the alveolar lining becomes damaged when adherent alveolar walls pull apart. As a result, injured alveoli leak plasma constituents, including fibrinogen and albumin, into airspaces. These proteins bind surfactant and further impair its function, thus exacerbating respiratory insufficiency. Many alveoli are perfused with blood but not ventilated by air, which leads to hypoxia and acidosis and further compromise in the ability

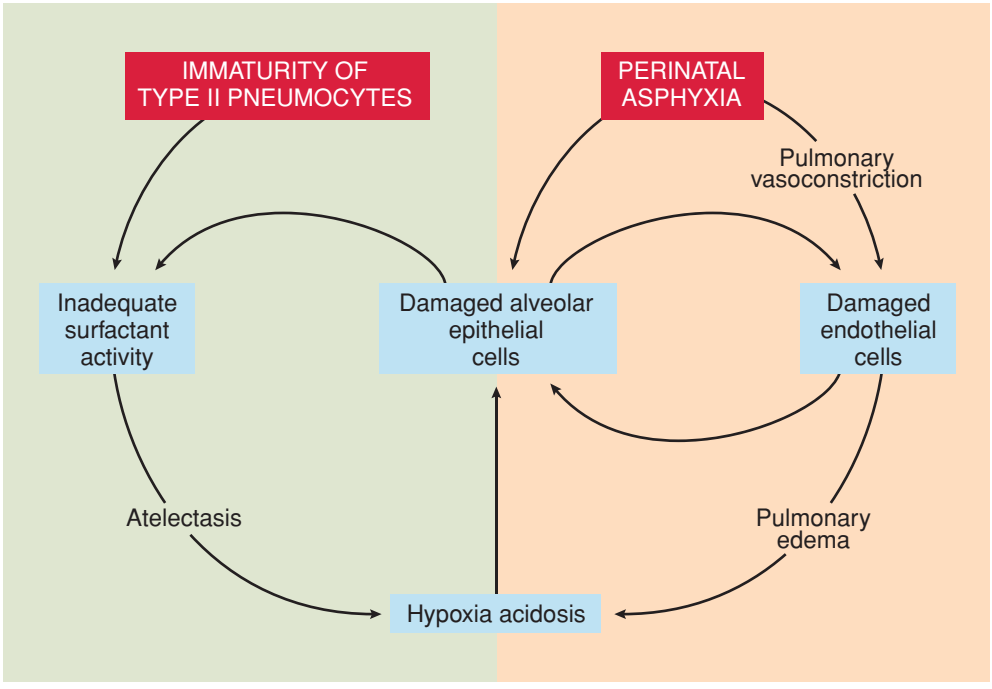

FIGURE 6-39. Pathogenesis of respiratory distress syndrome in the neonate. Immaturity of the lungs and perinatal asphyxia are the major pathogenetic factors.

of type II pneumocytes to produce surfactant. Intra-alveolar hypoxia induces pulmonary arterial vasoconstriction, thus increasing right-to-left shunting through the ductus arteriosus, through the foramen ovale and within the lung itself. Resulting pulmonary ischemia further aggravates alveolar epithelial damage and injures alveolar capillary endothelium. Leak of protein-rich fluid into alveolar spaces from the injured vascular bed contributes to the typical clinical and pathologic features of RDS.

The course of RDS is further complicated by the need to expose the infant to high concentrations of inspired oxygen (FiO_2) to maintain adequate arterial oxygen levels. Although respiratory support has improved greatly, the damage caused by high FiO_2 levels (see ROS-mediated damage, Chapter 1) adds to the already ongoing lung injury.

PATHOLOGY: The lungs in neonatal RDS are dark red, solid in consistency and airless. Alveoli are collapsed. Alveolar ducts and respiratory bronchioles are dilated and contain cellular debris, proteinaceous edema fluid and erythrocytes. Alveolar ducts are lined by conspicuous, eosinophilic, fibrin-rich, amorphous structures, called **hyaline membranes,** hence the original term **hyaline membrane disease** (Fig. 6-40). Collapsed alveoli have thick walls, capillaries are congested and lymphatics are filled with proteinaceous material.

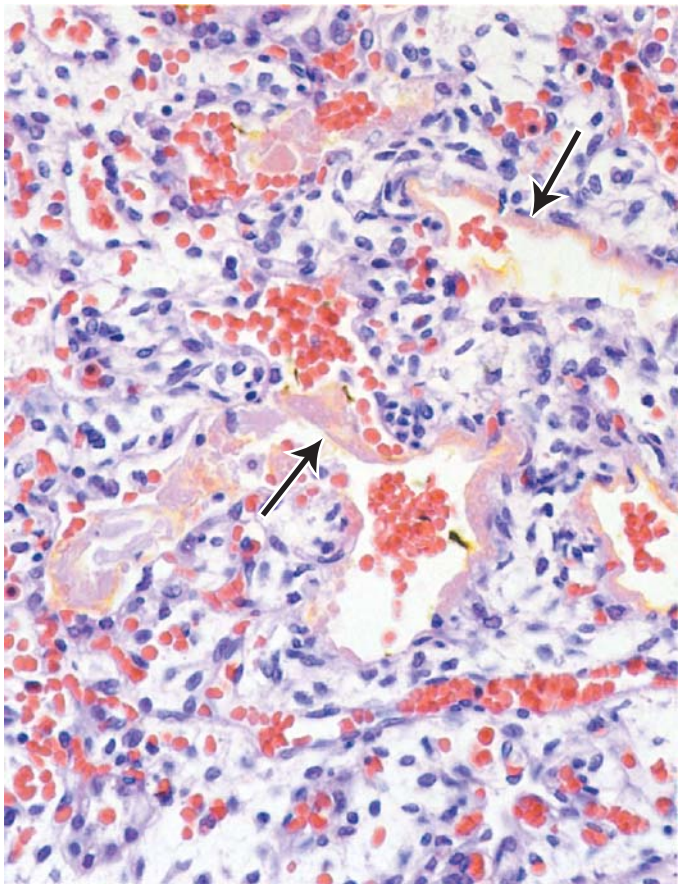

FIGURE 6-40. The lung in respiratory distress syndrome of the neonate. Alveoli are atelectatic, and dilated alveolar ducts are lined by fibrin-rich hyaline membranes (*arrows*).

CLINICAL FEATURES: Most newborns destined to develop RDS appear normal at birth and have high Apgar scores. The first symptom, appearing usually within an hour of birth, is increased respiratory effort, with forceful intercostal retraction and the use of accessory neck muscles. Respiratory rate increases to more than 100 breaths per minute, and the baby becomes cyanotic. Chest radiographs show a characteristic "ground-glass" granularity, and in terminal stages the fluid-filled alveoli appear as complete "white-out" of the lungs. In severe cases, infants become progressively obtunded and flaccid. Long periods of apnea ensue; infants eventually die of asphyxia.

Therapeutic advances in recent decades have improved survival in infants with RDS, allowed survival of very young premature babies who previously would have had almost no chance of living and decreased the incidence of many complications of RDS (see below). It is generally accepted that if labor threatens a preterm pregnancy, administration of corticosteroids to mothers hastens fetal lung maturation and decreases the incidence of RDS in preterm babies. Use of animal-derived surfactants (porcine or bovine), combined with improved ventilatory therapy, has dramatically improved the survival of infants with RDS. Currently, even very small premature infants have an 85%–90% chance of survival.

The major complications of RDS relate to anoxia and acidosis and include:

- **Intraventricular cerebral hemorrhage:** The periventricular germinal matrix in the newborn brain is particularly vulnerable to hemorrhage because the dilated, thin-walled veins in this area rupture easily (Fig. 6-41). The pathogenesis of this complication is not fully understood but is believed to reflect anoxic injury to the periventricular capillaries, venous sludging and thrombosis and impaired vascular autoregulation.
- **Persistent patent ductus arteriosus:** The ductus arteriosus remains patent in almost 1/3 of newborns who survive RDS. With recovery from the pulmonary disease, pulmonary arterial pressure declines, and the higher pressure in the aorta reverses the direction of blood flow in the ductus, thus creating a persistent left-to-right

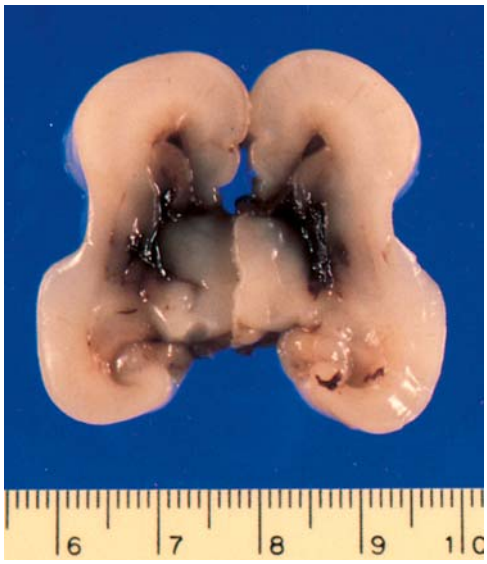

FIGURE 6-41. Intraventricular hemorrhage in a premature infant suffering from respiratory distress syndrome of the neonate.

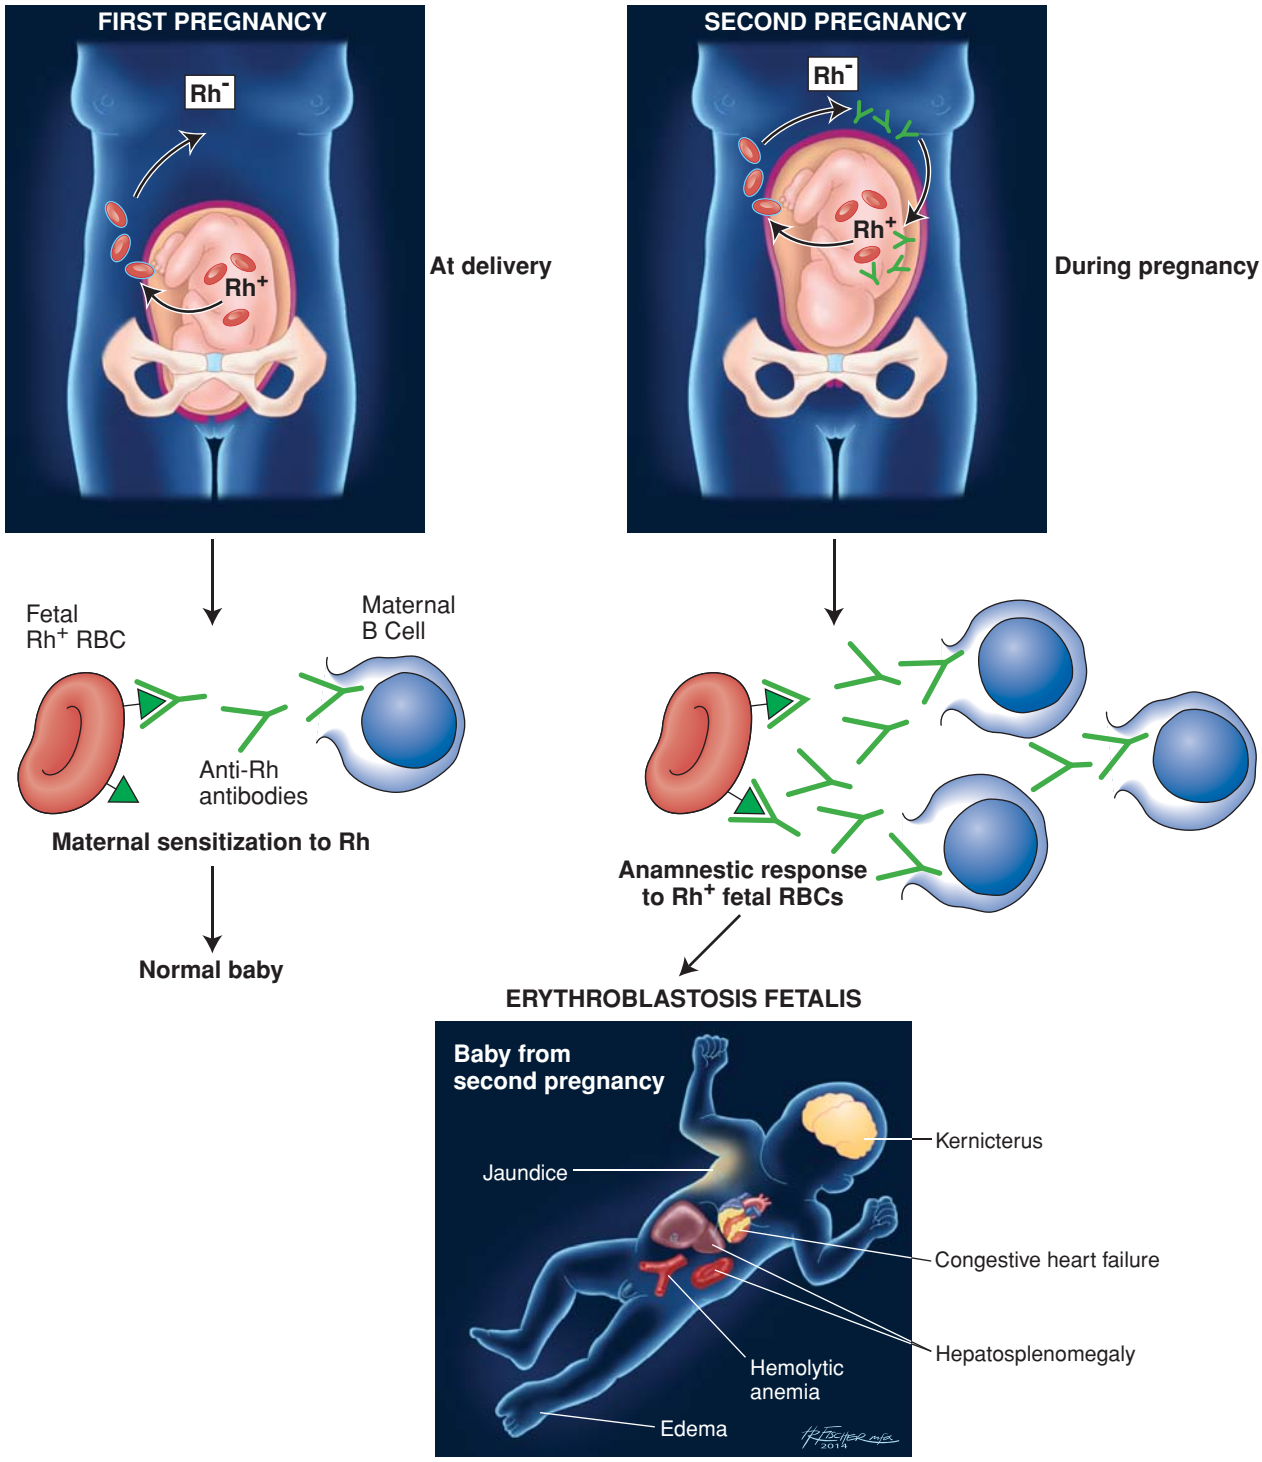

FIGURE 6-42. Pathogenesis of erythroblastosis fetalis due to maternal–fetal Rh incompatibility. Immunization of an Rh-negative mother with Rh-positive erythrocytes in the first pregnancy leads to formation of anti-Rh antibodies of the immunoglobulin (Ig) G type. These antibodies cross the placenta and damage the Rh-positive fetus in subsequent pregnancies.

shunt. Congestive heart failure may ensue and necessitate correction of the patent ductus.

- **Necrotizing enterocolitis:** This intestinal complication of RDS is the most common acquired gastrointestinal emergency in newborns. It is thought to be related to ischemia of the intestinal mucosa, which leads to bacterial colonization, usually with *Clostridium difficile.* Lesions vary from those of typical pseudomembranous enterocolitis to gangrene and bowel perforation.
- **Bronchopulmonary dysplasia (BPD):** BPD is a late complication of RDS usually in infants who weigh less than 1500 g and were maintained on positive-pressure respirators with high FiO_2. BPD affects about 1/3 of RDS survivors and is manifest by continuing need for increased

FiO_2 beyond 1 month postnatal age. In older infants, it probably results from oxygen toxicity superimposed on RDS. However, the BPD that occurs in very young premature infants (25–28 weeks' gestation) may differ in pathogenesis and be related, at least in part, to inadequate maturation of lung architecture. In such patients, respiratory distress persists after the third or fourth day and is reflected in hypoxia, acidosis, oxygen dependency and onset of right-sided heart failure. Radiographs of the lungs show a change from almost complete opacification to a sponge-like appearance, with small lucent areas alternating with denser foci. The bronchiolar epithelium is hyperplastic, with squamous metaplasia in the bronchi and bronchioles. Atelectasis, interstitial edema and thickening of alveolar basement membranes are also seen. BPD is a chronic disease; affected infants may continue to require oxygen supplementation into their second or third years of life, and some degree of respiratory impairment may persist, even into adolescence and beyond.

It should be noted that RDS may occur in term or near-term infants. Clinically, this syndrome mimics that seen in premature infants who lack adequate surfactant. A high proportion of term infants with RDS suffer from genetic deficiencies of one of the hydrophobic surfactant proteins (SP-B or SP-C) or have mutations in the ATP-binding cassette transporter (ABCA3) responsible for transporting surfactant phospholipids and proteins to the alveolar space.

Erythroblastosis Fetalis Is a Hemolytic Disease Caused by Maternal Antibodies against Fetal Erythrocytes

The disorder was first recognized by Hippocrates but was not explained until 1940, when Rh (Rhesus) antigen on erythrocytes was identified. More than 60 antigens on red blood cell membranes can elicit antibody responses, but only antibodies to Rh D and ABO antigens cause substantial hemolytic disease.

Rh Incompatibility

The distribution of Rh antigens among ethnic groups varies. In American whites, 15% are Rh negative (Rh D–); only 8% of blacks are Rh D–. Japanese, Chinese and Native Americans are essentially all Rh D+. By contrast, 35% of Basque people, among whom the Rh D– phenotype may have arisen, are Rh D–.

PATHOPHYSIOLOGY: The Rh blood group system consists of some 25 components, of which only the alleles cde/CDE need be considered here. Antibodies against D cause 90% of erythroblastosis fetalis related to Rh incompatibility; the remaining cases involve C or E. Rh-positive fetal erythrocytes (in >1 mL fetal blood) enter the circulation of an Rh-negative mother at the time of delivery and elicit maternal antibodies to the fetus's D antigen (Fig. 6-42). As the fetal blood required to sensitize a mother is introduced into her circulation only at the time of delivery, the disease does not ordinarily affect her first fetus. However, at subsequent pregnancies, when a now sensitized mother again carries an Rh-positive fetus, much smaller quantities of fetal D antigen boost antibody titer. Resulting IgG antibodies cross the placenta and thus cause hemolysis in the fetus. This cycle is magnified in multiparous women, the severity of erythroblastosis increasing progressively with each subsequent pregnancy.

About 15% of white women are Rh D–. Since they have an 85% chance of marrying an Rh D+ man, 13% of marriages are theoretically at risk for maternal–fetal Rh incompatibility. The actual incidence of erythroblastosis fetalis is much lower because (1) more than half of Rh-positive men are heterozygous (D/d), and thus only half of their offspring express Rh D antigen; (2) only half of all pregnancies have large enough fetal-to-maternal transfusions to sensitize the mother; and (3) even in those Rh-negative women who are exposed to significant amounts of fetal Rh-positive blood, many do not mount a substantial immune response. Even after multiple pregnancies, only 5% of Rh-negative women ever deliver infants with erythroblastosis fetalis.

PATHOLOGY AND CLINICAL FEATURES: The severity of hemolysis in erythroblastosis fetalis varies from mild to fatal anemia, the pathology being determined by disease severity.

- **Death in utero** occurs in the most extreme form of the disease, and severe maceration is evident on delivery. Many erythroblasts are seen in organs that are not extensively autolyzed.
- **Hydrops fetalis** is the most serious form of erythroblastosis fetalis (Fig. 6-43) in liveborn infants. ***It is characterized by severe edema due to congestive heart failure caused by***

FIGURE 6-43. Hydrops fetalis. The infant shows severe anasarca.

severe anemia. Affected infants generally die unless adequate exchange transfusions with Rh-negative cells correct the anemia and treat the hemolysis. Infants are not jaundiced at birth but rapidly develop progressive hyperbilirubinemia. Those who die have hepatosplenomegaly and bile-stained organs, erythroblastic hyperplasia in the bone marrow and extramedullary hematopoiesis in the liver, spleen, lymph nodes and other sites.

- **Kernicterus,** or **bilirubin encephalopathy,** is a neurologic condition associated with severe jaundice and characterized by bile staining of the brain, particularly the basal ganglia, pontine nuclei and cerebellar dentate nuclei**.** Although brain damage in jaundiced newborns was first noted in the 15th century, its association with elevated unconjugated bilirubin levels was first appreciated in 1952. Kernicterus (from the German *kern,* "nucleus") is largely limited to infants with severe unconjugated hyperbilirubinemia, as in erythroblastosis. Bilirubin from destruction of erythrocytes and catabolism of the released heme is poorly conjugated by the immature liver, which is deficient in glucuronyl transferase.

Kernicterus directly reflects levels of unconjugated bilirubin. It is rare in term infants if serum bilirubin levels are below 20 mg/dL. Premature infants are more vulnerable to hyperbilirubinemia and may develop kernicterus at levels as low as 12 mg/dL. Bilirubin is thought to injure the cells of the brain by interfering with mitochondrial function. Severe kernicterus leads initially to loss of the startle reflex and athetoid movements and progresses to lethargy and death in 75%. Most surviving infants have severe choreoathetosis and mental retardation; a minority have varying degrees of intellectual and motor retardation.

PREVENTION AND TREATMENT: Exchange transfusions may keep the maximum serum bilirubin at an acceptable level. However, phototherapy converts toxic unconjugated bilirubin into isomers that are nontoxic and can be excreted in the urine, and has greatly reduced the need for exchange transfusions.

The incidence of erythroblastosis fetalis due to Rh incompatibility has declined (to <1% of women at risk) when human anti-D globulin (RhoGAM) is given to mothers within 72 hours of delivery. RhoGAM neutralizes antigenicity of fetal cells that may have entered the maternal circulation during delivery and prevents development of maternal anti-Rh D antibodies.

ABO Incompatibility

With the decline in Rh-incompatible erythroblastosis, ABO incompatibility has become the main cause of hemolytic disease of the newborn. ABO incompatibility between mother and offspring occurs in 1/4 of pregnancies, but hemolytic disease develops in only 10% of such children, usually in infants with blood type A. Low antigenicity of ABO factors in the fetus accounts for the mildness of ABO hemolytic disease. Natural anti-A and anti-B antibodies are mostly IgM, which does not cross the placenta, but some antibodies to A antigen may be IgG, which does cross the placenta. ABO isoimmune disease may thus be seen in firstborn infants. Most cases of hemolytic anemia from ABO incompatibility follow a prior incompatible pregnancy.

Most infants with ABO incompatibility have mild jaundice as the only clinical feature. The extreme complications of erythroblastosis in cases of Rh incompatibility are unusual with ABO disease. Kernicterus occurs, but rarely.

Injury at Birth Ranges from Mechanical Trauma to Anoxic Damage

Some birth injuries relate to obstetric manipulation, but many are due to unavoidable events in routine delivery. Birth injuries occur in 5 per 1000 live births. Predisposing factors include cephalopelvic disproportion, dystocia (difficult labor), prematurity and breech presentation.

Cranial Injury

- **Caput succedaneum** is scalp edema caused by trauma to the head during passage through the birth canal. Swelling disappears rapidly and is of little clinical concern.
- **Cephalohematoma** is subperiosteal hemorrhage of a single cranial bone. It becomes apparent within a few hours after birth and may be associated with a linear fracture of the underlying bone. Most cephalohematomas resolve without complication and require no treatment.
- **Skull fractures** during birth result from the impact of the head on the pelvic bones or pressure from obstetric forceps. Linear fractures, the most common variety, are asymptomatic and do not require treatment. Depressed fractures are usually caused by trauma from forceps. Although many depressed fractures do not initially produce symptoms, they may require mechanical elevation to avoid underlying cranial trauma from persistent pressure. Unlike most cranial fractures, those of the occipital bone often extend through the underlying venous sinuses and may produce fatal hemorrhage.
- **Intracranial hemorrhage** is one of the most dangerous birth injuries and may be traumatic, secondary to asphyxia or a result of an underlying bleeding diathesis. Traumatic intracranial hemorrhage occurs in settings of (1) significant cephalopelvic disproportion, (2) precipitous delivery, (3) breech presentation, (4) prolonged labor or (5) inappropriate use of forceps. These traumas can result in **subdural or subarachnoid hemorrhage,** often due to lacerations of the falx cerebri or tentorium cerebelli that involve the vein of Galen or the venous sinuses. As noted above, anoxic injury from asphyxia, particularly in premature infants, is often associated with intraventricular hemorrhage.

The prognosis for newborns with intracranial hemorrhage depends on its extent. Massive hemorrhage is often rapidly fatal. Surviving infants may recover completely or have long-term impairment, usually in the form of cerebral palsy or hydrocephalus. However, many cases of cerebral palsy have been shown by ultrasound studies to be related to brain damage 2 weeks or more prior to birth rather than from birth trauma.

Peripheral Nerve Injury

- **Brachial palsy,** with varying degrees of paralysis of the arm, is caused by excessive traction on the head and neck or shoulders during delivery. If the nerves are severed, impairment may be permanent. Function may return within a few months if the palsy results from edema and hemorrhage.

- **Phrenic nerve paralysis** and associated paralysis of a hemidiaphragm may be associated with brachial palsy and lead to breathing difficulties. It generally resolves spontaneously within a few months.
- **Facial nerve palsy** usually presents as unilateral flaccid paralysis of the face caused by injury to the seventh cranial nerve during labor or delivery, especially with forceps. If severe, the entire affected side of the face is paralyzed and even the eyelid cannot be closed. Prognosis depends on the extent of nerve injury.

Fractures

The **clavicle** is most vulnerable to fracture during delivery, and there may be associated fracture of the **humerus**. Immobilization of the arm and shoulder usually allows for complete healing. Fractures of other long bones and the nose occasionally occur during birth but heal easily.

Rupture of the Liver

The liver is the only internal organ other than the brain that is injured with any frequency during labor and delivery. Mechanical pressure during difficult or premature births is responsible. Hepatic rupture may cause a hematoma large enough to be palpable and to cause anemia; surgical repair of the laceration may be required.

Sudden Infant Death Syndrome Is an Important Cause of Postperinatal Death

Sudden infant death syndrome (SIDS), also known as "crib death" or "cot death," is defined as "sudden death of an infant or young child which is unexpected by history and in which a thorough postmortem examination fails to demonstrate an adequate cause of death."[1] A diagnosis of SIDS is made only after excluding other specific causes of sudden death, such as infection, hemorrhage, aspiration and so forth. Homicide must be eliminated as a potential cause of SIDS, especially in settings in which more than one sibling has died of apparent SIDS. Descriptions of apparent SIDS date to the Bible, and the syndrome was noted in the American colonies in 1686. However, modern attention to the disorder dates to the late 1960s.

Typically, victims of SIDS are apparently healthy young infants who went to sleep without any hint of the impending calamity but did not wake up. As more predisposing factors and environmental, biochemical, structural and genetic contributors are identified, the number of deaths that truly have no identifiable pathogenesis has diminished. Nevertheless, many authorities still embrace a more inclusive definition of this syndrome.

EPIDEMIOLOGY: After the neonatal period, SIDS is the leading cause of death in the first year of life, accounting for more than 1/3 of deaths in this period. Its incidence in the United States has decreased from 1.2 in 1000 live births in 1992 to 0.5 in 1000 live births in 2006 but has not changed much since then. SIDS is still responsible for over 2000 infant deaths annually in the United States. Most (90%) cases occur before 6 months of age, although infants up to 1 year are included in currently accepted criteria. Reducing the risk of SIDS remains an important public health priority.

The majority of deaths from SIDS occur during the winter months, and a significantly higher percentage of infants dying of SIDS are reported to have experienced upper respiratory infections within the previous 4 weeks. However, deaths involving active infections are by definition excluded. Most deaths occur at night or during periods associated with sleep. Once it was determined that infants who slept prone or on their sides had much a higher incidence of SIDS than those who slept supine, a worldwide "Back to Sleep" campaign that encouraged parents to place infants on their backs for sleeping reduced the incidence of SIDS by about half.

Risk factors for SIDS are difficult to ascertain, and much of what is known is based on retrospective studies. There are both maternal and infant risk factors. The strongest **maternal risk factors** are:

- Low socioeconomic status (poor education, unmarried mother, poor prenatal care)
- Black or Native American parentage (in the United States, and independent of economic status; in other countries indigenous populations, like Maoris in New Zealand and Aborigines in Australia, are also at higher risk)
- Age younger than 20 years at first pregnancy
- Maternal cigarette smoking and/or alcohol consumption during and after pregnancy
- Use of illicit drugs during pregnancy
- Increased parity

Risk factors for the infant are more controversial. The consensus includes:

- Low birth weight.
- Prematurity.
- An illness, often respiratory, within the last 4 weeks before death.
- Subsequent siblings of SIDS victims.
- Survivors of an apparent life-threatening event (i.e., an episode of some combination of apnea, color change, marked alteration in muscle tone and choking or gagging). A definite cause, such as seizures or aspiration after vomiting, is known in only half the cases of an apparent life-threatening event.

PATHOPHYSIOLOGY AND ETIOLOGIC FACTORS: Studies of the etiology and pathogenesis of SIDS have provided important insight into the factors that contribute to this syndrome and, in some instances, the molecular bases for sudden infant death. While the original definition of SIDS excludes from the diagnosis known causes, we use a more expansive definition here because of our improved understanding of both molecular and environmental factors involved.

Channelopathies, inherited abnormalities in cell membrane ion channels (see Chapters 1 and 16), are felt to be responsible for 10%–12% of cases of SIDS, although this percentage may be higher (up to about 30%) in SIDS deaths between 6 and 12 months. Various inherited arrhythmia syndromes have been implicated in sudden infant death.

[1]Willinger M, James LS, Catz C. Defining the sudden infant death syndrome (SIDS): deliberations of an expert panel convened by the National Institute of Child Health and Human Development. Pediatr Pathol 1991;11:677–684.

All involve more than one different mutation, producing clustered phenotypes.

The most common of these is long QT syndrome, which is mostly due to loss-of-function mutations in cardiac potassium channels (*KCNQ1, KCNH2*), but mutations in other ion channel proteins have also been identified in some cases, including sodium channel (*SCN5A*) and L-type calcium channel (*CACNA1C*). Long QT syndrome is characterized by prolonged QT intervals on the surface electrocardiogram and is seen in about 10% of SIDS deaths.

Other channelopathies associated with SIDS include catecholaminergic polymorphic ventricular tachycardia (CPVT, mostly due to mutations in ryanodine receptor 2), Brugada syndrome (involving different mutations in the *SCN5A* sodium channel, and also mutations in calcium channels) and short QT syndrome (gain-of-function mutations in cardiac potassium channels, causing accelerated repolarization of cardiac muscle). While these mutations are seen disproportionately in SIDS deaths, the great majority of individuals with ion channelopathies survive infancy. Some experience sudden death in adolescence or later. Others may never be symptomatic.

Now that SIDS relating to prone sleeping position has diminished greatly, **maternal smoking during pregnancy is the most important single etiologic factor in SIDS,** accounting for 80% or more of SIDS deaths. The key factor appears to be exposure to nicotine in utero. There is a dose-response effect: the likelihood of an infant developing SIDS is a direct function of the number of cigarettes smoked by the mother during pregnancy. Babies born to women who smoked 20+ cigarettes daily while pregnant have a greater than 5-fold increased risk of SIDS, compared to children of nonsmokers.

Significant abnormalities have been detected in the brains of infants dying of SIDS. These include hypoplasia of the arcuate nucleus, decreased serotonin receptors and decreased muscarinic cholinergic activity in favor of increased, abnormal nicotinic activity. Comparable abnormalities are seen in experimental animals exposed to nicotine in utero and are associated with depressed ventilatory responses to hypercarbia and hypoxia. Low levels of serotonin, a brain chemical involved in regulating breathing and other vital functions, have been found in the brain stems of SIDS victims. Further, prospective studies of babies who later died of SIDS demonstrated abnormal autonomic nervous system physiology, including depressed gasping reflexes and abnormal regulation of heart rhythm.

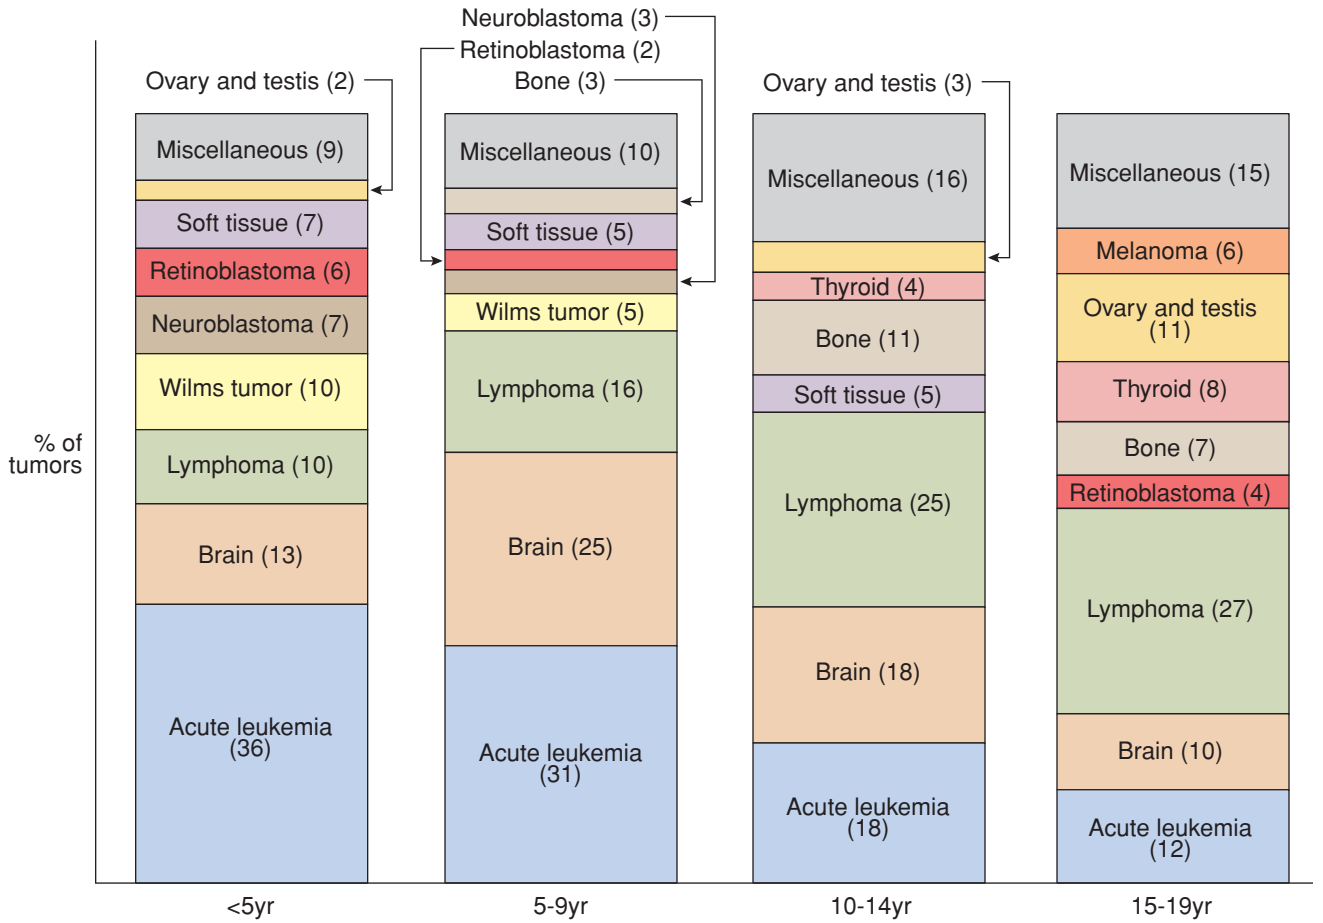

FIGURE 6-44. Distribution of childhood tumors according to age and primary site.

PATHOLOGY: At autopsy, several morphologic alterations have been noted in victims of SIDS, some of which may bear on SIDS pathogenesis, while the significance of others remains unclear. These include arcuate nucleus hypoplasia and brainstem gliosis. Medial hypertrophy of small pulmonary arteries, persistence of extramedullary hematopoiesis in the liver, right ventricular hypertrophy and increased periadrenal brown fat have also been seen and suggest a degree of chronic hypoxia. However, except for brainstem pathologies, none of these changes occurs with any regularity. Petechiae on the surfaces of the lungs, heart, pleura and thymus are reported in most infants dying of SIDS but probably reflect terminal events attributed to negative intrathoracic pressure produced by respiratory efforts.

NEOPLASMS OF INFANCY AND CHILDHOOD

Malignancies in children 1–15 years old are uncommon, but cancer remains the leading cause of death from disease in this age group. Ten percent of deaths in children are due to cancer, exceeded only by accidental trauma. Unlike adults, in whom most cancers are of epithelial origin (e.g., carcinomas of the lung, breast and GI tract), most malignant tumors in children arise from hematopoietic, nervous and soft tissues (Fig. 6-44). Many childhood cancers are part of developmental complexes (Table 6-4). Examples include short arm deletions of chromosome 11, especially 11p13, causing Wilms tumor associated with aniridia, genitourinary malformations and mental retardation (WAGR complex); hemihypertrophy of the body with Wilms tumor, hepatoblastoma and adrenal carcinoma; and tuberous sclerosis with renal tumors and cardiac rhabdomyomas. Loss of the long arm of chromosome 13 is associated with retinoblastoma due to the loss of the *Rb* tumor suppressor gene. Some tumors are evident at birth and so obviously develop in utero. In addition, abnormally developed organs, persistent organ primordia and displaced organ rests are all liable to neoplastic transformation.

Individual cancers of childhood are discussed in detail in chapters on the respective organs, and the principles of neoplasia and carcinogenesis are discussed in Chapter 5. FISH is used to identify specific genetic abnormalities in both childhood and adult cancers including amplifications, deletions and rearrangements involving specific oncogenes and/or tumor suppressors. Examples are listed in Table 6-13.

Tumor-Like Conditions Involve Displaced Tissues and Cells

HAMARTOMAS: These lesions are focal, benign overgrowths of one or more mature cellular elements of a normal tissue, often arranged irregularly. Many hamartomas are clonal and have defined DNA rearrangements, and so may be classified as true neoplasms.

CHORISTOMAS: Also called **heterotopias,** choristomas are tiny aggregates of normal tissue components in aberrant locations. They are not true tumors. Examples include pancreatic rests in the walls of gastrointestinal organs, and adrenal tissue in the renal cortex.

TABLE 6-13
FISH ANALYSIS OF TUMORS IN CHILDREN AND ADULTS

Tumor Type	DNA Probes	Chromosome Location	Abnormality Detected
Breast cancer (FDA approved)	D17Z1/HER-2/neu	Centromere 17 and 17q11.2-12	HER-2/neu amplification
Bladder cancer and cholangiocarcinoma (FDA approved)	D3Z1/D7Z1/D17Z1/p16	Centromere 3, 7, 17 and 9p21	Loss of centromere 3, 7, 17 and p16 loci
Lung cancer	D5S23/D5S721/D6Z1/EGFR/C-MYC	5p15.2/centromere 6/7p12/8q24	Loss or gain of 5p15.2/centromere 6/7p12/8q24
Retinoblastoma	RB1	13q14	Deletion of 13q14
Neuroblastoma	NMYC	2p24.1	NMYC amplification
Burkitt lymphoma	C-MYC	8q24	8q24 rearrangement
Ewing sarcoma	EWSR1	22q12	22q12/ t(11;22)(q24;q12) rearrangement
Oligodendroglioma	LSI 1p36 (TP73)/1p25(ABL2) LSI 19q13(ZNF)/19p13(CRX)	1p36/1p25/19q13/19p13	1p36 and 19q13 deletions
Gliomas	PTEN	10q23	10q23 deletion
Synovial sarcoma	SYT	18q11.2	18q11.2 rearrangement
Myxoid/round cell liposarcoma	CHOP	12q13	12q13 rearrangement
Alveolar rhabdomyosarcoma	FKHR	13q14	13q14 rearrangement

FDA = Food and Drug Administration; FISH = fluorescence in situ hybridization.

Benign Childhood Tumors of Vascular Origin Are Common

HEMANGIOMAS: These lesions, of varying size and in diverse locations, are the most common tumors in childhood. Whether they are true neoplasms is unclear, but half are present at birth and most regress with age. Large, rapidly growing hemangiomas, especially on the head or neck, may occasionally cause serious problems. **Port wine stains** are congenital capillary hemangiomas of the skin of the face and scalp. They are often disfiguring, giving the affected area a dark purple color. Unlike many small hemangiomas, they persist for life.

LYMPHANGIOMAS: Also called **cystic hygromas,** these are poorly circumscribed swellings that are usually present at birth and thereafter rapidly increase in size. Most occur on the head and neck, but the floor of the mouth, mediastinum and buttocks are not uncommon sites. Some authorities consider lymphangiomas to be developmental malformations; others call them neoplasms. They may be unilocular or multilocular and have thin, transparent walls and contain straw-colored fluid. Myriad dilated lymphatic channels are separated by fibrous septa. Unlike hemangiomas, these lesions do not regress spontaneously and should be resected.

SACROCOCCYGEAL TERATOMAS: These rare germ cell tumors, which occur in 1 in 40,000 live births, are the most common solid neoplasms in the newborn. Over 75% of sacrococcygeal teratomas occur in girls, and a substantial number are seen in twins. They are usually noticed at birth as masses near the sacrum and buttocks. They may be large, lobulated tumors, sometimes as large as the infant's head. One half grow externally and may be connected to the body by a stalk. Some have both external and intrapelvic components, and a few grow entirely in the pelvis. Sacrococcygeal teratomas contain multiple tissues, particularly of neural origin. Most (90%) detected before the age of 2 months are benign, but up to half of those found later in life are malignant. Associated congenital anomalies of vertebrae, the genitourinary system and the anorectum are common. These lesions should be resected promptly.

Pediatric Malignancies Are Mostly of Mesodermal Origin

The incidence of childhood cancer is 1.3 per 10,000 per year in children younger than 15. Mortality is determined by the intrinsic behavior of the tumor and its response to therapy, but overall, the death rate for childhood cancer is 1/3 of the incidence. Almost half of all such malignancies are acute leukemias and lymphomas. The former, particularly acute lymphoblastic leukemia, make up 1/3 of childhood cancers. Most of the rest are neuroblastomas, brain tumors, Wilms tumors, retinoblastomas, bone cancers and soft tissue sarcomas.

Genetic influences in the development of childhood tumors are well studied in the case of retinoblastoma, Wilms tumor and osteosarcoma. Interactions of heritable factors and environmental influences in the pathogenesis of malignant tumors in both children and adults are discussed in Chapter 5.

NORMAL CIRCULATION

Normal function and metabolism of organs and cells depend on an intact circulatory system for continuous delivery of oxygen, nutrients, hormones, electrolytes and water, as well as for removal of metabolic waste and carbon dioxide. The circulatory system is a vascular conduit made of a muscular pump connected to tubes (or blood vessels) that deliver blood to organs and tissues and return it to the heart to complete the circuit. Delivery and elimination at the cellular level are controlled by exchanges between the intravascular space, interstitial space, cellular space and lymphatic space, which occur via the smallest-diameter blood vessels in the body (the microcirculation).

The Heart Is a Two-Sided Pump with Vascular Circuits in Series

In this series circuit, the amount of blood handled by the right ventricle, which pumps blood to the lungs (pulmonary circulation), must, over time, exactly equal the amount of blood going through the left ventricle, which distributes blood to the body (systemic circulation). The hemodynamically important parameters are cardiac output, perfusion pressure and peripheral vascular resistance.

- **Cardiac output** is the volume of blood pumped by each ventricle per minute and represents the total blood flow in pulmonary and systemic circuits. Cardiac output is the product of heart rate and stroke volume and, as the **cardiac index,** is often adjusted for body surface area (in square meters) as an indicator of ventricular function.
- **Perfusion pressure** (also called **driving pressure**) is the difference in dynamic pressure between two points along a blood vessel. Blood flow to any segment of the circulation ultimately depends on arterial driving pressure. However, each organ can autoregulate flow and so determine the amount of blood it receives from the circulation. Such local control of perfusion depends on continuous modulation of microvascular beds by hormonal, neural, metabolic and hemodynamic factors.
- **Peripheral vascular resistance** is the sum of the factors that determine regional blood flow in each organ. Two thirds of the resistance in the systemic vasculature is determined by the arterioles.

The sum of all regional flows equals the **venous return,** which in turn determines the cardiac output. Assessment of the heart's response to inflow (preload) and outflow (afterload) relies on cardiac reflexes as well as cardiac muscle integrity and neurohormonal regulation.

The Aorta and Arteries Are Conducting Vessels

The major functions of the aorta and arteries are to transport blood to the organs and convert pulsatile flow into sustained regular flow. The latter function derives from the elastic properties of the aorta and the resistance produced by the arteriolar sphincters.

The Microcirculation Includes Arterioles, Capillaries and Venules

The blood vessels of the microcirculation are less than 100 μM in diameter. Blood from an arteriole enters capillaries, which

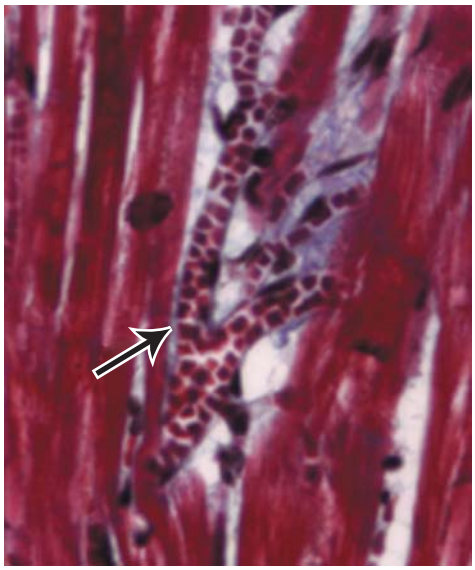

FIGURE 7-1. Microcirculation. Photomicrograph of myocardium showing capillaries and venules (*arrow*).

freely anastomose with each other (Fig. 7-1), either directly or through metarterioles. Capillary length, measured from terminal arteriole to collecting venule, ranges from 0.1 to 3 mm, averaging 1 mm. However, the path length by which blood cells traverse capillaries may actually be longer because of their extensive anastomoses. This fact is likely an important factor with respect to microvascular exchange of substances such as oxygen because it increases the time available for such exchange to take place. The large aggregate surface area of capillaries determines that velocity is low, which further enhances microvascular exchange (Fig. 7-2). The density of capillaries in a tissue also influences microvascular exchange by affecting the diffusion distance. For example, in

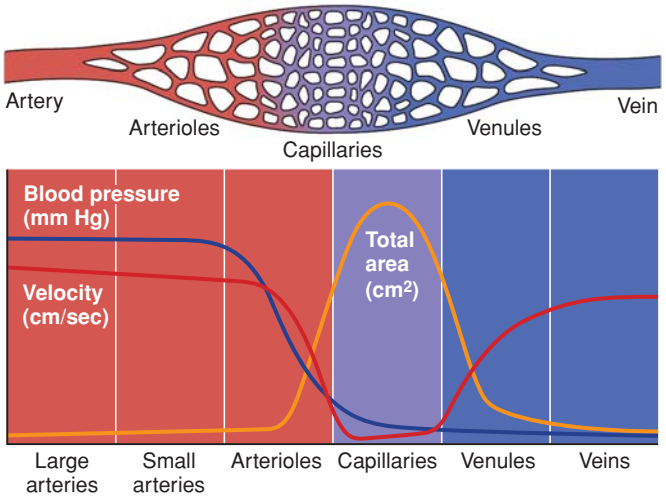

FIGURE 7-2. Blood pressure, velocity and total area within the circulatory system. Note that the higher resistance due to diameter reduction in the arterioles results in a drop in perfusion pressure, the capillary network constitutes the vast majority of vascular surface area and the venous system is a low-pressure, high-capacitance structure with a series of valves to prevent retrograde flow.

tissues with high oxygen demands, such as the heart, capillary density is very high. Entry into the capillary system is guarded by precapillary sphincters, except for **thoroughfare channels,** which bypass capillaries and are always open. Since not all capillaries are always open, blood flow to a structure can be increased by recruiting additional capillaries. The sum of blood flow through the capillary bed, the thoroughfare channels and the arteriovenous anastomoses determines the regional blood flow.

The exact means by which an organ regulates blood flow according to its metabolic needs are still debated, but there is a link between oxygen demand and blood flow. In the heart, blood flow is adjusted on a second-to-second basis. Factors that mediate and link metabolic vasodilation to cellular metabolism include adenosine, other nucleotides, nitric oxide, certain prostaglandins, carbon dioxide and pH. The microcirculation is an important contributor to all forms of hyperemia and edema, and is a target in septic shock (see below). Vasoregulation in conducting arteries, resistance arteries and veins relies on delicate interactions between blood, endothelium, smooth muscle cells and surrounding stroma.

The Endothelium Provides a Continuous Partition between Blood and Tissues

Endothelial cells play important roles in anticoagulation, facilitation of migration of substances from blood to tissue and back, regulation of vessel tone (particularly that of resistance arteries) and regulation of vasopermeability (see Chapters 2 and 16).

Veins and Venules Return Blood to the Heart

Blood from the capillaries enters venules and eventually veins on its route back to the heart. Veins not only serve as a conduit for blood but also act as a blood reservoir; 64% of the total blood volume resides in the venous system.

The Interstitium Represents 15% of Total Body Volume

The interstitial fluid between cells provides a means for the delivery of nutrients and the elimination of waste. Most interstitial water is bound to a dense network of glycosaminoglycans.

Lymphatics Reabsorb Interstitial Fluid

Interstitial fluid is reabsorbed into the circulation at the venous end of the capillary, and a small portion is drained through lymphatics. Lymphatic capillaries conduct lymph from the periphery to the central venous system via the thoracic duct. Normal oscillatory constrictions and relaxations of lymphatic vessels contribute to the steady return of lymph fluid to the central circulation. Lymph is a solvent for large molecules that cannot return to the circulation through blood capillaries.

DISORDERS OF PERFUSION

Hemodynamic disorders are characterized by disturbed perfusion that results in organ and cellular injury.

Hyperemia Is an Excess of Blood in an Organ

Hyperemia may be caused either by an increased supply of blood from the arterial system **(active hyperemia)** or by impaired exit of blood through venous pathways **(passive hyperemia** or **congestion)**.

Active Hyperemia

Active hyperemia is augmented supply of blood to an organ. It is usually a physiologic response to increased functional demand, as in the heart and skeletal muscle during exercise. Neurogenic and hormonal influences play a role in active hyperemia (e.g., the blushing bride and the menopausal flush). Although the utility of vasodilation in these examples is not clear, cutaneous hyperemia in febrile states serves to dissipate heat. In addition, skeletal muscle may increase its blood flow (and thus oxygen delivery) 20-fold during exercise. The increased blood supply occurs by arteriolar dilation and recruitment of unperfused capillaries.

The most striking active hyperemia occurs in association with inflammation. Vasoactive materials released by inflammatory cells (see Chapter 2) cause dilation of blood vessels; in the skin this contributes to classic "tumor, rubor and calor" of inflammation. In pneumonia, for example, alveolar capillaries are engorged with erythrocytes as a hyperemic response to inflammation. Because inflammation can also damage endothelial cells and increase capillary permeability, inflammatory hyperemia is often accompanied by edema and local extravasation of erythrocytes.

Reactive hyperemia occurs after temporary interruption of blood supply (ischemia). The release of the obstruction is followed by active hyperemia, probably due to ischemic tissue injury and release of inflammatory agents such as histamine. The degree and duration of hyperemia is proportional to the period of occlusion until a plateau of hyperemic response is reached.

Passive Hyperemia (Congestion)

Passive hyperemia, or congestion, is engorgement of an organ with venous blood. Acute passive congestion is clinically a consequence of acute left or right ventricular failure. Regarding the former, resultant venous engorgement of the lungs leads to accumulation of a transudate in the alveoli, which is called **pulmonary edema**. With acute failure of the right ventricle, the liver can become severely congested.

Generalized increases in venous pressure, typically from chronic heart failure, lead to slower blood flow and a consequent increase in blood volume in many organs, including liver, spleen and kidneys. In the past, heart failure from rheumatic mitral stenosis was a common cause of generalized venous congestion, but with the decline in the prevalence of rheumatic fever and the advent of surgical valve replacement, such cases are unusual. Congestive heart failure secondary to coronary artery disease and hypertension and right-sided failure due to pulmonary disease are now more common.

Passive congestion may also be confined to a limb or an organ as a result of more-localized obstruction to venous drainage. Examples include deep venous thrombosis of the leg veins, with resulting edema of the lower extremity, and thrombosis of hepatic veins (Budd-Chiari syndrome), with secondary chronic passive congestion of the liver.

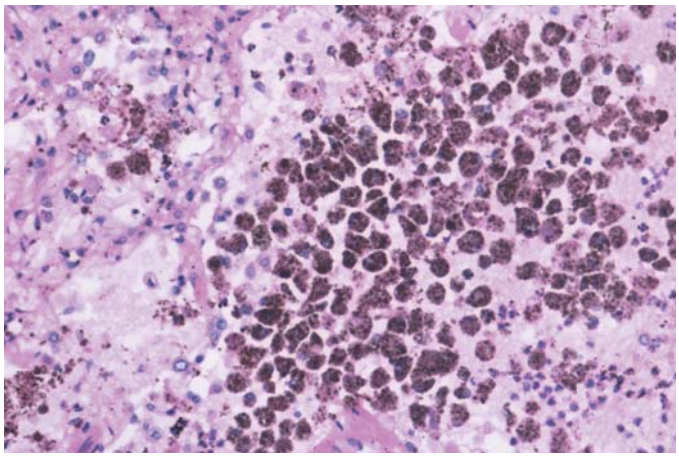

FIGURE 7-3. Passive congestion of lung. Hemosiderin-laden macrophages in the lung of a patient with congestive heart failure.

LUNGS: Chronic left ventricular failure impedes blood flow out of the lungs and gives rise to chronic passive pulmonary congestion. As a result, pressure in alveolar capillaries increases, and these vessels become engorged with blood. Increased pressure in the alveolar capillaries has four major consequences:

- Microhemorrhages release erythrocytes into alveolar spaces, where they are phagocytosed and degraded by alveolar macrophages. The released iron, in the form of hemosiderin, remains in these macrophages, which are then called "heart failure cells" (Fig. 7-3).
- Fluid is forced from the blood into the alveolar airspaces, resulting in pulmonary edema (Fig. 7-4), which interferes with gas exchange in the lung.
- Fibrosis increases in the interstitium of the lung. The presence of fibrosis and iron is viewed grossly as a firm, brown lung **(brown induration)**.
- **Pulmonary hypertension** occurs when the pressure is transmitted to the pulmonary arterial system. This may lead to right-sided heart failure and consequent generalized systemic venous congestion.

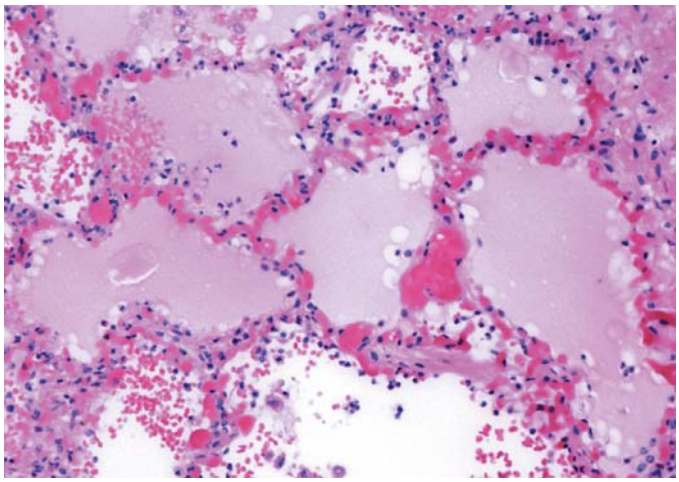

FIGURE 7-4. Pulmonary edema. A patient with congestive heart failure shows pink-staining fluid in the alveoli.

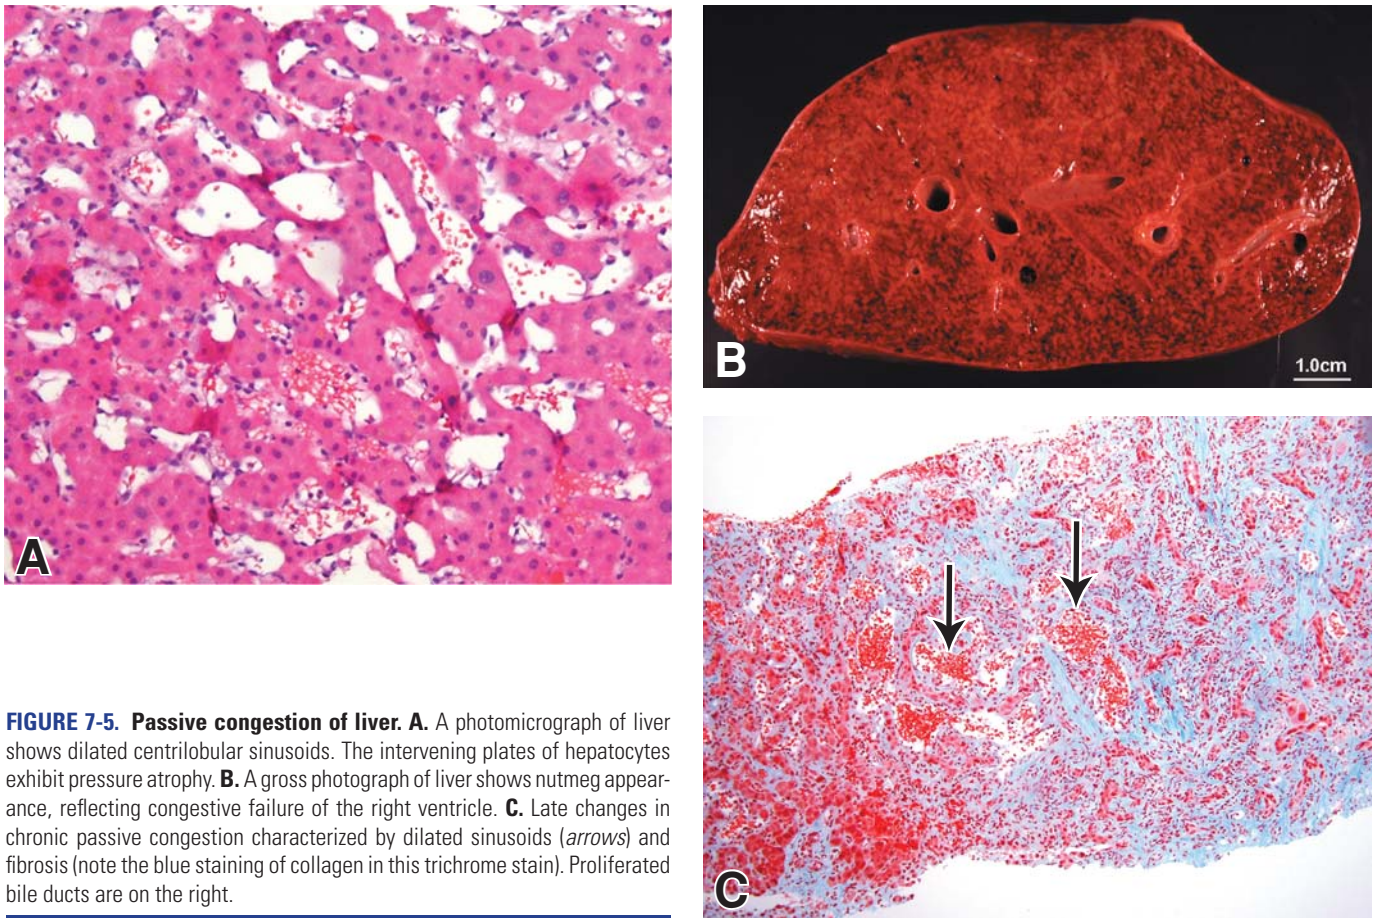

FIGURE 7-5. Passive congestion of liver. A. A photomicrograph of liver shows dilated centrilobular sinusoids. The intervening plates of hepatocytes exhibit pressure atrophy. **B.** A gross photograph of liver shows nutmeg appearance, reflecting congestive failure of the right ventricle. **C.** Late changes in chronic passive congestion characterized by dilated sinusoids (*arrows*) and fibrosis (note the blue staining of collagen in this trichrome stain). Proliferated bile ducts are on the right.

In Chapter 18, the morphologic changes associated with chronic passive congestion of the lungs are discussed.

LIVER: The hepatic veins empty into the vena cava just inferior to the heart, so the liver is particularly vulnerable to acute or chronic passive congestion (see Chapter 20). The central veins of hepatic lobules become dilated. The increased venous pressure is transmitted to the sinusoids, which dilate, and centrilobular hepatocytes undergo pressure atrophy (Fig. 7-5A). Grossly, the cut surface of a chronically congested liver exhibits dark foci of centrilobular congestion surrounded by paler zones of unaffected peripheral portions of the lobules. The result is a reticulated appearance that resembles a cross-section of a nutmeg ("nutmeg liver") (Fig. 7-5). In extreme cases associated with acute right ventricular failure, frank hemorrhagic necrosis of hepatocytes in the centrilobular zones is conspicuous. Prolonged hepatic venous congestion eventually leads to thickening of central veins and centrilobular fibrosis. Only in the most extreme cases of venous congestion (e.g., constrictive pericarditis or tricuspid stenosis) is the fibrosis sufficiently generalized and severe to justify the label **cardiac cirrhosis**.

SPLEEN: Increased intravascular pressure in the liver, from cardiac failure or an intrahepatic obstruction to blood flow (e.g., cirrhosis), generates higher pressure in the splenic vein and congestion of the spleen. The organ becomes enlarged and tense, and the cut section oozes dark blood. In long-standing congestion, diffuse splenic fibrosis develops, as do iron-containing, fibrotic and calcified foci of old hemorrhage (Gamna-Gandy bodies). Such a spleen may weigh 250–750 g, compared with a normal weight of 150 g. The enlarged spleen sometimes displays excessive functional activity—**hypersplenism**—which causes hematologic abnormalities (e.g., thrombocytopenia).

EDEMA AND ASCITES: Venous congestion impedes blood flow through the capillaries, thus increasing hydrostatic pressure and promoting edema formation (see below for a discussion of mechanisms of edema formation). Accumulation of edema fluid in heart failure is particularly noticeable in dependent tissues—legs and feet in ambulatory patients and the back in bedridden patients. **Ascites** is accumulation of fluid in the peritoneal space and reflects (among other factors) lack of tissue rigor, a condition in which there is no countervailing external pressure to oppose hydrostatic pressure within the blood vessels.

Hemorrhage Is a Discharge of Blood out of the Vascular Compartment

Blood can be released from the circulation to the exterior of the body or into nonvascular body spaces. The most common and obvious cause is trauma. Severe atherosclerosis may so weaken the wall of the abdominal aorta that it balloons to form an aneurysm, which then may rupture and bleed into the retroperitoneal space (see Chapter 16). In the same way, an aneurysm may complicate a congenitally weak cerebral artery (berry aneurysm) and cause subarachnoid hemorrhage (see Chapter 32). Certain infections (e.g., pulmonary tuberculosis) and invasive neoplasms may erode blood vessels and result in hemorrhage.

Hemorrhage also results from damage to capillaries. For instance, rupture of capillaries by blunt trauma creates a bruise. Increased venous pressure also causes extravasation of blood from pulmonary capillaries. Scurvy is associated with capillary fragility and bleeding, owing to defective supporting connective tissue structures. The capillary barrier by itself does not suffice to contain blood within the intravascular space. The minor trauma imposed on small vessels and capillaries by normal movement requires an intact coagulation system to prevent hemorrhage. Thus, a severe decrease in the number of platelets **(thrombocytopenia)** or deficiency of a coagulation factor (e.g., factor VIII in hemophilia A or von Willebrand factor in von Willebrand disease) is associated with spontaneous hemorrhage without apparent trauma (see Chapters 16).

Someone may exsanguinate into an internal cavity, as in gastrointestinal hemorrhage from a peptic ulcer (arterial hemorrhage) or esophageal varices (venous hemorrhage). In such cases, large amounts of fresh blood fill the entire gastrointestinal tract. Bleeding into a serous cavity can result in accumulation of a large amount of blood, even to the point of exsanguination.

A few definitions are in order:

- **Hematoma:** Hemorrhage into soft tissue. Such collections of blood can be merely painful, as in a muscle bruise, or fatal, if located in the brain.
- **Hemothorax:** Hemorrhage into the pleural cavity.
- **Hemopericardium:** Hemorrhage into the pericardial space.
- **Hemoperitoneum:** Bleeding into the peritoneal cavity.
- **Hemarthrosis:** Bleeding into a joint space.
- **Purpura:** Diffuse superficial hemorrhages in the skin, up to 1 cm in diameter.
- **Ecchymosis:** A large superficial hemorrhage in the skin (Fig. 7-6). It is purple at first, then turns green, then yellow before resolving. This sequence of events reflects progressive oxidation of bilirubin released from the hemoglobin of degraded erythrocytes. A good example of an ecchymosis is a "black eye."
- **Petechiae:** Pinpoint hemorrhages, usually in the skin or conjunctiva (Fig. 7-7). This lesion represents the rupture of a capillary or arteriole and occurs in conjunction with coagulopathies or vasculitis. Petechiae may also be produced by microemboli from infected heart valves (bacterial endocarditis).

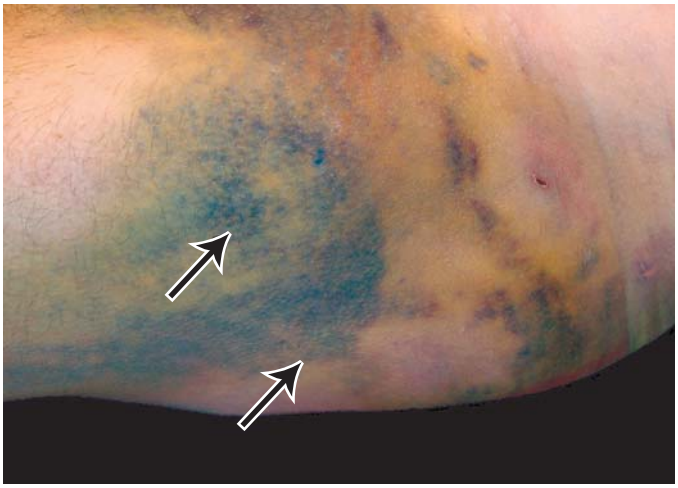

FIGURE 7-6. Ecchymosis. Superficial diffuse hemorrhage (*arrows*) on the thigh caused by blunt force trauma.

FIGURE 7-7 Petechiae. Periorbital microhemorrhages (*arrows*) appear as punctate red foci.

MOLECULAR PATHOGENESIS:

Coagulation

Coagulation has a significant genetic component. Rare, well-characterized, highly penetrant, monogenic causes of coagulopathies include von Willebrand disease and hemophilias. Hereditary factors control the circulating levels of several coagulation cascade proteins, including plasminogen activator inhibitor-1, factor XIII, factor VII, fibrinogen and tissue plasminogen activator.

Pharmacogenetics is the study of individual genetic variations on the action of drugs. Warfarin is an anticoagulant with a narrow therapeutic index and greater than 10-fold variability in dose requirements. Clinically, this necessitates regular measurements of the international normalized ratio (INR). This appears to be dependent on genetic variants of the metabolic enzyme cytochrome P450 2C9 (CYP2C9) and vitamin K epoxide reductase complex 1 (VKORC1). Allelic variants CYP2C9*2 or CYP2C9*3 result in increased metabolic clearance of warfarin. Among several VKORC1 mutations, the -1639G>A is the strongest predictor of warfarin dose requirements. The thienopyridine antiplatelet agent, clopidogrel, is a prodrug requiring hepatic activation by cytochrome P450 (CYP) enzymes. Clopidogrel is susceptible to genetic polymorphisms in CYP2C19, which can result in clopidogrel resistance. On the other hand, newer-generation thienopyridines, such as Ticagrelor, are not CYP dependent and thus have a more rapid and consistent level of activity.

THROMBOSIS

Thrombosis refers to the formation of a thrombus, defined as an aggregate of coagulated blood containing platelets, fibrin and entrapped cellular elements, within a vascular lumen.

A **thrombus** by definition adheres to vascular endothelium and should be distinguished from a simple blood clot, which reflects only activation of the coagulation cascade and can form in vitro or even postmortem. Similarly, a thrombus differs from a hematoma, which results from hemorrhage and subsequent clotting outside the vascular system. Thrombus formation and the coagulation cascade are discussed in more detail in Chapters 16 and 26. Although pathogenesis of venous and arterial thrombosis has been considered distinct, recent epidemiologic evidence has demonstrated commonalities in risk factors and association between these entities, suggesting mechanistic overlap. Here we present the causes and consequences of thrombosis in these different vascular sites.

Thrombosis in the Arterial System Is Usually Due to Atherosclerosis

MOLECULAR PATHOGENESIS AND ETIOLOGIC FACTORS: The vessels most commonly involved in arterial thrombosis are coronary, cerebral, mesenteric and renal arteries and arteries of the lower extremities. Less commonly, arterial thrombosis occurs in other disorders, including inflammation of arteries (arteritis), trauma and blood diseases. Thrombi are common in aneurysms (localized dilations of the lumen) of the aorta and its major branches, in which the distortion of blood flow, combined with intrinsic vascular disease, promotes thrombosis. A major risk factor for thrombosis is immobilization after surgery or after leg casting. Other risk factors include metabolic syndrome, which typically includes obesity, hyperglycemia, insulin resistance, dyslipidemia and hypertension; advanced age; tobacco use; previous thrombosis; and cancer. The pathogenesis of arterial thrombosis involves principally three factors:

- **Damage to endothelium,** usually by atherosclerosis, disturbs the anticoagulant properties of the vessel wall and serves as a nidus for platelet aggregation and fibrin formation.
- **Alterations in blood flow,** whether from turbulence in an aneurysm or at sites of arterial bifurcation, is conducive to thrombosis. Slowing of blood flow in narrowed arteries favors thrombosis.
- **Increased coagulability of the blood,** as seen in polycythemia vera or in association with some cancers, entails an increased risk of thrombosis.

MOLECULAR PATHOGENESIS

Arterial Thromboembolism

Compared with the study of venous thrombosis, for which several mutations in key genes have been identified, genetic studies of arterial thrombosis have not yielded a mutation with a large population-attributable risk. This is likely due to the complex polygenetic and multifactorial nature of an atherosclerotic plaque rupture or erosion. Weak associations have been shown between certain coagulation factors, fibrinolytic factors, inflammatory mediators and others. The most consistent genetic associations with arterial thrombosis are with factor VII and fibrinogen. Hyperhomocysteinemia is also associated with coronary artery disease and cardiac ischemia events.

FIGURE 7-8. Arterial thrombus. Gross photograph of a thrombus from an aortic aneurysm shows the laminations of fibrin and platelets known as the lines of Zahn.

PATHOLOGY: Arterial thrombi attached to vessel walls are soft, friable, and dark red at first, with fine alternating bands of yellowish platelets and fibrin, the lines of Zahn (Fig. 7-8). Then, arterial thrombi have several possible fates.

- **Lysis,** owing to the potent thrombolytic activity of the blood.
- **Propagation** (i.e., increase in size), as the thrombus acts as a focus for further thrombosis.
- **Organization,** the eventual invasion of connective tissue elements, which causes a thrombus to become firm and grayish white.
- **Canalization,** by which new lumina lined by endothelial cells form in an organized thrombus (Fig. 7-9). Its functional significance is often uncertain.
- **Embolization,** when part or all of the thrombus becomes dislodged, travels through the circulation and lodges in a blood vessel some distance from the site of thrombus formation (see below for further discussion).

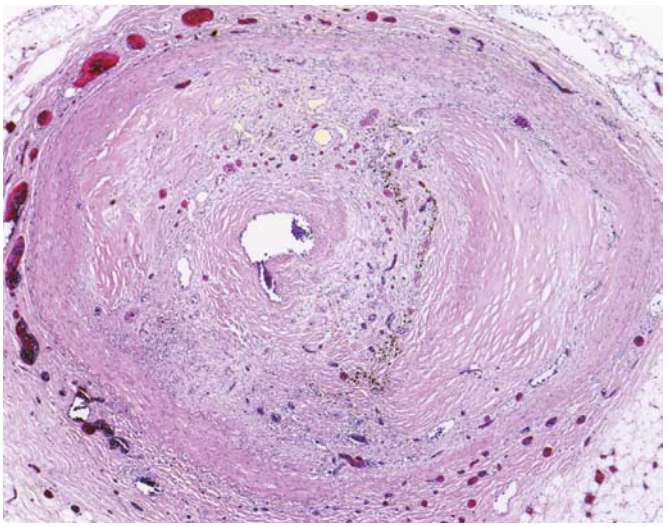

FIGURE 7-9. Canalization of thrombus. Photomicrograph of the left anterior descending coronary artery shows severe atherosclerosis and canalization.

The organized structure of a thrombus reflects a tight interaction between platelets and fibrin and differs in appearance from a postmortem clot or one formed in a test tube. Determination of whether a clot formed during life (antemortem clot) or after death (postmortem clot) is often important in a medical autopsy and in forensic pathology. Lines of Zahn stabilize a thrombus formed during life, while a postmortem clot has a more gelatinous structure. Postmortem clots occur in stagnant blood in which gravity fractionates the blood. The part of the clot containing many red blood cells has a reddish, gelatinous appearance and is referred to as "currant jelly." The overlying clot is firmer and yellow-white, representing coagulated plasma without red blood cells. It is called "chicken fat" because of its color and consistency.

CLINICAL FEATURES: ***Arterial thrombosis due to atherosclerosis is the most common cause of death in industrialized countries.*** Since most arterial thrombi occlude the vessel, they often lead to ischemic necrosis of tissue supplied by that artery (i.e., an **infarct**). Thus, thrombosis of a coronary or cerebral atherosclerotic plaque (Fig. 7-10) results in **myocardial infarct** (heart attack) or **cerebral infarct** (stroke), respectively. Other end-arteries that are affected often by atherosclerosis and often suffer thrombosis include mesenteric arteries (intestinal infarction), renal arteries (kidney infarcts) and arteries of the leg (ischemic leg and gangrene).

Thrombosis in the Heart Develops on the Endocardium

As in the arterial system, endocardial injury and changes in blood flow in the heart may lead to mural thrombosis (i.e., a thrombus adhering to the underlying wall of the heart). The disorders in which mural thrombosis occurs include:

- **Myocardial infarction:** Mural thrombi adhere to the left ventricular wall, over areas of myocardial infarction, owing to damaged endocardium and alterations in blood flow associated with an akinetic or dyskinetic segment of the myocardium.
- **Atrial fibrillation:** Disordered atrial activity (atrial fibrillation) leads to slower blood flow and impairs left atrial contractility, a situation that predisposes to formation of mural thrombi, most often in the left atrial appendage.
- **Cardiomyopathy:** Primary myocardial diseases are associated with mural thrombi in the left ventricle, presumably because of endocardial injury and altered hemodynamics associated with poor myocardial contractility.
- **Endocarditis:** Small thrombi, **vegetations,** may also develop on cardiac valves, usually mitral or aortic, that are damaged by a bacterial infection (bacterial endocarditis) (Fig. 7-11). Occasionally, vegetations form in the absence of valve infection, on a mitral or tricuspid valve injured by systemic lupus erythematosus (Libman-Sacks endocarditis). In chronic wasting states, as in terminal cancer, large, friable vegetations may appear on cardiac valves (marantic endocarditis), possibly reflecting a hypercoagulable state.

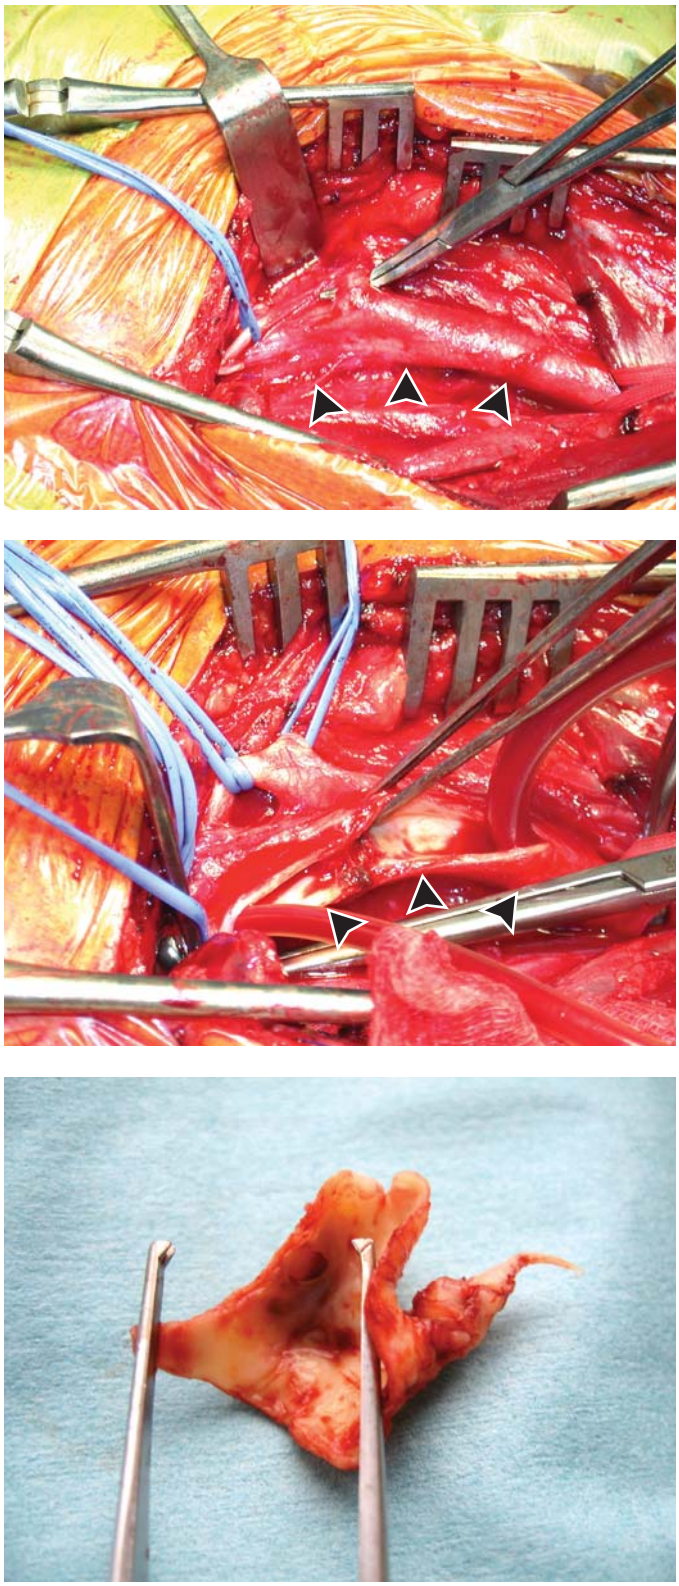

FIGURE 7-10. Endarterectomy. Intraoperative image of a carotid artery (*above, arrowheads*) postarteriotomy displaying a near-occlusive atherosclerotic plaque in situ (*middle, arrowheads*) and the atherosclerotic plaque itself after carotid endarterectomy (*below*).

FIGURE 7-11. Endocarditis. The anterior leaflet of the mitral valve is damaged by a friable bacterial vegetation.

The major complication of thrombi in any location in the heart is detachment of fragments and their lodging in blood vessels at distant sites **(embolization)**.

Thrombosis in the Venous System Is Multifactorial

At one time, venous thrombosis was widely referred to as **thrombophlebitis,** implying that an inflammatory or infectious process had injured the vein, thus causing thrombosis. However, with recognition that there is no evidence of inflammation in most cases, the term **phlebothrombosis** is more accurate. Nevertheless, both terms have been replaced for the most part by the expression **deep venous thrombosis.** This last term is particularly appropriate for the most common manifestation of the disorder, namely, thrombosis of the deep venous system of the legs.

MOLECULAR PATHOGENESIS AND ETIOLOGIC FACTORS: Deep venous thrombosis is caused by the same factors that favor arterial and cardiac thrombosis—endothelial injury, stasis and a hypercoagulable state. Conditions that favor the development of deep venous thrombosis include:

- **Stasis** (heart failure, chronic venous insufficiency, postoperative immobilization, prolonged bed rest, hospitalization and travel)
- **Injury and inflammation** (trauma, surgery, childbirth, infection)
- **Hypercoagulability** (oral contraceptives, late pregnancy, cancer, inherited thrombophilic disorders [see Chapter 26])
- **Advanced age** (venous varicosities, phlebosclerosis)
- **Sickle cell disease** (see Chapter 26)

MOLECULAR PATHOGENESIS:

Venous Thromboembolism

Genetic factors account for 60% of the risk for deep venous thrombosis (DVT) according to twin and family studies. However, few genetic associations have been consistently identified. Epidemiologic data from the United States demonstrated that blacks are more susceptible to the development of DVT as compared to whites, but Asians and Hispanics are less so. Single nucleotide polymorphisms (SNPs) represent 90% of the common variation in the human genome and are the main focus of disease-related genetic studies. The most common gene variant associated with venous thrombosis is factor V Leiden, which results in a poor inactivation and anticoagulant response to activated protein C. Another common but mild risk factor is the prothrombin G20210A mutation. Deficiencies in proteins C and S and antithrombin are rare but strong risk factors for DVT. Any single SNP or combination of such SNPs can carry an increased risk of venous thromboembolic episodes in childhood and adolescence.

PATHOLOGY: Most (>90%) venous thromboses occur in deep veins of the legs; the rest usually involve pelvic veins. Most begin in the calf veins, often in the sinuses above venous valves. There, venous thrombi have several potential fates:

- **Lysis:** They may stay small, eventually be lysed and pose no further danger.
- **Organization:** Many undergo organization similar to those of arterial origin. Small, organized venous thrombi may be incorporated into the vessel wall; larger ones may undergo canalization, with partial restoration of venous drainage.
- **Propagation:** Venous thrombi often serve to elicit further thrombosis and so propagate proximally to involve the larger iliofemoral veins (Fig. 7-12).

FIGURE 7-12. Phlegmasia cerulea dolens in the right foot. The cause is venous obstruction due to deep vein thrombosis and is associated with cyanosis, edema, swelling and pain.

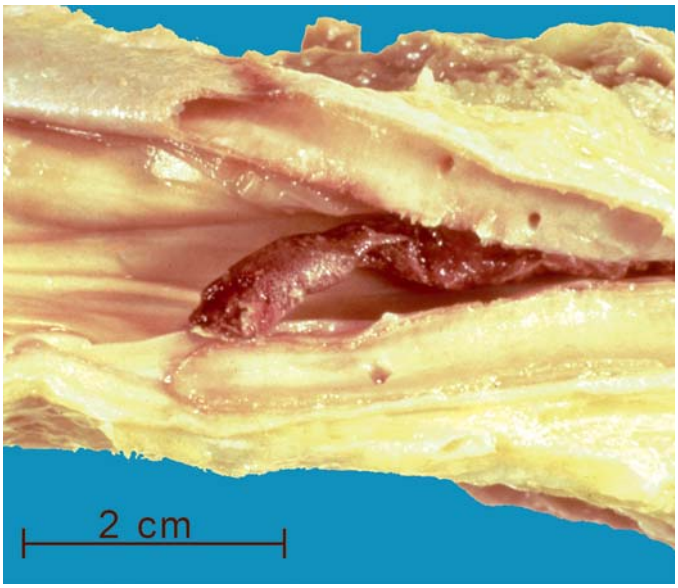

FIGURE 7-13. Venous thrombus. The femoral vein has been opened to reveal a large thrombus within the lumen.

- **Embolization:** Large venous thrombi or those that have propagated proximally represent a significant hazard to life: they may dislodge and be carried to the lungs as pulmonary emboli. In severe cases, complete or near-complete venous obstruction in a limb may result in phlegmasia cerulea dolens, characterized by pain, swelling, edema and cyanosis (Fig. 7-13).

CLINICAL FEATURES: Small thrombi in the calf veins are ordinarily asymptomatic, and even larger thrombi in the iliofemoral system may cause no symptoms. Some patients have calf tenderness, often associated with forced dorsiflexion of the foot **(Homan sign)**. Occlusive thrombosis of femoral or iliac veins leads to severe congestion, edema and cyanosis of the lower extremity. Symptomatic deep venous thrombosis is treated with systemic anticoagulants, and thrombolytic therapy may be useful in selected cases. In some cases, a filter is inserted into the vena cava to prevent pulmonary embolization.

The function of venous valves is always impaired in a vein subjected to thrombosis and organization. As a result, chronic deep venous insufficiency (i.e., impaired venous drainage) is virtually inevitable. If a lesion is restricted to a small segment of the deep venous system, the condition may remain asymptomatic. However, more extensive involvement leads to pigmentation, edema and induration of leg skin. Ulceration above the medial malleolus can occur and is often difficult to treat.

Venous thrombi elsewhere may also be dangerous. Thrombosis of mesenteric veins can cause hemorrhagic small bowel infarction; thrombosis of cerebral veins may be fatal; hepatic vein thrombosis (Budd-Chiari syndrome) tends to destroy the liver.

Inherited disorders of blood clotting increase susceptibility to these types of events. These diseases are covered in detail in Chapter 26.

EMBOLISM

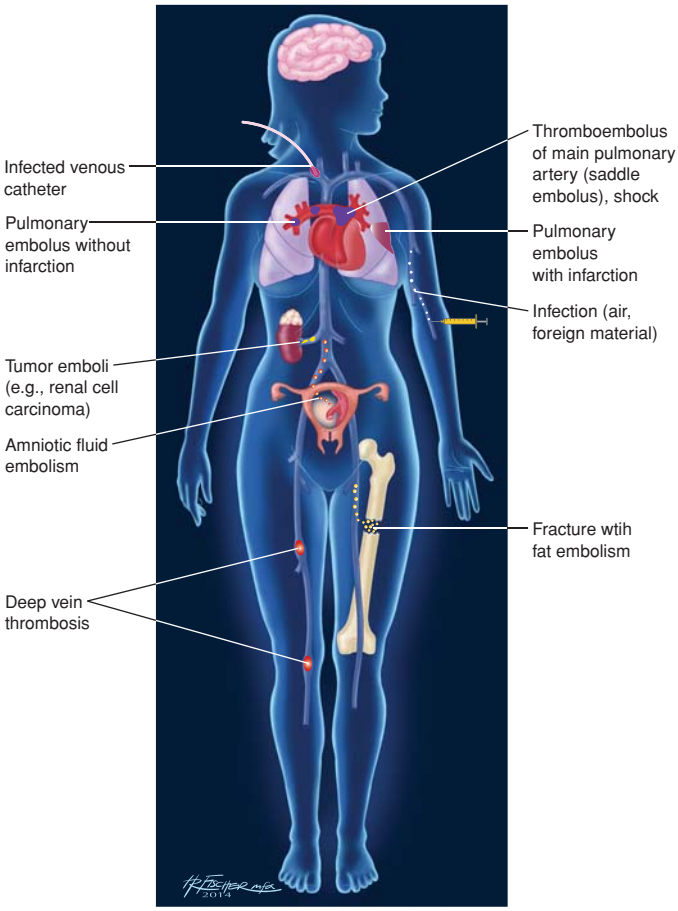
Embolism is passage through venous or arterial circulations of any material that can lodge in a blood vessel and obstruct its lumen. The most common embolus is a thromboembolus—that is, a thrombus formed in one location that detaches from a vessel wall at its point of origin and travels to a distant site.

Pulmonary Arterial Embolism Is Potentially Fatal

Pulmonary thromboemboli occur in over half of autopsies. As well, this complication occurs in 1%–2% of postoperative patients over the age of 40. The risk of pulmonary embolism after surgery increases with advancing age, obesity, length and type of operative procedure, postoperative infection, cancer and preexisting venous disease.

Most pulmonary emboli (90%) arise from deep veins of the lower extremities; most fatal ones form in iliofemoral veins (Fig. 7-14). Only half of patients with such emboli have signs of deep vein thrombosis. Some thromboemboli arise from the pelvic venous plexus and others from the right side of the heart. Emboli are also derived from thrombi around indwelling lines in the systemic venous system or pulmonary artery. The upper extremities are rarely sources of thromboemboli.

The clinical features of pulmonary embolism are determined by the size of the embolus, the health of the patient



Infected venous catheter
Pulmonary embolus without infarction
Tumor emboli (e.g., renal cell carcinoma)
Amniotic fluid embolism
Deep vein thrombosis
Thromboembolus of main pulmonary artery (saddle embolus), shock
Pulmonary embolus with infarction
Infection (air, foreign material)
Fracture wtih fat embolism

FIGURE 7-14. Sources and effects of venous emboli.

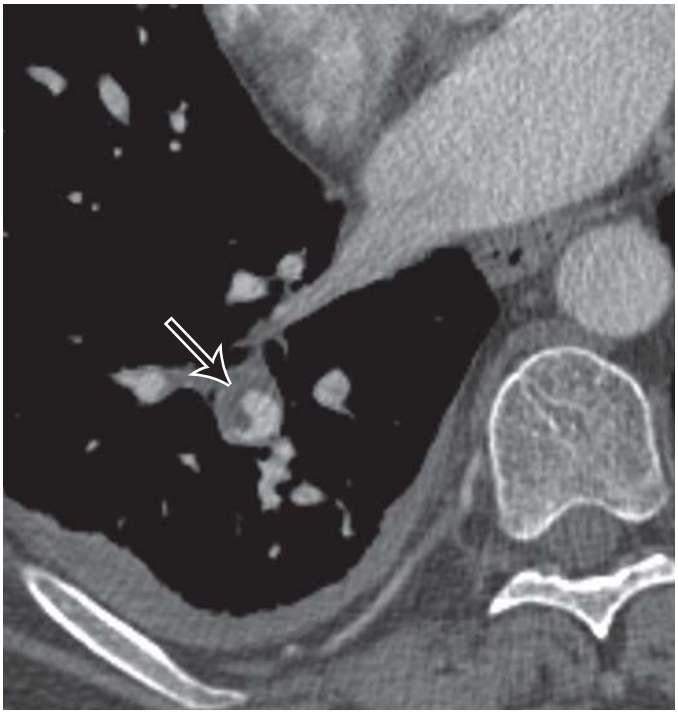


FIGURE 7-15. Contrast-enhanced computed tomographic image of chronic pulmonary embolism. A low attenuation (dark) nonocclusive thrombus is seen in a right segmental pulmonary artery (*arrow*).

and whether embolization occurs acutely or chronically. Acute pulmonary embolism is divided into the following syndromes:

- Asymptomatic small pulmonary emboli
- Transient dyspnea and tachypnea without other symptoms
- Pulmonary infarction, with pleuritic chest pain, hemoptysis and pleural effusion
- Cardiovascular collapse with sudden death

Chronic pulmonary embolism, with numerous (usually asymptomatic) emboli lodged in small arteries of the lung, can lead to pulmonary hypertension and right-sided heart failure (Fig. 7-15; see below).

Massive Pulmonary Embolism

One of the most dramatic calamities complicating hospitalization is the sudden collapse and death of a patient who had appeared to be well on the way to an uneventful recovery. The cause of this catastrophe is often massive pulmonary embolism due to release of a large deep venous thrombus from a lower extremity. Classically, a postoperative patient succumbs upon getting out of bed for the first time. The muscular activity dislodges a thrombus that formed as a result of the stasis from prolonged bed rest. Excluding deaths related to surgery itself, pulmonary embolism is the most common cause of death after major orthopedic surgery and is the most frequent nonobstetric cause of postpartum death. It also is an especially common cause of death in patients who suffer from chronic heart and lung diseases and in those subjected to prolonged immobilization for any reason. Inactivity associated with air travel can also lead to venous thrombosis and, occasionally, sudden death from a pulmonary embolus.

A large pulmonary embolus may lodge at the bifurcation of the main pulmonary artery **(saddle embolus)** and obstruct blood flow to both lungs (Fig. 7-16). Large lethal emboli may also block the right or left main pulmonary arteries or their first branches. Multiple smaller emboli may lodge in secondary branches and prove fatal. With acute obstruction of more than half of the pulmonary arterial tree, the patient often experiences immediate severe hypotension (or shock) and may die within minutes.

The hemodynamic consequences of such massive pulmonary embolism are acute right ventricular failure from sudden obstruction of outflow and pronounced reduction in left ventricular cardiac output, secondary to the loss of right ventricular function. The low cardiac output is responsible for the sudden appearance of severe hypotension.

Pulmonary Infarction

Small pulmonary emboli are not ordinarily lethal. They tend to lodge in peripheral pulmonary arteries and sometimes (15%–20% of all pulmonary emboli) they produce lung infarcts. Clinically, pulmonary infarction is usually seen in the context of congestive heart failure or chronic lung disease, because the normal dual circulation of the lung ordinarily protects against ischemic necrosis; since the bronchial artery supplies blood to the necrotic area, pulmonary infarcts are typically hemorrhagic. They tend to be pyramidal, with the base of the pyramid on the pleural surface. Patients experience cough, stabbing pleuritic pain, shortness of breath and occasional hemoptysis. Pleural effusion is common and

FIGURE 7-16. Pulmonary embolism. The main pulmonary artery and its bifurcation have been opened to reveal a large saddle embolus.

often bloody. With time, the blood in the infarct is resorbed, and the center of the infarct becomes pale. Granulation tissue forms on the edge of the infarct, after which it is organized to form a fibrous scar.

Pulmonary Embolism without Infarction

Since the lung is supplied by both the bronchial arteries and the pulmonary artery, most (75%) small pulmonary emboli do not produce infarcts. Although such emboli usually do not attract clinical attention, a few give rise to a syndrome characterized by dyspnea, cough, chest pain and hypotension. Rarely (3%), recurrent pulmonary emboli cause pulmonary hypertension by mechanical blockage of the arterial bed. In this circumstance, reflex vasoconstriction and bronchial constriction, due to release of vasoactive substances, may contribute to shrinkage of the functional pulmonary vascular bed.

In the clinical syndrome of "partial infarction," patients have the clinical and radiologic findings of pulmonary infarction due to thromboembolism. However, the lesion resolves instead of contracting to leave a scar. In such cases, hemorrhage and necrosis of the lung tissue in the affected area occur, but the tissue framework remains. Collateral circulation maintains tissue viability and enables its regeneration.

Fate of Pulmonary Thromboemboli

Small pulmonary emboli may completely resolve, depending on (1) the embolic load, (2) the adequacy of the pulmonary vascular reserve, (3) the state of the bronchial collateral circulation and (4) the thrombolytic process. Alternatively, thromboemboli may become organized and leave strings of fibrous tissue attached to a vessel wall in the lumen of pulmonary arteries. Radiologic studies have indicated that half of all pulmonary thromboemboli are resorbed and organized within 8 weeks, with little narrowing of the vessels.

Paradoxical Embolism

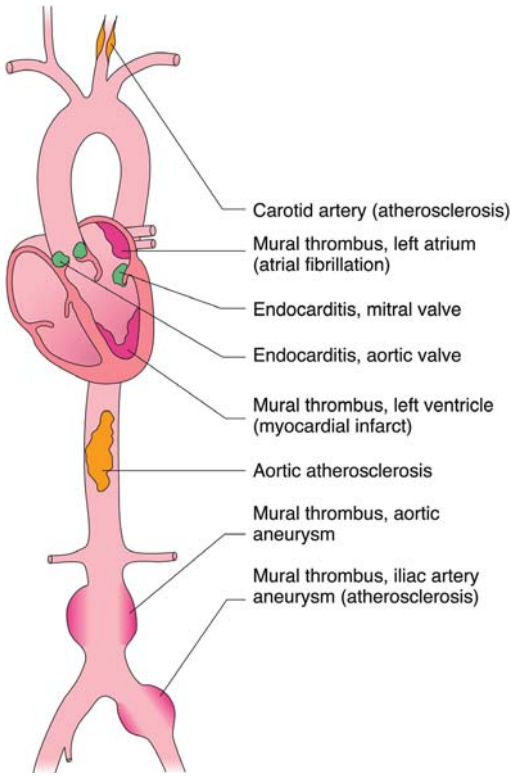
Paradoxical embolism refers to emboli that arise in the venous circulation and bypass the lungs by traveling through an incompletely closed foramen ovale, subsequently entering the left side of the heart and blocking flow to the systemic arteries. Since left atrial pressure usually exceeds that in the right, most of these cases occur in the context of a right-to-left shunt (see Chapter 17).

Systemic Arterial Embolism Often Causes Infarcts

Thromboembolism

The heart is the most common source of arterial thromboemboli (Fig. 7-17), which usually arise from mural thrombi (Fig. 7-18) or diseased valves. These emboli tend to lodge at points where vessel lumens narrow abruptly (e.g., at bifurcations or near atherosclerotic plaques). The viability of tissue supplied by the vessel depends on the available collateral circulation and the fate of the embolus itself. The thromboembolus may propagate locally and lead to a more severe obstruction, or it may fragment and lyse. Organs that suffer the most from arterial thromboembolism include:

- **Brain:** Arterial emboli to the brain cause ischemic necrosis (strokes).



Carotid artery (atherosclerosis)
Mural thrombus, left atrium (atrial fibrillation)
Endocarditis, mitral valve
Endocarditis, aortic valve
Mural thrombus, left ventricle (myocardial infarct)
Aortic atherosclerosis
Mural thrombus, aortic aneurysm
Mural thrombus, iliac artery aneurysm (atherosclerosis)

FIGURE 7-17. Sources of arterial emboli.

- **Intestine:** In the mesenteric circulation, emboli cause bowel infarction, which manifests as an acute abdomen and requires immediate surgery.
- **Legs:** Embolism to an artery of the leg leads to sudden pain, absence of pulses and a cold limb (Fig. 7-19). In some cases, the limb may require amputation.
- **Kidney:** Renal artery embolism may infarct an entire kidney but more commonly causes small peripheral infarcts.
- **Heart:** Coronary artery embolism and resulting infarction occur but are rare.

The more common sites of infarction from arterial emboli are shown in Fig. 7-20.

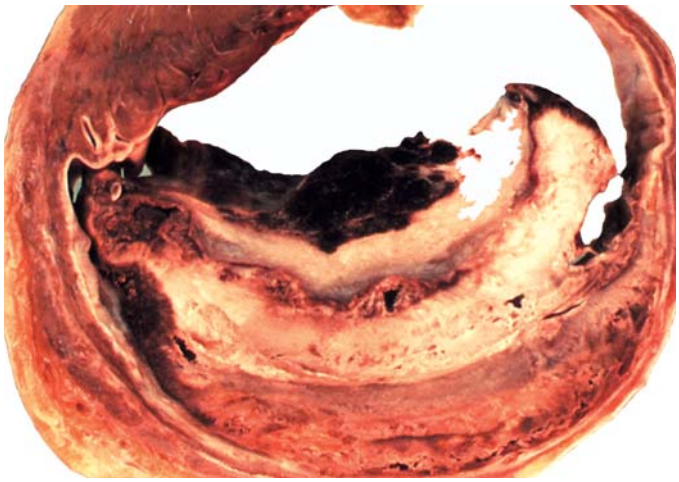


FIGURE 7-18. Mural thrombus of the left ventricle. A laminated thrombus adheres to the endocardium overlying a healed aneurysmal myocardial infarct.

FIGURE 7-19. Acute ischemic right foot. A condition of sudden poor arterial perfusion, usually the consequence of acute thrombosis of an atherosclerotic plaque or embolism. This foot has a red dusky hue with second-toe necrosis. Symptoms may include pain, paresthesia and paralysis.

Air Embolism

Air may enter the venous circulation through neck wounds, thoracentesis or punctures of the great veins during invasive procedures or intraoperatively during cardiac surgery. Small amounts of circulating air in the form of bubbles are of little consequence, but quantities of 100 mL or more can result in sudden death. Air bubbles tend to coalesce and physically obstruct blood flow in the right side of the heart, the pulmonary circulation, and the brain. Histologically, air bubbles appear as empty spaces in capillaries and small vessels of the lung.

People exposed to increased atmospheric pressure, such as scuba divers and workers in underwater occupations (e.g., tunnels, drilling platform construction), are subject to **decompression sickness,** a unique form of gas embolism. During descent, large amounts of inert gas (nitrogen or helium) are dissolved in bodily fluids. When the diver ascends, this gas is released from solution and exhaled. However, if ascent is too rapid, gas bubbles form in the circulation and within tissues, obstructing blood flow and directly injuring cells. Air embolism is the second most common cause of death in sport diving (drowning is the first).

Acute decompression sickness, "the bends," is characterized by temporary muscular and joint pain, due to small vessel obstruction in these tissues. However, severe involvement of cerebral blood vessels may cause coma or even death.

Caisson disease refers to decompression sickness in which vascular obstruction causes multiple foci of ischemic (avascular) necrosis of bone, particularly affecting the head of the femur, tibia and humerus. This complication was originally described in construction workers in diving bells (or caissons).

Amniotic Fluid Embolism

In amniotic fluid embolism, amniotic fluid containing fetal cells and debris enters the maternal circulation through open uterine and cervical veins. It is a rare maternal complication of childbirth, but can be catastrophic when it occurs. This disorder usually occurs at the end of labor when the pulmonary emboli are composed of the solid epithelial constituents (squames) contained in the amniotic fluid (Fig. 7-21). Of greater importance is the initiation of a potentially fatal consumptive coagulopathy caused by the high thromboplastin activity of the amniotic fluid.

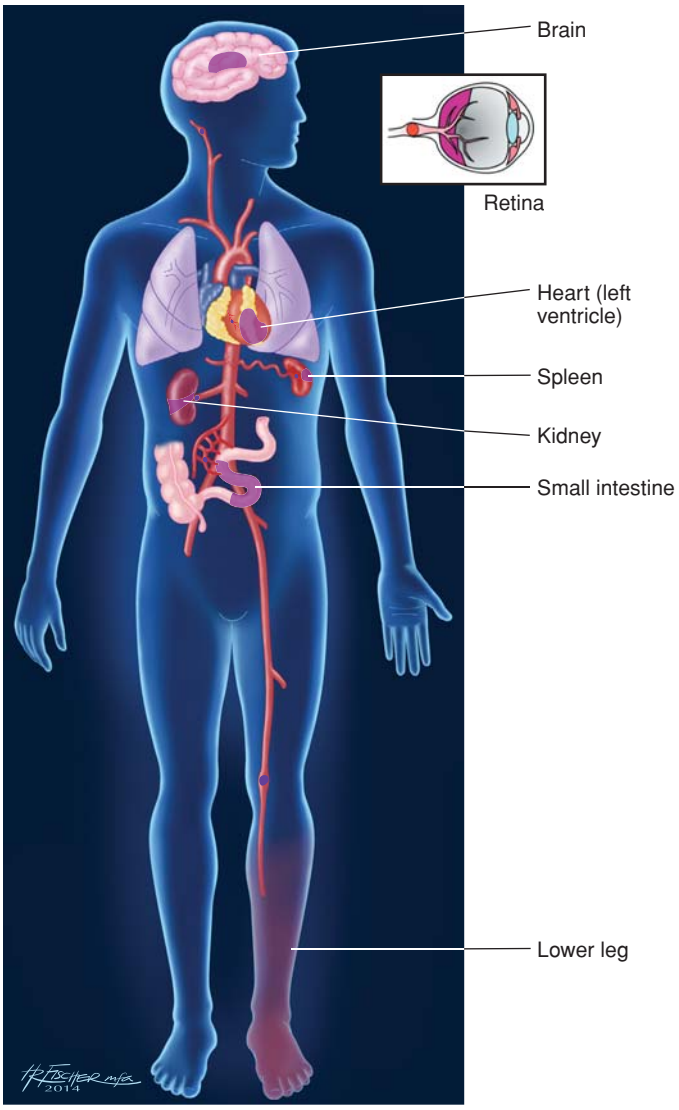

FIGURE 7-20. Common sites of infarction from arterial emboli.

The clinical presentation of amniotic fluid embolism can be dramatic, with sudden onset of cyanosis and shock, followed by coma and death. If the mother survives this acute episode, she may die of disseminated intravascular coagulation. Should she overcome this complication, she is at substantial risk of developing **acute respiratory distress syndrome** (see Chapter 18). Minor amniotic fluid embolism is probably common and asymptomatic, since autopsies of mothers who have died of other causes in the perinatal period frequently show evidence of this event.

Fat Embolism

Fat embolism is release of emboli of fatty marrow (Fig. 7-22) into damaged blood vessels following severe trauma to

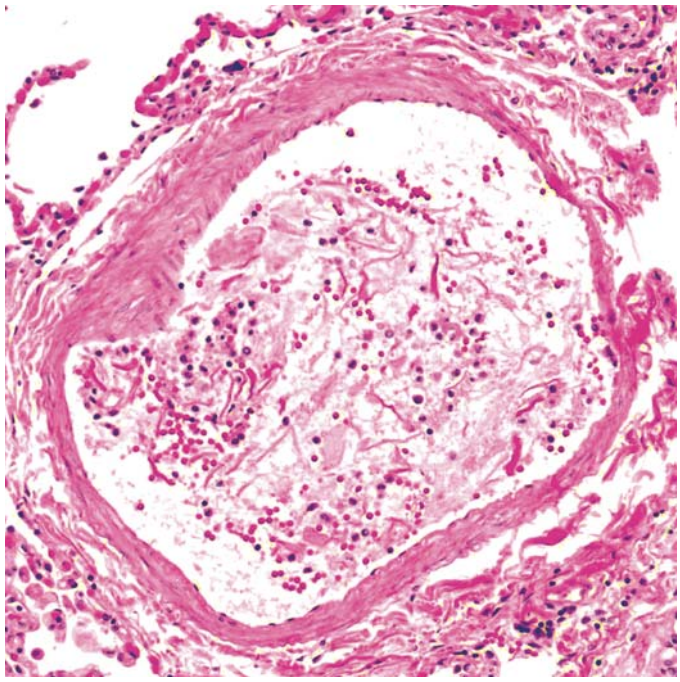

FIGURE 7-21. Amniotic fluid embolism. A section of lung shows a pulmonary artery filled with epithelial squames.

fat-containing tissue, particularly accompanying bone fractures. In most instances, fat embolism is clinically inapparent. However, severe fat embolism induces **fat embolism syndrome** 1–3 days after the injury. In its most severe form, which may be fatal, this syndrome is characterized by respiratory failure, mental changes, thrombocytopenia and widespread petechiae. Chest radiography reveals diffuse opacity of the lungs, which may progress to a "whiteout" typical of acute respiratory distress syndrome. At autopsy, innumerable fat globules are seen in the microvasculature of the lungs (Fig. 7-22B) and brain and sometimes other organs. Morphologically, the lungs typically exhibit the changes of acute respiratory distress syndrome (see Chapter 18). The lesions in the brain include cerebral edema, small hemorrhages and occasionally microinfarcts.

Fat embolism is usually considered a direct consequence of trauma, with fat entering ruptured capillaries at the site of the fracture. However, this explanation may be too simplistic. It has been suggested that hemorrhage into the marrow and perhaps also into the subcutaneous fat increases interstitial pressure above capillary pressure, so fat is forced into the circulation. Moreover, there is more fat in the pulmonary vascular system than can be accounted for by simple transfer of fat from peripheral depots, and the chemical composition of the fat in the lung differs from that in tissue. Finally, there is a discrepancy between the frequency of fat embolism and bone marrow embolism.

Bone Marrow Embolism

Bone marrow emboli to the lungs, complete with hematopoietic cells and fat, are often encountered at autopsy after cardiac resuscitation, a procedure in which fractures of the sternum and ribs commonly occur. They also occasionally occur after fractures of long bones. In most cases no symptoms are attributed to bone marrow embolism.

Miscellaneous Pulmonary Emboli

Intravenous drug abusers who use talc as a carrier for illicit drugs may introduce it into the lung via the bloodstream. **Talc emboli** produce a granulomatous response in the lungs (Fig. 7-23). **Cotton emboli** are surprisingly common and are due to cleansing of the skin prior to venipuncture. **Schistosomiasis** may be associated with the embolization of ova to the lungs from bladder or gut, in which case they incite

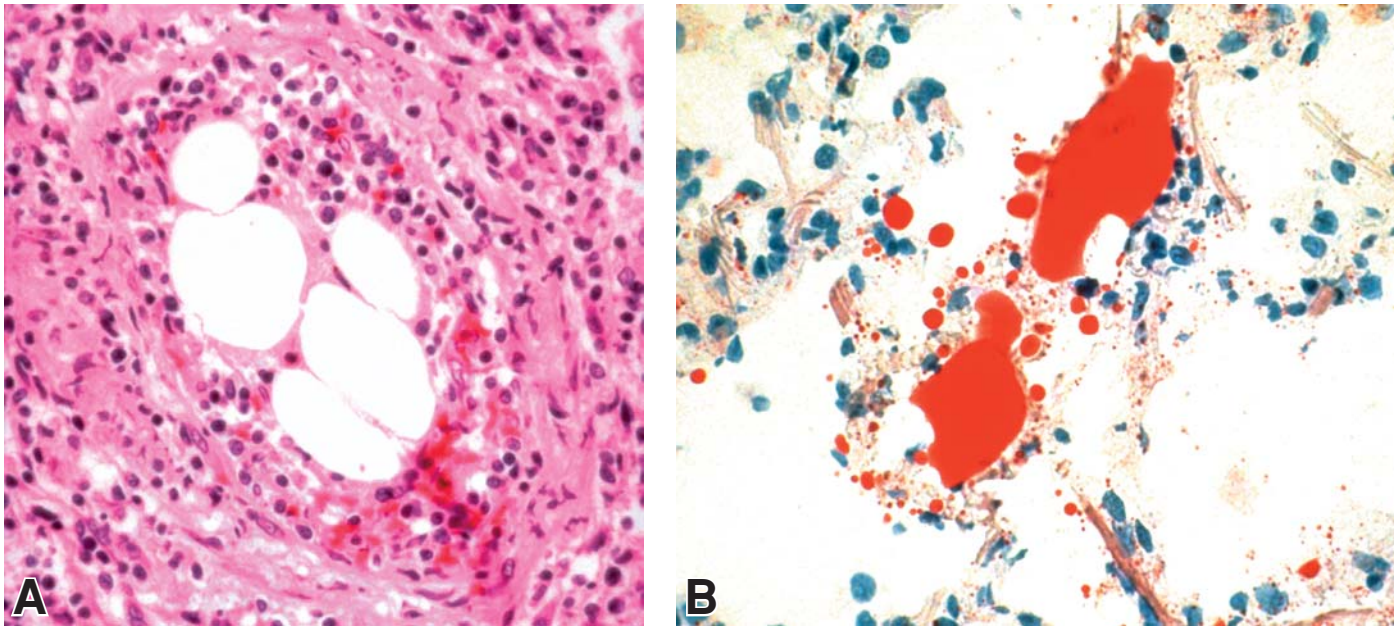

FIGURE 7-22. Fat embolism. A. The lumen of a small pulmonary artery is occluded by a fragment of bone marrow consisting of fat cells and hematopoietic elements. **B.** A frozen section of lung stained with Sudan red shows capillaries occluded by red-staining fat emboli.

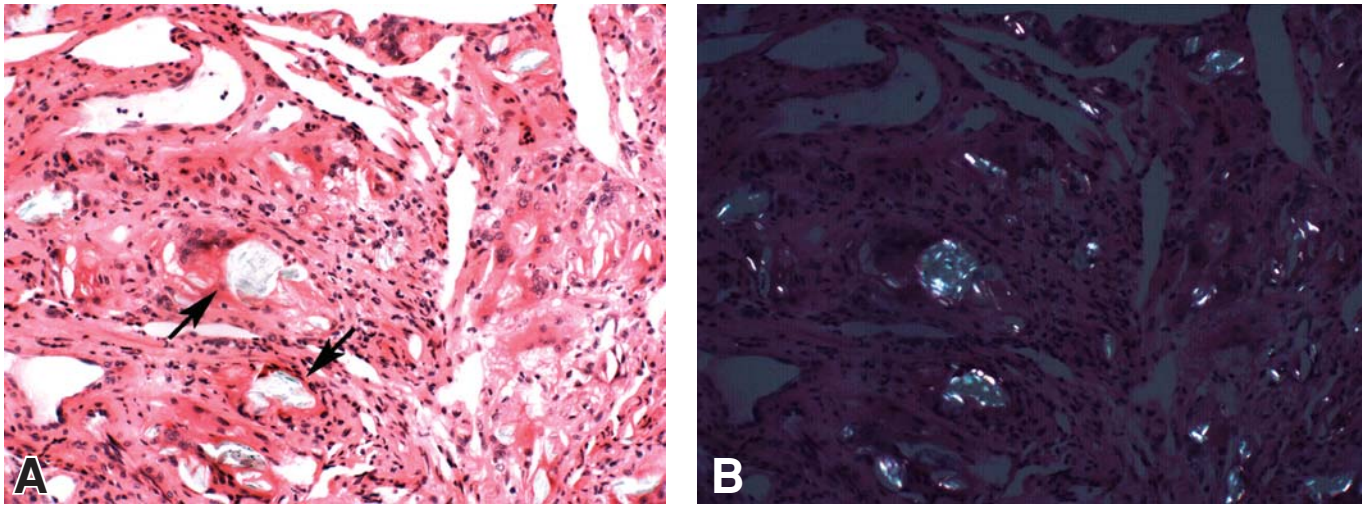

FIGURE 7-23. Talc emboli. A section of lung from an intravenous drug abuser shows talc particles (*arrows*) before **(A)** and after **(B)** polarization of light.

a foreign body granulomatous reaction. **Tumor emboli** are occasionally seen in the lung during hematogenous dissemination of cancer.

INFARCTION

Infarction is the process by which coagulative necrosis develops in an area distal to occlusion of an end-artery. The necrotic zone is an **infarct**. Infarcts of vital organs such as heart, brain and intestine are serious medical conditions and are major causes of morbidity and mortality. If the victim survives, the infarct heals with a scar. Partial arterial occlusion (i.e., stenosis) occasionally causes necrosis, but it more commonly leads to atrophic changes associated with chronic ischemia. For example, in the heart, these changes include vacuolization of cardiac myocytes, atrophy, loss of muscle cell myofibrils and interstitial fibrosis.

PATHOLOGY: The gross and microscopic appearance of an infarct depends on its location and age. Upon arterial occlusion, the area supplied by the vessel rapidly becomes swollen and deep red.

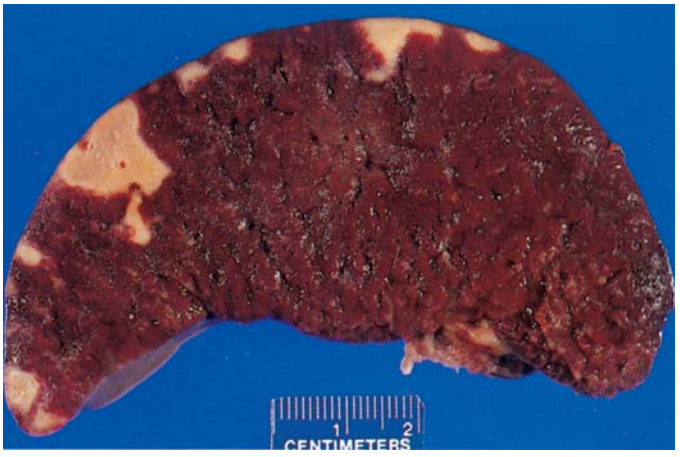

FIGURE 7-24. Spleen infarcts. A cut section of spleen displays multiple pale, wedge-shaped infarcts beneath the capsule.

Microscopically, vascular dilation and congestion and occasionally interstitial hemorrhage are noted. Subsequently, several types of infarcts are distinguishable by gross examination.

Pale infarcts are typical in the heart, kidneys and spleen (Fig. 7-24), although certain renal infarcts may be cystic. **Dry gangrene** of the leg due to arterial occlusion (often noted in diabetes) is actually a large pale infarct. Within 1 or 2 days after the initial hyperemia, an infarct becomes soft, sharply delineated and light yellow (Fig. 7-25). The border tends to be dark red, reflecting hemorrhage into surrounding viable tissue. Microscopically, a pale infarct exhibits uniform coagulative necrosis.

Red infarcts may result from either arterial or venous occlusion and are also characterized by coagulative necrosis. However, they are distinguished by bleeding into the affected area from adjacent vessels. ***Red infarcts occur mainly in organs with a dual blood supply,*** such as the lung, or those with extensive collateral circulation (e.g., the small intestine and brain). In the heart, a red infarct occurs when the infarcted area is reperfused, as may occur after

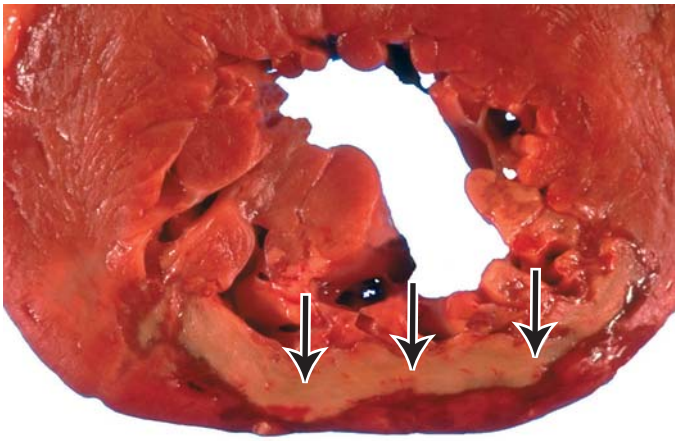

FIGURE 7-25. Acute myocardial infarct. A cross-section of the left ventricle reveals a sharply circumscribed, soft, yellow area of necrosis in the posterior free wall (*arrows*).

FIGURE 7-26. Red infarct. A sagittal slice of lung shows a hemorrhagic infarct in upper segments of the lower lobe.

spontaneous or therapeutically induced lysis of an occluding thrombus. Red infarcts are sharply circumscribed, firm and dark red to purple (Fig. 7-26). For several days, acute inflammatory cells infiltrate the necrotic area from the viable border. Cellular debris is phagocytosed and digested by neutrophils and later by macrophages. Granulation tissue eventually forms, to be replaced ultimately by a scar. In a large infarct of an organ such as the heart or kidney, the necrotic center may remain inaccessible to the inflammatory exudate and may persist for months. In the brain, an infarct typically undergoes liquefactive necrosis and may become a fluid-filled cyst, which is referred to as a **cystic infarct** (Fig. 7-27).

Septic infarction results when the necrotic tissue of an infarct is seeded by pyogenic bacteria and becomes infected. Pulmonary infarcts are not uncommonly infected, presumably because necrotic tissue offers little resistance to inhaled bacteria. In the case of bacterial endocarditis, the emboli themselves are infected and resulting infarcts are often septic. A septic infarct may become a frank abscess (Fig. 7-28).

FIGURE 7-27. Cystic infarct. A cross-section of brain in the frontal plane shows a healed cystic infarct.

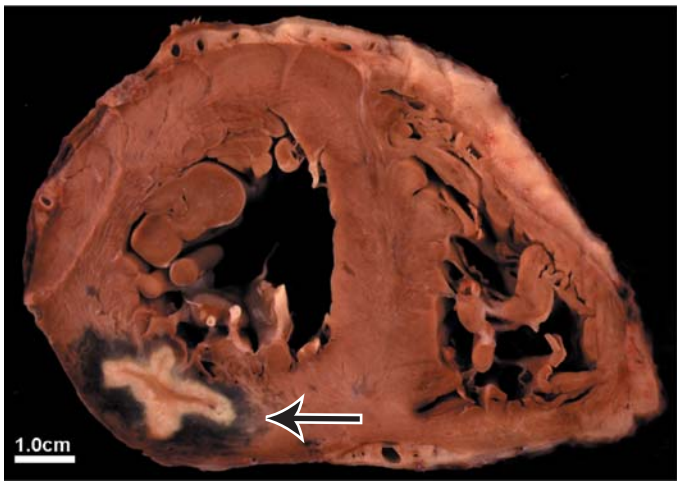

FIGURE 7-28. Septic infarct. A myocardial abscess (*arrow*) within the left ventricular free wall was due to infection with *Staphylococcus aureus*.

Infarction in Specific Locations Is Often Fatal

Myocardial Infarcts

Myocardial infarcts are transmural (through the entire wall) or subendocardial. A transmural infarct results from complete occlusion of a major extramural coronary artery. Subendocardial infarction reflects prolonged ischemia caused by partially occluding, atherosclerotic, stenotic coronary artery lesions when the requirement for oxygen exceeds the supply. This happens in, for example, shock, anoxia or severe tachycardia (rapid pulse). A myocardial infarct may be pale or red, depending on the extent of reflow of blood into the infarcted area (Fig. 7-29).

Pulmonary Infarcts

Only about 10% of pulmonary emboli elicit clinical symptoms referable to pulmonary infarction, usually after occlusion of a middle-sized pulmonary artery. Infarction occurs only if circulation from bronchial arteries is inadequate to compensate for supply lost from the pulmonary arteries. This circumstance is often found in congestive heart failure, although stasis in the pulmonary circulation may contribute. Hemorrhage into the alveolar spaces of the necrotic lining tissue occurs within 48 hours.

Cerebral Infarcts

Infarction of the brain may result from local ischemia or a generalized reduction in blood flow. The latter often results from systemic hypotension, as in shock, and produces infarction in the border zones between the distributions of the major cerebral arteries **(watershed infarct)**. If prolonged, severe hypotension can cause widespread brain necrosis. The occlusion of a single vessel in the brain (e.g., after an embolus has lodged) causes ischemia and necrosis in a well-defined area. This type of cerebral infarct may be pale or red, the latter being common with embolic occlusions. The occlusion of a large artery produces a wide area of necrosis, which may ultimately resolve as a large fluid-filled cavity in the brain (cystic infarct).

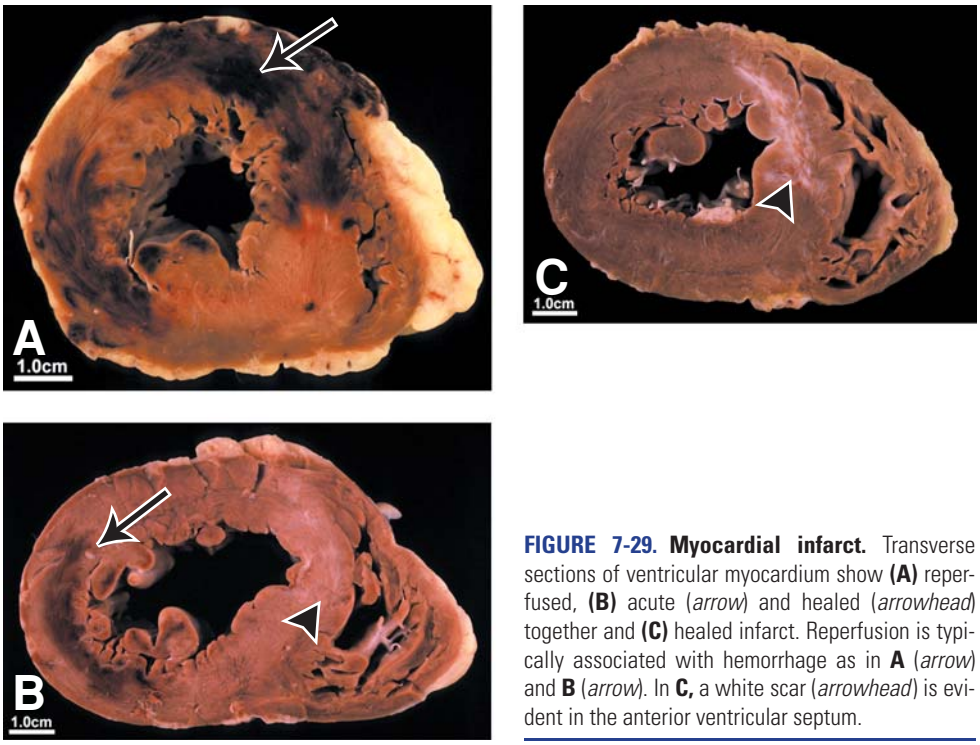

FIGURE 7-29. Myocardial infarct. Transverse sections of ventricular myocardium show **(A)** reperfused, **(B)** acute (*arrow*) and healed (*arrowhead*) together and **(C)** healed infarct. Reperfusion is typically associated with hemorrhage as in **A** (*arrow*) and **B** (*arrow*). In **C,** a white scar (*arrowhead*) is evident in the anterior ventricular septum.

Intestinal Infarcts

The earliest tissue changes in intestinal ischemia are necrosis of the tips of the villi in the small intestine and necrosis of the superficial mucosa in the large intestine. In either case, more severe ischemia causes hemorrhagic necrosis of the submucosa and muscularis but not the serosa. Small mucosal infarcts heal within a few days, but more severe injury leads to ulceration. These ulcers can eventually reepithelialize. However, if ulcers are large, they are repaired by scarring, a process that may give rise to strictures. Severe transmural necrosis is associated with massive bleeding or bowel perforation, complications that often result in irreversible shock, sepsis and death.

EDEMA

Edema is excess fluid in interstitial tissue spaces, which may be local or generalized. **Local edema** in most instances occurs with inflammation, the "tumor" of "tumor, rubor and calor." Local edema of a limb, usually the leg, results from venous or lymphatic obstruction. Burns cause prominent local edema by altering the permeability of local vasculature. Local edema may be a prominent component of an immune reaction, for example, urticaria (hives) or edema of the epiglottis or larynx (angioneurotic edema).

Generalized edema, affecting visceral organs and the skin of the trunk and lower extremities (Fig. 7-30), reflects a global disorder of fluid and electrolyte metabolism, most often due to heart failure. Generalized edema is also seen in certain renal diseases associated with loss of serum proteins into the urine (nephrotic syndrome) and in cirrhosis of the liver. **Anasarca** is extreme generalized edema, a condition evidenced by conspicuous fluid accumulation in subcutaneous tissues, visceral organs and body cavities. Edema fluid may accumulate in body spaces, such as the pleural cavity **(hydrothorax)**, peritoneal cavity **(ascites)** or pericardial space **(hydropericardium)**.

Normal Capillary Filtration

Normal formation and retention of interstitial fluid depends on filtration and reabsorption at the level of the capillaries

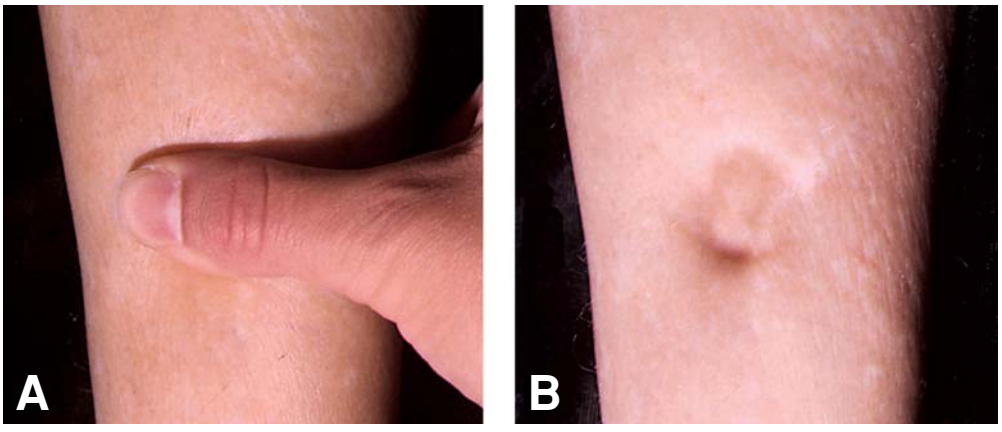

FIGURE 7-30. Pitting edema of the leg. A. In a patient with congestive heart failure, severe edema of the leg is demonstrated by applying pressure with a finger. **B.** The resulting "pitting" reflects the inelasticity of the fluid-filled tissue.

(Starling forces). The internal or hydrostatic pressure in the arteriolar segment of the capillary is 32 mm Hg. At the middle of the capillary, it is 20 mm Hg. Since interstitial hydrostatic pressure is only 3 mm Hg, there is an outward fluid filtration of 14 mL/min. Hydrostatic pressure is opposed by plasma oncotic pressure (26 mm Hg), which results in osmotic reabsorption at 12 mL/min at the venous end of the capillary. Thus, interstitial fluid is formed at the rate of 2 mL/min and is reabsorbed by the lymphatics. As a result, in equilibrium there is no net fluid gain or loss in the interstitium.

Sodium and Water Metabolism

Water represents 50%–70% of body weight and is divided between the extracellular and intracellular fluid spaces. Extracellular fluid is further divided into interstitial and vascular compartments. Interstitial fluid constitutes about 75% of the latter.

Total body sodium is the principal determinant of extracellular fluid volume because it is the major cation in the extracellular fluid. In other words, increased total body sodium must be balanced by more extracellular water to maintain constant osmolality. Control of extracellular fluid volume depends to a large extent on regulation of renal sodium excretion, which is influenced by (1) atrial natriuretic factor, (2) the renin–angiotensin system of the juxtaglomerular apparatus and (3) sympathetic nervous system activity (see Chapter 22).

Edema Caused by Increased Hydrostatic Pressure

Unopposed increases in hydrostatic pressure result in greater filtration of fluid into the interstitial space and its retention as edema. Such a situation is particularly prominent in decompensated heart disease, in which back-pressure in the lungs secondary to left ventricular failure causes acute pulmonary edema and right-sided heart failure, and contributes to systemic edema. Similarly, back-pressure caused by venous obstruction in the lower extremity causes edema of the leg. Obstruction to portal blood flow in cirrhosis of the liver contributes to formation of abdominal fluid (ascites).

Edema Caused by Decreased Oncotic Pressure

The difference in pressure between intravascular and interstitial compartments is largely determined by the concentration of plasma proteins, especially albumin. Any condition that lowers plasma albumin levels, whether it is albuminuria in the nephrotic syndrome, reduced albumin synthesis in chronic liver disease or severe malnutrition, tends to promote generalized edema.

Edema Caused by Lymphatic Obstruction

Under normal circumstances, more fluid is filtered into the interstitial spaces than is reabsorbed into the vascular bed. This excess interstitial fluid is removed by lymphatics. Thus, obstruction to lymphatic flow leads to localized edema. Lymphatic channels can be obstructed by (1) malignant neoplasms, (2) fibrosis resulting from inflammation or irradiation and (3) surgical ablation. For instance, the inflammatory response to filarial worms (Bancroftian and Malayan filariasis; see Chapter 9) can result in lymphatic obstruction that produces massive lymphedema of the scrotum and lower extremities **(elephantiasis)** (Fig. 7-31). Lymphedema of the arm often complicates radical mastectomies for breast cancer, owing to removal of axillary lymph nodes and lymphatics.

FIGURE 7-31. Edema secondary to lymphatic obstruction. Massive edema of the right lower extremity (elephantiasis) in a patient with obstruction of lymphatic drainage.

Lymphatic edema differs from other forms of edema in its high protein content, since lymph is the vehicle by which proteins and interstitial cells are returned to the circulation. The increased protein concentration may be a fibrogenic stimulus in the formation of dermal fibrosis in chronic edema (indurated edema).

The Role of Sodium Retention in Edema

Generalized edema and ascites invariably reflect increased total body sodium, as a consequence of renal sodium retention. When peripheral edema is first detectable clinically, extracellular fluid volume has already expanded by at least 5 L. The most common conditions in which generalized edema is found include congestive heart failure, cirrhosis of the liver, nephrotic syndrome and some cases of chronic renal insufficiency. The mechanisms of edema formation and representative disorders associated with them are summarized in Fig. 7-32 and Table 7-1.

Congestive Heart Failure Is the Consequence of Inadequate Cardiac Output

It is estimated that 5 to 6 million people in the United States suffer congestive heart failure, of whom 15% die annually. Half of all patients with congestive heart failure who require admission to the hospital will die within 1 year. In the United States, this disorder is most commonly associated

with ischemic heart disease, although virtually any chronic cardiac disorder may eventuate in congestive heart failure (see Chapter 17).

MOLECULAR PATHOGENESIS AND ETIOLOGIC FACTORS: The argument regarding the relative contributions of "forward failure" (low cardiac output) versus "backward failure" (venous congestion) in the pathogenesis of edema in congestive heart failure is no longer a burning issue. Both systolic and diastolic dysfunction contribute to the low cardiac output and high ventricular filling pressure characteristic of congestive heart failure. However, systolic dysfunction is more important in most patients.

Inadequate cardiac output in congestive heart failure gives rise to decreased glomerular filtration and increased renin secretion. The latter activates angiotensin, inducing the release of aldosterone, subsequent sodium reabsorption and fluid retention. Furthermore, reduced hepatic blood flow impairs catabolism of aldosterone, thus further raising its concentration in the blood. As a compensatory mechanism, increased fluid volume preserves an adequate intracardiac pressure. In addition, increased sympathetic discharge leads to augmented levels of catecholamines, which stimulate cardiac contractility and further counteract the impairment in cardiac performance. At the same time, distention of the atria by the increased blood volume promotes release of atrial natriuretic peptide, which stimulates renal sodium excretion.

After long-standing heart failure, these compensatory mechanisms fail, in which case renal sodium retention again becomes important. Further expansion of plasma volume increases pulmonary and systemic venous pressure, thus increasing hydrostatic pressure in the respective capillary beds. The increased capillary pressure, together with decreased plasma oncotic pressure, results in the edema of congestive heart failure.

PATHOLOGY: Failure of the left ventricle is associated principally with passive congestion of the lungs and pulmonary edema (Fig. 7-33). When chronic, these conditions result in pulmonary hypertension and eventual failure of the right ventricle. Right ventricular failure is characterized by generalized subcutaneous edema (most prominent in the dependent portions of the body), ascites and pleural effusions. The liver, spleen and other splanchnic organs are typically congested. At autopsy, the heart is enlarged and its chambers dilated.

CLINICAL FEATURES: The effects of heart failure depend on which ventricle is failing, recognizing that both may be failing simultaneously. Patients in left-sided heart failure complain of shortness of breath **(dyspnea)** on exertion and when recumbent **(orthopnea)**. They may be awakened from sleep by sudden episodes of shortness of breath **(paroxysmal nocturnal dyspnea)**. Physical examination usually reveals distended jugular veins. People with right-sided failure have pitting edema of the legs and an enlarged and tender liver. When ascites is present, the abdomen is distended. Patients in congestive heart failure with pulmonary edema have crackling breath sounds **(rales)** caused by expansion of fluid-filled alveoli.

In Pulmonary Edema Fluid Fills the Air Spaces and Interstitium of the Lung

Pulmonary edema leads to decreased gas exchange in the lung, causing hypoxia and retention of carbon dioxide **(hypercapnia)**.

FIGURE 7-32. The capillary system and mechanisms of edema formation. A. Normal. The differential between the hydrostatic and oncotic pressures at the arterial end of the capillary system is responsible for the filtration into the interstitial space of approximately 14 mL of fluid per minute. This fluid is reabsorbed at the venous end at the rate of 12 mL/min. It is also drained through the lymphatic capillaries at a rate of 2 mL/min. Proteins are removed by the lymphatics from the interstitial space. **B. Hydrostatic edema.** If the hydrostatic pressure at the venous end of the capillary system is elevated, reabsorption decreases. As long as the lymphatics can drain the surplus fluid, no edema results. If their capacity is exceeded, however, edema fluid accumulates. **C. Oncotic edema.** Edema fluid also accumulates if reabsorption is diminished by decreased oncotic pressure of the vascular bed, owing to a loss of albumin. **D. Inflammatory and traumatic edema.** Edema, either local or systemic, results if the vascular bed becomes leaky following injury to the endothelium. **E. Lymphedema.** Lymphatic obstruction causes the accumulation of interstitial fluid because of insufficient reabsorption and deficient removal of proteins, the latter increasing the oncotic pressure of the fluid in the interstitial space.

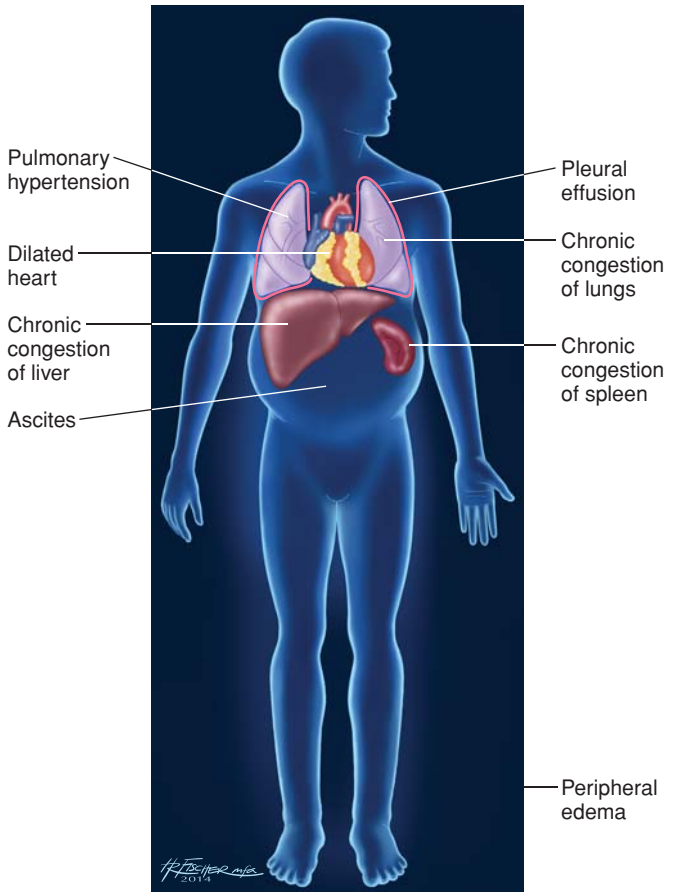

FIGURE 7-33. Pathologic consequences of chronic congestive heart failure.

ETIOLOGIC FACTORS AND PATHOLOGY: The lung is a loose tissue with little connective tissue support and so requires certain conditions to prevent the development of edema. Among these protective devices are:

- Low perfusion pressure in lung capillaries, due to low right ventricular pressure
- Effective drainage of the interstitial space of the lung by lymphatics, which are under a slightly negative pressure and can accommodate up to 10 times the regular lymph flow
- Tight cellular junctions between endothelial cells, which control capillary permeability

Pulmonary edema results when these protective mechanisms are disturbed. The most common causes of pulmonary edema relate to hemodynamic alterations in the heart that increase perfusion pressure in pulmonary capillaries and block effective lymphatic drainage. These conditions include left ventricular failure (the most common cause), mitral stenosis and mitral insufficiency. Disruption of capillary permeability is the cause of pulmonary edema in acute lung injury associated with adult respiratory distress syndrome, inhalation of toxic gases, aspiration of gastric contents, viral infections and uremia. Acute lung injury is reflected in destruction of endothelial cells or disruption of their tight junctions (see Chapter 18).

Pulmonary edema may be interstitial or alveolar. Interstitial edema is the earliest phase and is an exaggeration of normal fluid filtration. Lymphatics become distended and fluid accumulates in the interstitium of lobular septa and around veins and bronchovascular bundles. Radiologic examination reveals a reticulonodular pattern, more marked at lung bases. Lobular septa become edematous and produce linear shadows ("Kerley B lines") on chest radiographs. Edema results in shunting of blood flow from the lung bases to the upper lobes, and increased airflow resistance occurs because of edema of the bronchovascular tree. Patients are often asymptomatic in this early stage.

When the fluid can no longer be accommodated in the interstitial space, it spills into the alveoli, which is called **alveolar edema**. At this stage, a radiologic alveolar pattern is seen, usually worse in central portions of the lung and in lower zones. The patient becomes acutely short of breath and bubbly rales are heard. In extreme cases, frothy fluid is coughed up or wells up out of the trachea.

Microscopically, the edematous lung shows severely congested alveolar capillaries and alveoli filled with a homogeneous, pink-staining fluid permeated by air bubbles (Fig. 7-3). If pulmonary edema is caused by alveolar damage, cell debris, fibrin and proteins form films of proteinaceous material in the alveoli, called **hyaline membranes** (Fig. 7-34).

CLINICAL FEATURES: Fluid accumulation may go unnoticed initially, but eventually dyspnea and coughing become prominent. If edema is severe, large amounts of frothy pink sputum are expectorated. Hypoxemia is manifested as cyanosis.

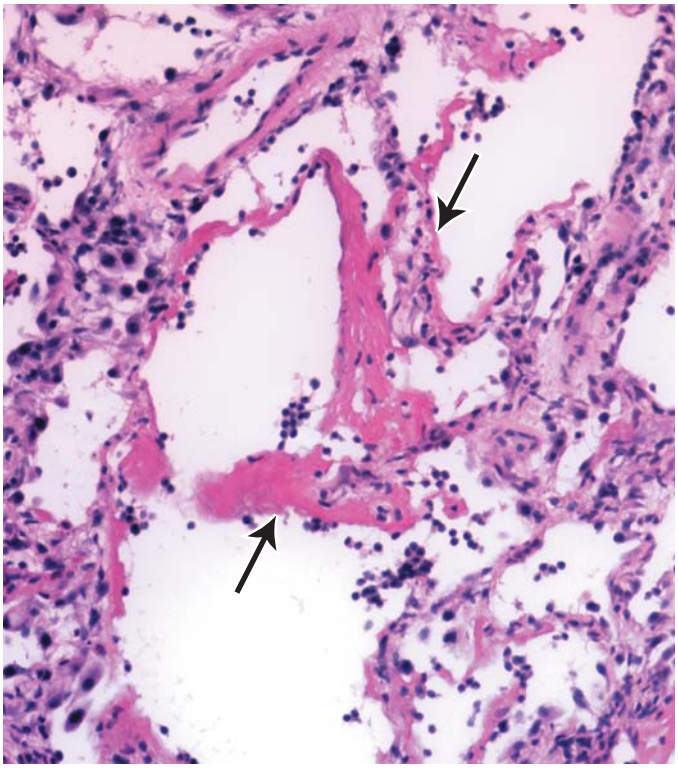

FIGURE 7-34. Pulmonary edema due to diffuse alveolar damage. A section of lung shows hyaline membranes (*arrows*) in alveoli.

Pulmonary function is restricted in severe congestion and in interstitial pulmonary edema because fluid accumulation in the interstitial space causes reduced pulmonary compliance (i.e., stiffening of the lung tissue). Thus, increased respiratory work is required to maintain ventilation. Since alveolar walls are thickened, there is a greater barrier to exchange of oxygen and carbon dioxide. The latter is less affected than the former, resulting in hypoxia with near-normal carbon dioxide levels. Mismatch between ventilation (which is reduced) and perfusion (which persists) contributes to development of hypoxemia in patients with pulmonary edema.

Edema in Cirrhosis of the Liver Is Commonly an End-Stage Condition

Cirrhosis of the liver is often accompanied by ascites and peripheral edema (see Chapter 20). Liver scarring obstructs portal blood flow and leads to portal hypertension and increased hydrostatic pressure in the splanchnic circulation. This situation is compounded by decreased hepatic synthesis of albumin as a result of liver dysfunction. Consequent accumulation of peritoneal fluid causes a lower effective blood volume, which results in renal retention of sodium by mechanisms similar to those operative in congestive heart failure. Alternatively, chronic liver disease itself causes renal retention of sodium. Subsequent expansion of extracellular fluid volume further promotes ascites and edema, thus establishing a vicious circle. In addition, increased transudation of lymph from the liver capsule adds to accumulation of fluid in the abdomen.

The Nephrotic Syndrome Reflects Massive Proteinuria

In the nephrotic syndrome, the magnitude of protein loss in the urine exceeds the rate at which it is replaced by the liver (see Chapter 22). The resulting decline in the concentration of plasma proteins, particularly albumin, reduces plasma oncotic pressure and promotes edema. The ensuing decrease in blood volume stimulates the renin–angiotensin–aldosterone mechanism and causes sodium retention. The edema is generalized but appears preferentially in soft connective tissues, the eyes, the eyelids and subcutaneous tissues. Ascites and pleural effusions also occur.

Cerebral Edema Often Causes a Fatal Increase in Intracranial Pressure

Edema of the brain is dangerous because the rigidity of the cranium allows little room for expansion. Increased intracranial pressure from edema compromises cerebral blood supply, distorts the gross structure of the brain and interferes with central nervous system function (see Chapter 32). Cerebral edema is divided into vasogenic, cytotoxic and interstitial forms.

- **Vasogenic edema,** the most common variety of edema, is excess fluid in the extracellular space of the brain. It results from increased vascular permeability, mainly in white matter. The tight endothelial junctions of the blood-brain barrier are disrupted and fluid filters into the interstitial space. Disorders causing cerebral vasogenic edema include trauma, neoplasms, encephalitis, abscesses, infarcts, hemorrhage and toxic brain injury (e.g., lead poisoning).
- **Cytotoxic edema** is equivalent to hydropic cell swelling (i.e., accumulation of intracellular water). It is usually a response to cell injury, such as that produced by ischemia. Cytotoxic cerebral edema preferentially affects the gray matter.
- **Interstitial edema** is a consequence of hydrocephalus, in which fluid accumulates in the cerebral ventricles and periventricular white matter.

At autopsy, an edematous brain is soft and heavy. Gyri are flattened and sulci narrowed. Because of alterations in brain function, patients with cerebral edema suffer vomiting, disorientation and convulsions. Severe cerebral edema results in herniation of the cerebellar tonsils, ordinarily a lethal event.

Fluid Accumulates in Body Cavities as Extensions of the Interstitial Space

The Pleural Space

Pleural effusion (fluid in the pleural space) is a straw-colored transudate of low specific gravity that contains few cells (mainly exfoliated mesothelial cells). Fluid commonly accumulates as an expression of a generalized tendency to form edema in diseases such as the nephrotic syndrome, cirrhosis of the liver and congestive heart failure. Pleural effusion is also a frequent response to an inflammatory process or tumor in the lung or on the pleural surface.

The Pericardium

Fluid in the pericardial sac may result from either hemorrhage **(hemopericardium)** or injury to the pericardium **(pericardial effusion)**. Pericardial effusions occur with pericardial infections, metastatic neoplasms to the pericardium, uremia and systemic lupus erythematosus. They are also occasionally encountered after cardiac operations **(postpericardiotomy syndrome)** or radiation therapy for cancer.

Pericardial fluid may accumulate rapidly (e.g., with hemorrhage from a ruptured myocardial infarct, dissecting aortic aneurysm or trauma). In these cases, pericardial cavity pressure rises to exceed the filling pressure of the heart, which is called **cardiac tamponade** (Fig. 7-35). The resulting

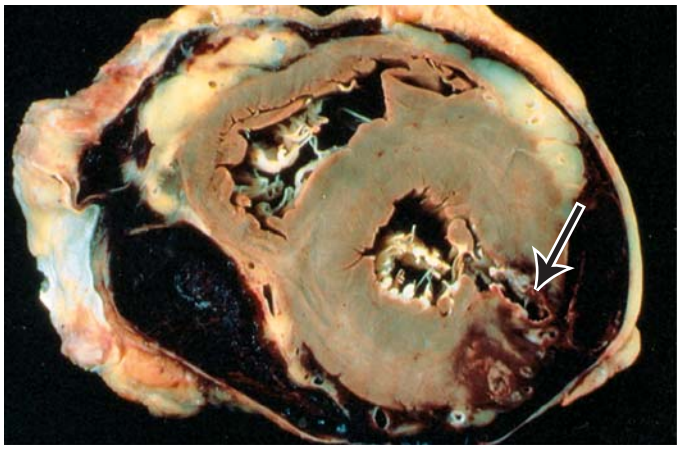

FIGURE 7-35. Cardiac tamponade. A cross-section of the heart shows rupture of a myocardial infarct (*arrow*) with the accumulation of a large quantity of blood in the pericardial cavity.

precipitous decline in cardiac output is often fatal. If pericardial fluid accumulates rapidly, the tolerable limit may be only 90–120 mL, but a liter or more of fluid can be accommodated if the process is gradual.

Peritoneum

Peritoneal effusion, also called **ascites,** is caused mainly by cirrhosis of the liver, abdominal neoplasms, pancreatitis, cardiac failure, the nephrotic syndrome and hepatic venous obstruction (Budd-Chiari syndrome). Obstruction of the thoracic duct by cancer may lead to **chylous ascites,** in which the fluid has a milky appearance and a high fat content. The pathogenesis of ascites in cirrhosis of the liver is discussed above.

Patients with severe ascites accumulate many liters of fluid and have hugely distended abdomens. The complications of ascites derive from increased abdominal pressure and include anorexia and vomiting, reflux esophagitis, dyspnea, ventral hernia and leakage of fluid into the pleural space.

FLUID LOSS AND OVERLOAD

Excessive fluid loss (dehydration) and fluid overload are clinical situations that have potentially grave consequences. Fluid imbalance causes hemodynamic disorders; alterations in osmolality and the quantity of fluid in intravascular, interstitial and cellular spaces may affect perfusion or delivery of substrates, electrolytes or fluids.

Dehydration Features Inadequate Fluid to Fill the Fluid Compartments

Dehydration results from insufficient fluid intake, excessive fluid loss or both. Water loss may exceed intake in cases of vomiting, diarrhea, burns, excessive sweating and diabetes insipidus. When excessive fluid loss occurs, fluid recruited from the interstitial space enters the plasma. Fluids in the cells and within the interstitial and vascular compartments become more concentrated, particularly if there is a preferential loss of water, such as during inappropriate secretion of antidiuretic hormone in diabetes insipidus. When patients suffer from burns, vomiting, excessive sweating or diarrhea, they not only lose fluid but also suffer electrolyte disturbances.

Clinically, only dryness of the skin and mucous membranes is noted initially, but as dehydration progresses, skin turgor is lost. If dehydration persists, **oliguria** (reduced urine output) occurs as a compensation for the fluid loss. More severe fluid loss is accompanied by a shift of water from the intracellular space to the extracellular space, causing severe cell dysfunction, particularly in the brain. Shrinkage of brain tissue may result in the rupture of small vessels and subsequent bleeding. Systemic blood pressure falls with continuous dehydration, and declining perfusion eventually leads to death.

In Overhydration, Fluid Intake Exceeds Renal Excretory Capacity

Overhydration is rare, unless renal injury limits fluid excretion or kidneys cannot properly counterregulate (e.g., via excessive secretion of antidiuretic hormone). Fluid overload today is mostly caused by administration of excessive amounts of intravenous fluids. The most serious effect of such fluid overload is induction of cerebral edema or congestive heart failure in patients with cardiac dysfunction.

PATHOPHYSIOLOGY:

Blood Pressure Control

Data from twin and family studies indicate that genetics accounts for some 30% of blood pressure (BP) regulation. This finding may also account for the tremendous variation in patient response to BP-lowering medication. Human genetic linkage and whole genome association studies have identified a host of mutations in key blood pressure regulatory processes. Prominent are genes of the renin–angiotensin system, which regulates vasoconstriction and sodium and water balance. SNPs in genes encoding angiotensin, angiotensin-converting enzyme, angiotensin II receptor, renin and renin-binding protein are associated with altered blood pressure control. Hypertension has been associated with SNPs in the vasoconstrictor endothelin and its receptor, the vasodilator nitric oxide synthase and endothelial sodium channel subunits. Polymorphisms of β-adrenergic receptors 1 and 2 have been associated with hypertension and altered response to β-agonists.

SHOCK

Shock is a condition of profound hemodynamic and metabolic disturbance characterized by failure of the circulatory system to maintain an appropriate blood supply to the microcirculation, with consequent inadequate perfusion of vital organs. In this often catastrophic circumstance, tissue perfusion and oxygen delivery fall below levels required to meet normal demands, including failure to remove metabolites adequately. The term **shock** encompasses all the reactions that occur in response to such disturbances. In the course of uncompensated shock, a rapid circulatory collapse leads to impaired cellular metabolism and death. However, in many cases, compensatory mechanisms sustain the patient, at least for a while. When these adaptations fail, shock becomes irreversible. Shock has been a major cause of morbidity and mortality in intensive care units, and despite endeavors to suppress portions of the immune response, the outcome of shock has been unchanged in the past 50 years.

Shock is not synonymous with low blood pressure, although hypotension is often part of shock syndrome. Hypotension is actually a late sign in shock and indicates failure of compensation. At the same time that peripheral blood flow falls below critical levels, extreme vasoconstriction can maintain arterial blood pressure. The distinction between shock and hypotension is important clinically because rapid restoration of systemic blood flow is the primary goal in treating shock. When blood pressure alone is raised with vasopressive drugs, systemic blood flow may actually be diminished.

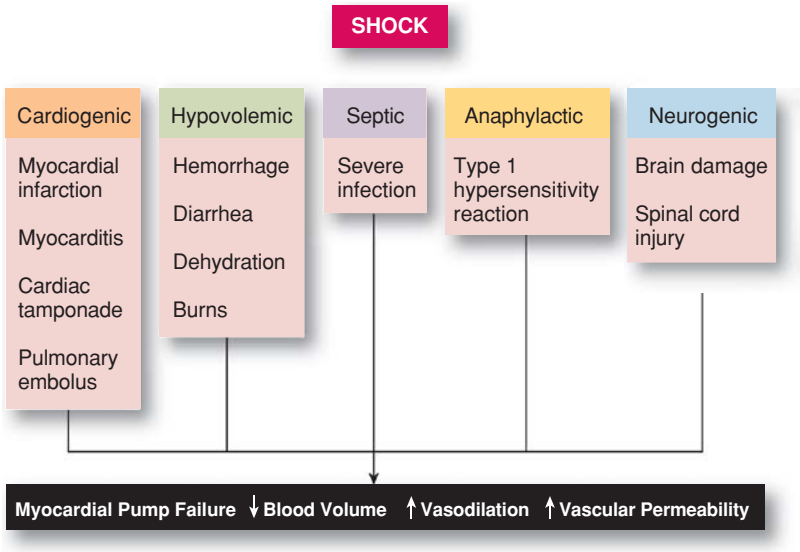

FIGURE 7-36. Classification of shock. Shock results from (1) an inability of the heart to pump adequately (cardiogenic shock), (2) decreased effective blood volume as a consequence of severely reduced blood or plasma volume (hypovolemic shock) or (3) widespread vasodilation (septic, anaphylactic or neurogenic shock). Increased vascular permeability may complicate vasodilation by contributing to reduced effective blood volume.

MOLECULAR PATHOGENESIS AND ETIOLOGIC FACTORS: Decreased perfusion in shock most commonly results from decreased cardiac output, due either to the inability of the heart to pump normal venous return or to decreased effective blood volume that results in decreased venous return. These two mechanisms underlie two of the major types of shock: **cardiogenic** and **hypovolemic** shock. Systemic vasodilation, with or without increased vascular permeability, is responsible for the other broad category of shock, referred to as a **distributive** shock. This condition has several key subcategories: septic, anaphylactic and neurogenic shock (Fig. 7-36).

- **Cardiogenic shock** is caused by myocardial pump failure. It usually arises after massive myocardial infarction, but myocarditis may also be responsible. Disorders that prevent left or right heart filling reduce cardiac output, resulting in "obstructive" shock. Such conditions include pulmonary embolism, cardiac tamponade (Fig. 7-35) and (rarely) atrial myxoma.
- **Hypovolemic shock** occurs owing to pronounced decreases in blood or plasma volume, caused by loss of fluid from the vascular compartment. Hemorrhage, fluid loss from severe burns, diarrhea, excessive urine formation, perspiration and trauma all lead to fluid loss that can trigger hypovolemic shock. Burns or trauma directly damages the microcirculation, increasing vascular permeability.
- **Septic shock** is caused by severe systemic microbial infections. The pathogenesis of septic shock is complex and is discussed in detail below.
- **Anaphylactic shock** is a consequence of a systemic type I hypersensitivity reaction, which generates widespread vasodilation and increased vascular permeability.
- **Neurogenic shock** can follow acute injury to the brain or spinal cord, which impairs neural control of vasomotor tone and causes generalized vasodilation. In the case of both anaphylactic and neurogenic shock, the subsequent redistribution of blood to the periphery, with or without increased vascular permeability, reduces the effective circulating blood and plasma volume. This ultimately leads to the same consequences as in hypovolemic shock.

In hypovolemic and cardiogenic shock, lower cardiac output and resultant decreased tissue perfusion are the key steps in the progression from reversible to irreversible shock. Cellular hypoxia is the common consequence of the initial decrease in tissue perfusion. Although such changes do not initially result in irreversible injury, a vicious circle of decreasing tissue perfusion and further cell injury is perpetuated by several mechanisms:

- Injury to endothelial cells, secondary to hypoxia caused by decreased tissue perfusion and increased vascular permeability, provokes escape of fluid from the vascular compartment.
- Increased exudation of fluid from the circulation reduces (1) blood volume, (2) venous return and (3) cardiac output, thus aggravating hypoxic cell injury.
- Decreased perfusion of kidneys and skeletal muscles results in metabolic acidosis, which in turn further decreases cardiac output and tissue perfusion.
- Decreased perfusion of the heart injures myocardial cells and decreases their ability to pump blood, further reducing cardiac output and tissue perfusion.

Systemic Inflammatory Response Syndrome Characterizes Septic Shock

Systemic inflammatory response syndrome (SIRS) is an exaggerated and generalized manifestation of a local immune or inflammatory reaction, and is often fatal. SIRS is a hypermetabolic state characterized by two or more signs of systemic inflammation. These include fever, tachycardia, tachypnea, leukocytosis or leukopenia, in the setting of a known cause of inflammation. **Septic shock** is defined as clinical SIRS so severe that it causes organ dysfunction and hypotension. Mechanisms leading to septic shock are illustrated in Fig. 7-37. These processes often progress to **multiple organ dysfunction syndrome** (MODS; see Chapter 12), a term used to describe otherwise unexplained abnormalities of organ function in critically ill patients (see below).

The massive inflammatory reaction defined by SIRS results from systemic release of cytokines, the most important being tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-6 and platelet-activating factor (PAF). Over 30

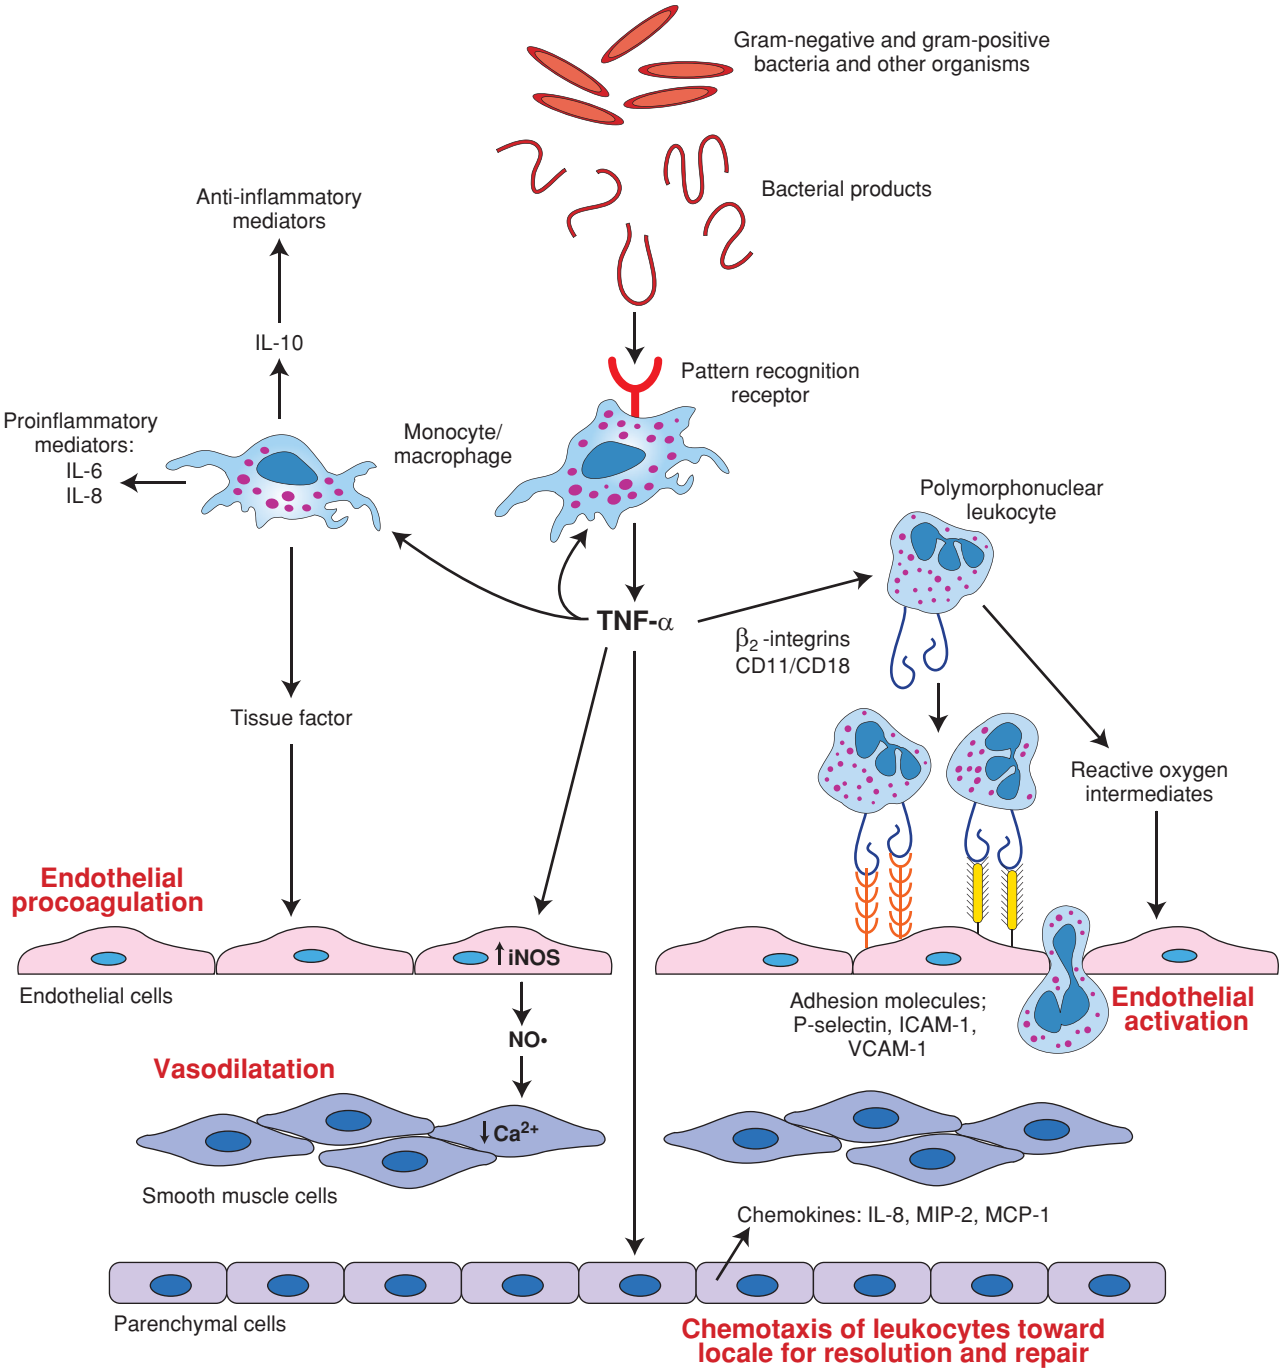

FIGURE 7-37. Pathogenesis of endotoxic shock. Sepsis is caused primarily by gram-negative bacteria and bacterial products such as endotoxin (lipopolysaccharide [LPS]), which is released into the circulation, where it binds to a pattern recognition receptor on the surface of monocyte/macrophages. Such binding stimulates the secretion of substantial quantities of tumor necrosis factor-α (TNF-α). TNF-α mediates septic shock by a number of mechanisms: (1) stimulation of the release of various pro- and anti-inflammatory mediators; (2) induction of endothelial procoagulation by tissue factor, thus leading to thrombosis and local ischemia; (3) direct cytotoxic damage to endothelial cells; (4) endothelial activation, which enhances the adherence of polymorphonuclear leukocytes; (5) stimulation of endothelial cell nitric oxide production and vasodilation; and (6) release of chemokines to attract leukocytes for resolution and repair of tissue injury. *Ca^{2+}* = calcium ion; *ICAM* = intercellular adhesion molecule; *IL* = interleukin; *iNOS* = inducible nitric oxide synthetase; *MCP-1* = monocyte chemotactic protein-1; *MIP-2* = macrophage-inflammatory protein-2; *NO•* = nitric oxide; *VCAM-1* = vascular cell adhesion molecule-1.

endogenous mediators of SIRS have been identified. Their interactions may be important in the pathogenesis of SIRS.

Septicemia with gram-negative organisms is the most common cause of septic shock, followed by gram-positive and fungal infections. The most common primary sources of infection are pulmonary, abdominal and urinary. The invading bacteria release **endotoxin,** a lipopolysaccharide (LPS) whose toxic activity resides in the lipid A component. On entry into the circulation, LPS, via lipid A, binds to LPS-binding protein, after which the complex binds to the CD14 receptor on

the surface of monocyte/macrophages. Toll-like receptors (TLRs) are transmembrane pattern recognition receptors (PRRs), which also collectively recognize bacteria, fungi and protozoa on antigen-presenting cells. TLRs trigger (1) downstream myeloid differentiation protein 88 (MyD88), (2) toll-interleukin-1 (TIR) domain-containing adaptor protein, (3) TIR receptor domain-containing adaptor protein-inducing interferon-β (TRIF) and (4) TRIF-related adaptor molecule. They mediate signaling through activation of the transcription factor, nuclear factor-κB (NF-κB), and upregulate TNF expression. LPS binding to TLR-4 causes mononuclear phagocytes to secrete large quantities of cytokines, such as TNF, IL-1, IL-6, IL-8, IL-12, macrophage inhibitory factor and others, all of which mediate a variety of responses. Cytosolic PRRs include the Nod-like receptors, the most extensively studied of which is the NLRP3 inflammasome complex. This structure is a multiprotein caspase-activating complex that triggers downstream IL-1β and IL-19 activation. Importantly, antigen-presenting cells expose CD4 T lymphocytes to microbial antigens to stimulate the adaptive arm of the immune response.

Cytokine activation and subsequent production of nitric oxide (NO) and procoagulant proteins ultimately cause the overwhelming cardiovascular collapse characteristic of septic shock. In this context, activation of inducible NO synthase (iNOS) by TNF upregulates NO synthesis from L-arginine, an effect that is primarily responsible for the drop in blood pressure during sepsis. TNF is also involved in the pathogenesis of shock unassociated with endotoxemia (e.g., cardiogenic shock). LPS is the most potent stimulus for TNF release, but other antigens also promote its secretion. These include toxin-1 of the toxic shock syndrome; enterotoxin; antigens of mycobacteria, fungi, parasites and viruses; and products of complement activation.

Although TNF exerts beneficial effects by enhancing tissue remodeling, wound healing and defense against local infections, when macrophages are exposed to LPS in septic shock, TNF is suddenly released in great excess, often with lethal consequences. Administering anti-TNF antibody before exposing an animal to endotoxin or to gram-negative bacteria completely protects from septic shock. Unfortunately, comparable studies in humans have not been successful.

TNF released by monocyte/macrophages exerts a direct toxic effect on endothelial cells by compromising membrane permeability and inducing endothelial cell apoptosis. It also acts indirectly by (1) initiating a cascade of other mediators that amplify its deleterious effects, (2) promoting the adhesion of polymorphonuclear leukocytes to endothelial surfaces and (3) activating the extrinsic coagulation pathway. The presence of TNF stimulates the release of IL-1 and IL-6, PAF and other eicosanoids that mediate tissue injury. Interestingly, nonlethal doses of TNF become fatal when administered together with IL-1. TNF also increases expression of adhesion molecules, such as intercellular adhesion molecules (ICAMs), vascular cell adhesion molecules (VCAMs), P-selectin and endothelial–leukocyte adhesion molecules (ELAMs) on endothelial surfaces, thus promoting leukocyte adhesion and leukostasis. This mechanism presumably plays a role in the respiratory distress syndrome, in which activated neutrophils are sequestered in the pulmonary circulation and damage the alveoli. Other vasoactive peptides include the vasodilatory prostacyclins and endothelin (ET)-1, a potent vasoconstrictor (Fig. 7-37). Note that the term "septic syndrome" refers to the physiologic and metabolic response characteristic of sepsis in the absence of an infection.

Multiple Organ Dysfunction Syndrome Is the End-Result of Shock

Improvements in the early treatment of shock and sepsis have allowed patients to survive long enough to manifest a new problem, progressive deterioration of organ function. Almost all septic shock patients suffer from dysfunction of at least one organ. However, multiple organ dysfunction occurs in one third of patients with septic shock, trauma or burns, and a quarter of those with acute pancreatitis. Whatever the cause, the clinical deterioration of MODS is held to result from common mechanisms of tissue injury subsumed under the rubric of SIRS. Mortality of SIRS/MODS exceeds 50%, making it responsible for most deaths in noncoronary intensive care units in the United States. In most circumstances, the inflammatory reaction and the progression from sepsis to organ dysfunction reflects a balance between proinflammatory and anti-inflammatory factors. As mentioned above, TNF-α, IL-1 and NO have systemic effects.

Also, reactive oxygen species (ROS) are important triggers of end-organ dysfunction. The acute response to sepsis is characterized by release of adrenocorticotropic hormone (ACTH), cortisol, adrenaline and noradrenaline, vasopressin, glucagon and growth hormone. The net result is shutdown of noncritical systems and an overall catabolic state. Although proinflammatory mediators predominate in SIRS, counterinflammatory factors play an important role in some patients. It is now thought that following bacterial infection, there is an initial response of excessive inflammation and septic shock characteristic of SIRS. Such uncontrolled cytokine induction is preceded by a stage of anergy and immune repression.

Vascular Compensatory Mechanisms

Changes in the macrovascular and microvascular circulation are at least partly responsible for variable organ injury in SIRS. Compensatory mechanisms in shock shift blood flow away from the periphery, so as to maintain flow to the heart and the brain. These responses involve the sympathetic nervous system, release of endogenous vasoconstrictors and hormonal substances, and local vasoregulation. The result is increased cardiac output achieved by increasing heart rate and myocardial contractility while constricting arteries and arterioles.

- **Increased sympathetic discharge** augments catecholamine release by the adrenal medulla. Skeletal muscle, splanchnic bed and skin arterioles respond to increased sympathetic discharge; cardiac and cerebral arterioles are less reactive. Thus, increased sympathetic tone works to shift blood flow from the periphery to the heart and brain. The marked arteriolar vasoconstriction reduces capillary hydrostatic pressure and decreases fluid shifted into the interstitium. This facilitates an osmotic fluid shift from the interstitium to the vascular system. This sympathetic–adrenal response can completely compensate for blood loss of 10% of intravascular volume. With a greater volume deficit, cardiac output and blood pressure are affected and blood flow to tissues is reduced.
- **The renin–angiotensin–aldosterone system** also helps compensate by stimulating sodium and water reabsorption, thus helping to maintain intravascular volume. A

similar water-preserving action is provided by pituitary antidiuretic hormone.

- **Vascular autoregulation** preserves regional blood flow to vital organs, particularly the heart and brain, by vasodilation in the coronary and cerebral circulations in response to hypoxia and acidosis. Vasoconstriction mediated largely by α-adrenergic receptors in mesenteric venules and veins helps maintain cardiac filling and arterial pressure. Circulation to organs such as skin and skeletal muscles, which are less sensitive to hypoxia, does not display such tightly controlled autoregulation.

MOLECULAR PATHOGENESIS: Genetic Polymorphisms in Toll-Like Receptors and Tumor Necrosis Factor Participate in the Pathogenesis of Sepsis

Epidemiologic studies have shown that death from infection has a higher genetic background than that of cardiovascular disease or cancer. Gene mutations in several cytokines, cell surface receptors and other circulating markers have been associated with susceptibility to sepsis. TLR pattern recognition receptors recognize pathogen-associated microbial patterns and thus are critical in triggering innate immune responses. Toll-like receptor-4 (TLR4) is critical in recognizing LPS of gram-negative bacteria. A mutation of TRL4 (aspartic acid to glycine at amino acid 299) has been associated with patients with septic shock in a number of studies. As mentioned earlier, TLR4 is important in the exacerbation of the endotoxin response, and in sepsis, polymorphisms in TLRs and other PRRs may help explain why patients respond so differently to a given infective agent.

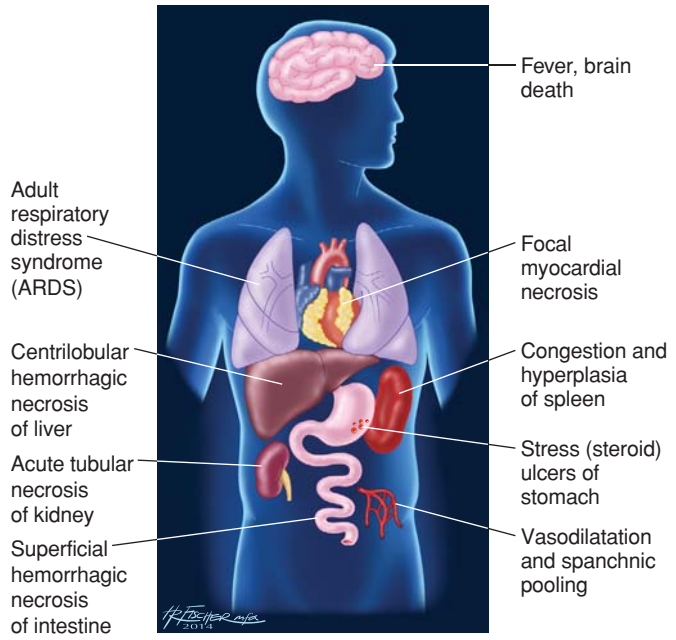
Similarly, recently discovered mutations in the TNF-α gene have improved our understanding of the role of TNF-α in sepsis. A mutation in the TNF-α promoter, TNF2, has been associated with increased susceptibility to sepsis and shock.

Other gene mutations associated with worse prognosis in sepsis are found in IL-1 receptor agonist, CD14 and plasminogen activator inhibitor-1 (PAI-1). Finally, gene profiling studies have found unique molecular signatures in circulating neutrophils and mononuclear cells from patients with sepsis.

PATHOLOGY: Shock is associated with specific changes in a number of organs (Fig. 7-38), including acute renal tubular necrosis, acute respiratory distress syndrome, liver failure, depression of host defense mechanisms and heart failure. Interestingly, paracrine cross-talk from molecules in one injured organ, such as proinflammatory mediators from the lung, can effect distant organ injury.

Heart

Systolic and diastolic dysfunction occurs during sepsis, likely secondary to paracrine injury and possibly hypoperfusion. In sepsis, the heart shows petechial hemorrhages of the epicardium and endocardium. Microscopically, necrotic foci in the myocardium range from loss of single fibers to large areas of necrosis. Prominent contraction bands are visible by light microscopy but are better seen by electron microscopy. Ultrastructurally, flattened areas of the intercalated disk are a sign of cell swelling, and invagination of adjacent cells is considered to be a catecholamine-induced lesion.



Fever, brain death
Adult respiratory distress syndrome (ARDS)
Focal myocardial necrosis
Centrilobular hemorrhagic necrosis of liver
Congestion and hyperplasia of spleen
Acute tubular necrosis of kidney
Stress (steroid) ulcers of stomach
Superficial hemorrhagic necrosis of intestine
Vasodilatation and spanchnic pooling

FIGURE 7-38. Complications of shock.

Kidney

Acute tubular necrosis (ATN, acute renal failure), a major complication of shock, has been divided into three phases: (1) **initiation,** from the onset of injury to the beginning of renal failure; (2) **maintenance,** from the onset of renal failure to a stable, reduced renal function; and (3) **recovery**. In those who survive an episode of shock, the recovery phase begins about 10 days after its onset and may last up to 8 weeks.

Renal blood flow is restricted to 1/3 of normal after the acute ischemic phase. This effect is even more severe in the outer cortex. Constriction of arterioles reduces the filtration pressure, thus reducing the amount of filtrate and contributing to oliguria. Interstitial edema occurs, possibly through a process called **backflow**. Excessive vasoconstriction is also related to stimulation of the renin–angiotensin system.

During acute renal failure, the kidney is large, swollen and congested, although the cortex may be pale. A cross-section reveals blood pooling in the outer stripe of the medulla. Microscopically, fully developed acute tubular necrosis is evidenced by dilation of the proximal tubules and focal necrosis of cells (Fig. 7-39). Often, pigmented casts in tubular lumina indicate leakage of hemoglobin or myoglobin. Coarse "ropy" casts are seen in the distal nephron and distal convoluted tubules. Interstitial edema is prominent in the cortex, and mononuclear cells accumulate within tubules and surrounding interstitium. ATN is discussed in more detail in Chapter 22.

Lung

After the onset of severe and prolonged shock, injury to alveolar walls can lead to **shock lung,** which is a cause of **acute respiratory distress syndrome** (ARDS) (see Chapter 18). The sequence of changes is mediated by polymorphonuclear leukocytes and includes interstitial edema, necrosis of endothelial and alveolar epithelial cells and formation of

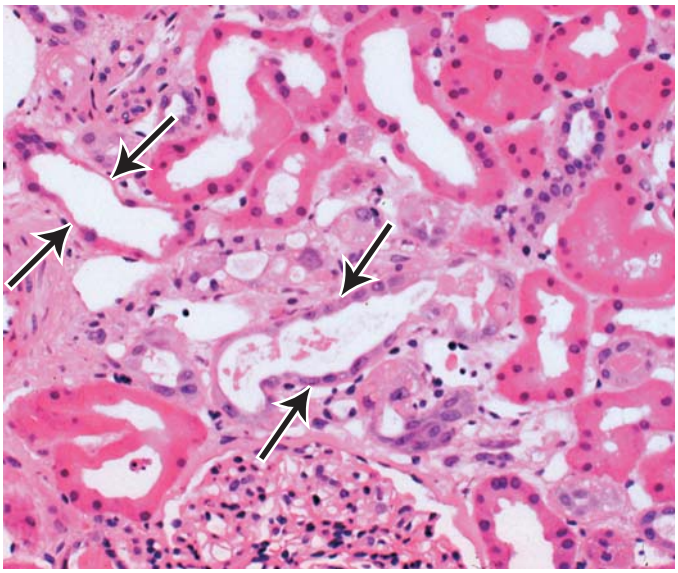


FIGURE 7-39. Acute tubular necrosis. A section of kidney shows swelling and degeneration of tubular epithelium. *Arrows* indicate the thinned and damaged epithelium.

intravascular microthrombi and hyaline membranes lining the alveolar surface.

Macroscopically, the lung is firm and congested and a frothy fluid often exudes from the cut surface. Interstitial edema is first seen around peribronchial connective tissue and lymphatics, subsequently filling the interstitial connective tissue. In this initial period, a large fluid volume drains into the pulmonary lymphatics. If removal of this fluid becomes inadequate, or if the balance of forces that keep the fluid in the interstitial space is disturbed, alveolar edema develops.

Shock-induced lung injury leads to alveolar hyaline membranes (Fig. 7-34), which also frequently line alveolar ducts and terminal bronchioles. These changes may heal entirely, but in half of patients, repair processes cause thickening of the alveolar wall. Type II pneumocytes proliferate to replace damaged type I pneumocytes and line the alveoli. Fibrous tissue proliferation gives rise to organization of the alveolar exudate. These chronic changes may result in persistent respiratory distress and even death. Shock lung and ARDS are more fully discussed in Chapter 18.

Gastrointestinal Tract

Shock often results in diffuse gastrointestinal hemorrhage. Erosions of the gastric mucosa and superficial ischemic necrosis in the intestines are the usual sources of this bleeding. Interruption of the barrier function of the intestine may result in septicemia. More-severe necrotizing lesions contribute to deterioration in the final phase of shock.

Liver

In patients who die in shock, the liver is enlarged and has a mottled cut surface that reflects marked centrilobular pooling of blood. The most prominent histologic lesion is centrilobular congestion and necrosis. The basis for the apparent increased sensitivity of centrilobular hepatocytes to shock may not simply represent their greater distance from the source of blood via the portal tracts, a matter that is not settled (see Chapter 20).

FIGURE 7-40. Waterhouse-Friderichsen syndrome. A normal adrenal gland (*left*) in contrast to an adrenal gland enlarged by extensive hemorrhage (*right*), obtained from a patient who died of meningococcemic shock.

Pancreas

The splanchnic vascular bed, which supplies the pancreas, is particularly affected by impaired circulation during shock. Resulting ischemic damage to the exocrine pancreas unleashes activated catalytic enzymes and causes acute pancreatitis, a complication that further promotes shock.

Brain

Although septic patients often develop clinical encephalopathy, brain lesions are rare in SIRS and shock. Microscopic hemorrhages may be seen, but patients who recover do not ordinarily have neurologic deficits. In severe cases, particularly in people with cerebral atherosclerosis, hemorrhage and necrosis may appear in the overlapping region between the terminal distributions of major arteries, so-called **watershed infarcts** (see Chapter 32).

Adrenals

In severe shock, adrenal glands exhibit conspicuous hemorrhage in the inner cortex. Although the hemorrhage is often focal, it can be massive and accompanied by hemorrhagic necrosis of the entire gland, as seen in the **Waterhouse-Friderichsen syndrome** (Fig. 7-40), typically associated with overwhelming meningococcal septicemia.

Host Defenses

The changes in immune function and host defenses in shock are not well understood, although it is common for patients who survive the acute phase of shock to succumb to subsequent overwhelming infection. It may well be that several factors interact, namely, ischemic colitis, tissue trauma and immune and metabolic suppression of host defenses. Humoral immunity and phagocytic activity by leukocytes and macrophages are both depressed, but the mechanisms underlying these effects are not clear.

Environmental pathology is the study of diseases caused by exposure to harmful external agents and deficiencies of vital substances. With heightened awareness of the fact that chemical agents may mediate tissue changes and recognition that many of these are environmental contaminants, "occupational pathology" has developed. In this chapter we concentrate on diseases caused by (1) exposure to toxic agents, (2) physical damage and (3) nutritional deficiencies.

SMOKING

Smoking tobacco is the single largest preventable cause of death in the United States. ***About 480,000 deaths per year—or 1/5 of the total deaths in the United States—occur prematurely because of smoking.*** The Surgeon General in 2014[1] incriminates tobacco in 48% of deaths from cancer, 19% of deaths from cardiovascular and metabolic diseases, 61% of deaths from nonmalignant lung diseases and 8% of perinatal deaths. Life expectancy is shortened and overall mortality is proportional to the amount and duration of cigarette smoking, commonly quantitated as "pack-years" (Fig. 8-1).

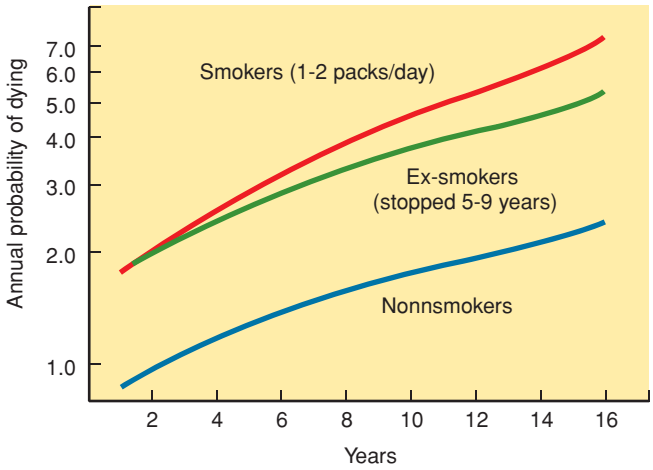

FIGURE 8-1. The risk of dying in smokers and nonsmokers. Note that the annual probability of an individual dying, indicated on the ordinate, is a logarithmic scale. Individuals who have smoked for 1 year have a twofold greater probability of dying than a nonsmoker, while those who have smoked for more than 15 years have more than a threefold greater probability of dying.

[1]The Health Consequences of Smoking—50 Years of Progress: A Report of the Surgeon General. 2014. U.S. Department of Health and Human Services, Rockville, MD.

For example, a person who smokes two packs of cigarettes a day at the age of 30 years will live an average of 8 years less than a nonsmoker.

As women have taken to smoking as much as men, the previous male preponderance of smoking-related illness has equalized between the sexes. Thus, the development of smoking-related illnesses reflects the amount smoked, not the gender of the smoker. In fact, mortality from lung cancer, almost all of which is related to cigarette smoking, exceeds that from cancers of the breast and prostate, which are the most common cancers of women and men, respectively, in the United States. The excess mortality associated with cigarette smoking declines after one quits smoking: by 15 years of abstinence from cigarettes, mortality in ex-smokers from all causes approaches that of people who have never smoked. Cancer mortality among those who smoke only cigars or pipes is somewhat greater than that of the nonsmoking population. Use of smokeless tobacco (snuff, chewing tobacco) entails little, if any, increased risk of malignancy.

The major diseases responsible for excess mortality reported in cigarette smokers are, in order of frequency, many types of cancers, cardiovascular and metabolic diseases and chronic pulmonary diseases. Cancers of the oral cavity, larynx, esophagus, pancreas, bladder, kidney, colon, liver and cervix are all more common in smokers than in nonsmokers. Also, smokers show excess mortality from tuberculosis, atherosclerotic aortic aneurysms and peptic ulcers. The effects of cigarette smoking on the various organs of smokers are illustrated in Fig. 8-2.

Cardiovascular Disease Is a Major Complication of Smoking

Cigarette smoking is a major independent risk factor for myocardial infarction. It acts synergistically with other risk factors, such as elevated blood pressure and blood cholesterol levels (Fig. 8-3). Smoking precipitates initial myocardial infarction, increases the risk for second heart attacks and diminishes survival after a heart attack among those who continue to smoke. Smoking also increases the incidence of sudden cardiac death: it contributes to development of atherosclerotic plaques and may lead to ischemia and arrhythmias.

Cigarette smoking is an independent risk factor for **ischemic stroke**. The risk correlates with the number of cigarettes smoked and is reduced after cessation of smoking. Tobacco use also increases risk of certain forms of **intracranial hemorrhage**. The combination of smoking and oral contraceptive use in women older than 35 years of age increases the likelihood of **myocardial infarction**. Similarly, use of cigarettes by women who are using oral contraceptives significantly increases their risk of stroke.

Atherosclerosis of the coronary arteries and aorta is more severe and extensive among cigarette smokers than among nonsmokers, and the effect is dose related. As a consequence, cigarette smoking is a strong risk factor for **atherosclerotic aortic aneurysms**. The incidence and severity of **atherosclerotic peripheral vascular disease** are also remarkably increased by smoking. Smoking is also a major risk factor

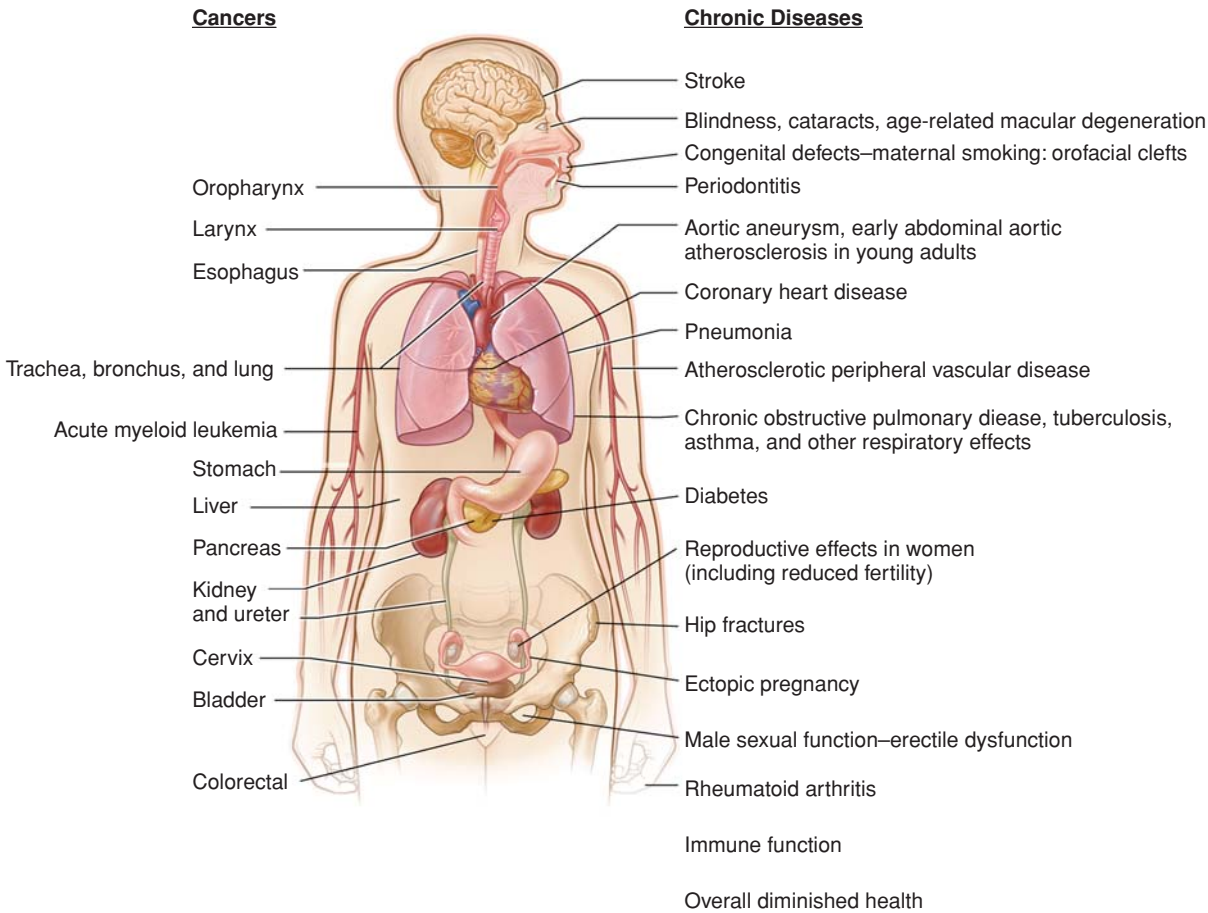

FIGURE 8-2. Organs affected by active cigarette smoking.

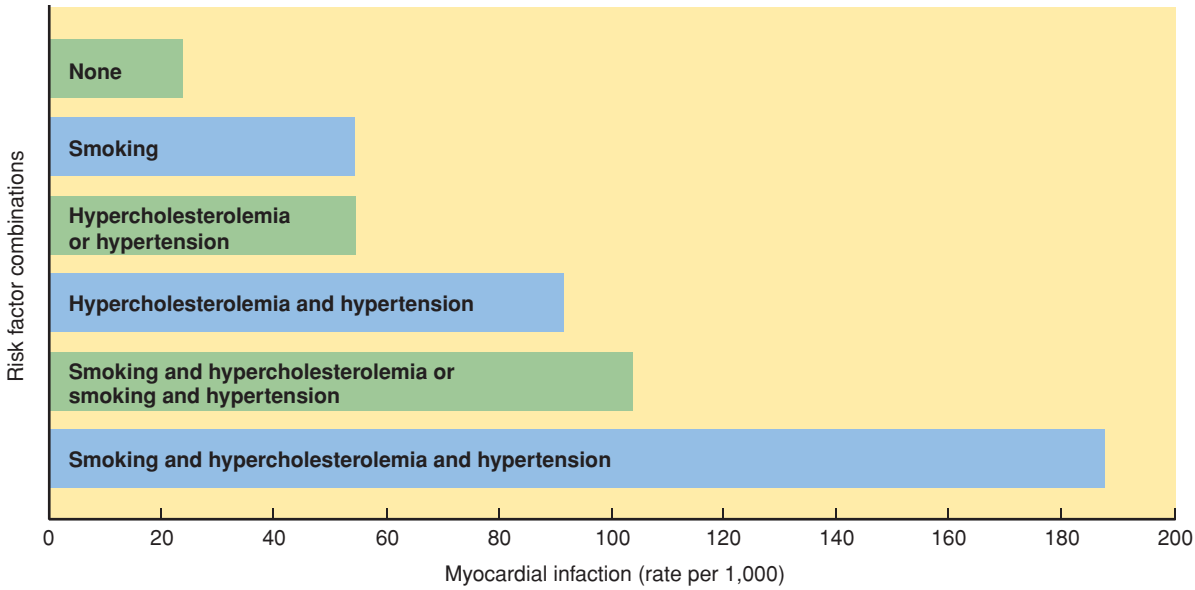

FIGURE 8-3. The risk of myocardial infarction in cigarette smokers. Smoking is an independent risk factor and increases the risk of a myocardial infarction to about the same extent as does hypertension or hypercholesterolemia alone. The effects of smoking are additive to those of these other two risk factors.

for **coronary vasospasm**. It disturbs regional coronary blood flow in patients with coronary artery disease and lowers the threshold for ventricular fibrillation and cardiac arrest in patients with established ischemic heart disease. The pharmacologic actions of nicotine itself, carbon monoxide (CO) inhalation, reduced plasma high-density lipoprotein levels, increased plasma fibrinogen levels and higher leukocyte counts are all consequences of smoking that may predispose to myocardial infarction.

Buerger disease, a peculiar inflammatory and occlusive disease of the lower leg vasculature, occurs almost only in heavy smokers (see Chapter 16).

Lung Cancer Is Largely a Disease of Cigarette Smokers

More than 85% of deaths from lung cancer, the single most common cancer death in both men and women in the United States today, are DUE to cigarette smoking (Fig. 8-4). Although the precise offenders in cigarette smoke have not been identified, clearly cigarette smoke is toxic and carcinogenic to the bronchial mucosa. Passing cigarette smoke through a filter separates it into gas and particulate phases. Cigarette tar, the material deposited on the filter, contains over 3000 compounds, many of which have been identified as carcinogens, mucosal toxins and ciliotoxic agents. Compounds with similar harmful properties are found in the gas phase, but they are fewer. Among smokers, the risk of lung cancer is directly related to the number of cigarettes smoked.

The pathology of lung cancers has changed over the years. Previously, squamous carcinoma was the predominant lung cancer in smokers. This has declined as smoking has become less prevalent. In recent years, adenocarcinoma has become more common. The Surgeon General's report on smoking (2014, see above) links this to changes in the composition and configuration of cigarettes.

Cigarette smoking is also an important factor in the induction of **lung cancer** that is associated with certain occupational exposures. For instance, uranium miners have an increased rate of lung cancer, presumably because of inhalation of radon daughters. The rate of lung cancer among miners who smoke is considerably higher than for nonminers with similar smoking habits. Another example is the case of asbestos workers. While heavy smokers in the general population have a risk of lung cancer some 20 times

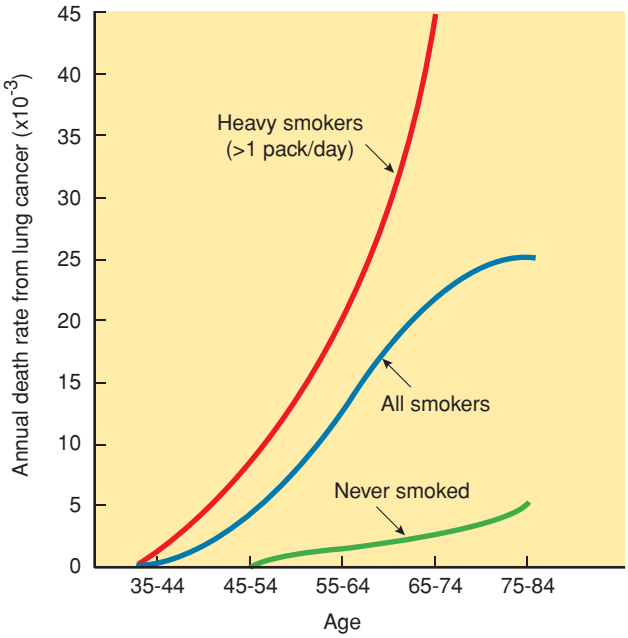

FIGURE 8-4. Death rate from lung cancer among smokers and nonsmokers. Nonsmokers exhibit a small, linear rise in the death rate from lung cancer from the age of 50 onward. By contrast, those who smoke more than one pack per day show an exponential rise in the annual death rate from lung cancer starting at about age 35. By age 70, heavy smokers have about a 20-fold greater death rate from lung cancer than nonsmokers.

greater than nonsmokers, asbestos workers who have interstitial pulmonary fibrosis and smoke heavily have a risk over 60 times that of nonsmokers.

- **Cancers of the lip, tongue and buccal mucosa** occur principally (>90%) in tobacco users. All forms of tobacco use—cigarette, cigar and pipe smoking, as well as tobacco chewing—expose the oral cavity to the compounds found in raw tobacco or tobacco smoke.
- **Cancer of the larynx** is similarly related to cigarette smoking. In some large studies, white male smokers have a 6–13 times greater death rate from laryngeal cancer than nonsmokers.
- **Cancer of the esophagus** in the United States and Great Britain is estimated to result from smoking in 80% of cases.
- **Cancer of the bladder** is twice as frequent a cause of death in cigarette smokers as in nonsmokers. In fact, 30%–40% of all bladder cancers are attributable to smoking. As with most tobacco-related disorders, there is a clear dose-response relationship between incidence of bladder cancer, numbers of cigarettes smoked per day and duration of cigarette smoking.
- **Carcinoma of the kidney** is increased 50%–100% among smokers. A modest increase in cancer of the renal pelvis has also been documented.
- **Cancer of the pancreas** has shown a steady increase in incidence, which is, at least in part, related to cigarette smoking. The risk ratio in male smokers for adenocarcinoma of the pancreas is 2–3, and a dose-response relationship exists. Men who smoke over two packs a day have a five times greater risk of developing pancreatic cancer than nonsmokers.
- **Cancer of the uterine cervix** is significantly increased in women smokers. It has been estimated that about 30% of cervical cancer mortality is associated with this habit.
- **Acute myelogenous leukemia (AML)** is associated with smoking: in men, smoking doubles the risk of AML compared to male nonsmokers.
- **Colon and rectum cancers** are more common in active smokers, particularly heavy smokers, than in nonsmokers. The magnitude of the relative risk (RR, the ratio of the risk for smokers to that in nonsmokers) is estimated to be about 1.25. As well, smokers are at increased risk for colonic adenomatous polyps, which are premalignant precursors of adenocarcinomas (RR, about 1.5).
- **Liver cancers** may be caused by many environmental influences, such as hepatitis viruses (see Chapters 9 and 20). However, there are sufficient epidemiologic and biological data to conclude that cigarette smoking increases the risk of developing hepatic malignancies (RR, about 1.6) independently of other known risk factors.
- **Breast cancer** has been linked to cigarette smoking in both active smokers and people exposed to environmental smoke (see below). This association is best documented for premenopausal women. There is a relationship between risk for tobacco-related breast cancer and rapid acetylator phenotypes for the enzyme N-acetyltransferase-2.
- **Ovarian tumors** are more tenuously linked to tobacco smoking. A slightly increased incidence of borderline mucinous tumors of the ovary with cigarette smoking is reported. No such relationship is reported for other types of ovarian tumors.

Smokers Are at Higher Risk for Certain Nonneoplastic Diseases

- **Chronic bronchitis and emphysema** occur primarily in cigarette smokers. The incidence of these diseases is a function of the number of cigarettes smoked (Fig. 8-5; see Chapter 18).
- **Peptic ulcers** are 70% more common in male cigarette smokers than in nonsmokers.
- **Diabetes mellitus,** type II, occurs 30%–40% more often in smokers. Several different mechanisms may contribute to this effect, including nicotine-related insulin resistance and beta cell apoptosis, increased central adiposity and altered metabolism of estrogens and androgens in smokers.
- **The course of tuberculosis** is more severe in smokers, who are at increased risk for its recrudescence and for tuberculosis-related death.

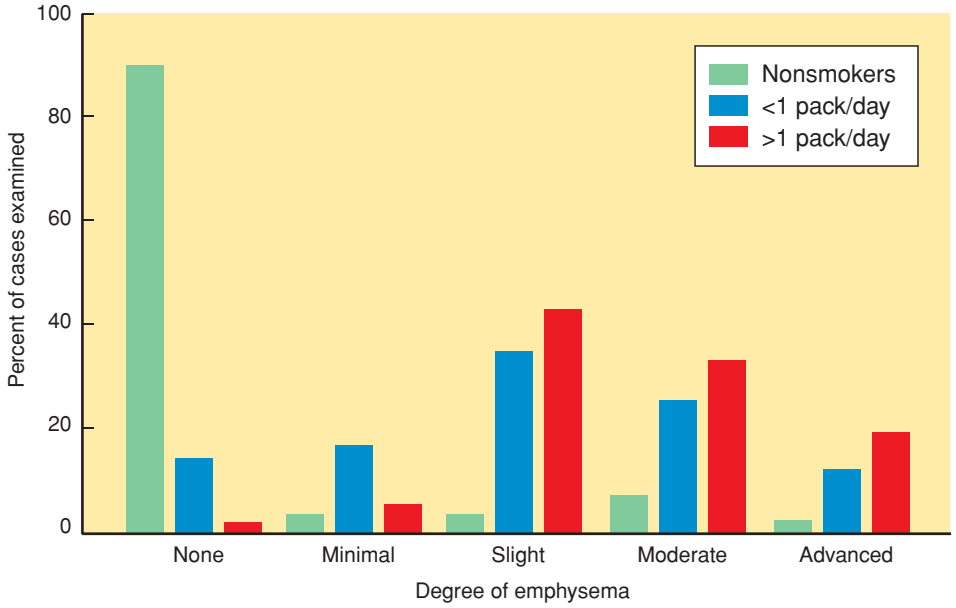

FIGURE 8-5. The association between cigarette smoking and pulmonary emphysema. Some 90% of nonsmokers have no detectable emphysema at autopsy. In contrast, virtually all those who smoke more than one pack per day have morphologic evidence of emphysema at autopsy. Emphysema shows a slight dose dependence on the number of cigarettes smoked. Those who smoke less than one pack per day tend to have less severe emphysema, but 85%–90% of such smokers have some emphysema at autopsy.

- **Asthma** incidence and exacerbations are increased in smokers, compared to nonsmokers.
- **Impaired immune function,** affecting both innate and adaptive arms of the immune system, characterizes smokers. These effects are complex and difficult to summarize briefly. They are mediated via cigarette smoke's prooxidant effects, as well as by specific responses induced by individual smoke components. However, although it acts as an irritant, smoke also impairs innate immune system recognition and other responses to pathogens, such that smokers have increased risk of respiratory infections. Cigarette smoke also alters T- and B-cell–mediated immune functions.
- **Seropositive rheumatoid arthritis** can result from cigarette smoking. People who smoke more develop rheumatoid arthritis more often.
- **Osteoporosis** in women is exacerbated by tobacco use. Women who smoke one pack of cigarettes daily during their reproductive period will have a 5%–10% deficit in bone density at menopause. This deficit is enough to increase the risk of bone fractures.
- **Thyroid diseases** are linked to cigarette smoking, especially Graves disease, and particularly when hyperthyroidism is complicated by exophthalmos.
- **Ocular diseases,** particularly macular degeneration and cataracts, are reportedly more frequent in smokers.
- **Brain development** may be impaired by nicotine in adolescent smokers.

Smoking Impairs Reproductive Function

Men who smoke are more susceptible to erectile dysfunction. Smoking women experience an **earlier menopause** than do nonsmokers, possibly because of the effects of tobacco on estrogen metabolism.

PATHOPHYSIOLOGY: In the liver, estradiol is hydroxylated to estrone, which then enters one of two irreversible metabolic pathways. In one, 16-hydroxylation leads to production of estriol, a potent estrogen. In the other, 2-hydroxylation yields methoxyestrone, which has no estrogenic activity. In female smokers, the latter pathway (i.e., the one that leads to the inactive metabolite) is stimulated. Consequently, circulating levels of estriol, the active estrogen, are reduced. The increased incidence of postmenopausal osteoporosis in smokers has been attributed to decreased estriol levels.

Fetal Tobacco Syndrome Produces Smaller Infants

Maternal cigarette smoking impairs the development of the fetus. Infants born to women who smoke during pregnancy are, on average, 200 g lighter than infants born to comparable women who do not smoke. ***These infants are not born preterm but rather are small for gestational age at every stage of pregnancy.*** In fact, 20%–40% of the incidence of low birth weight can be attributed to maternal cigarette smoking (Fig. 8-6). Thus, this effect of smoking is not idiosyncratic but reflects a direct retardation of fetal growth.

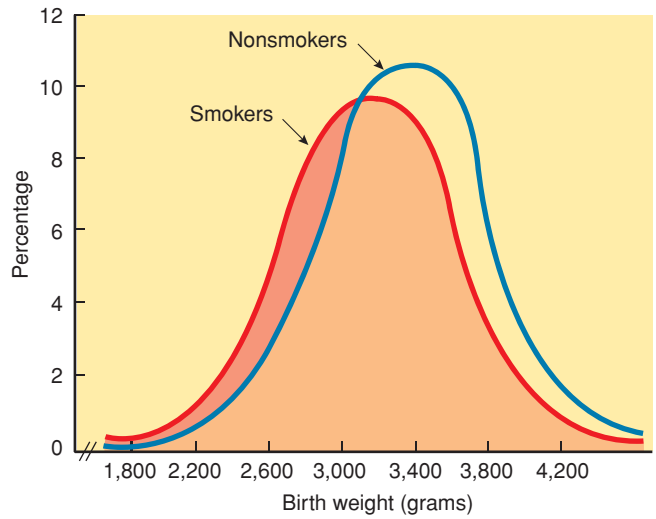

FIGURE 8-6. Effect of smoking on birth weight. Mothers who smoke give birth to smaller infants. In particular, the incidence of babies weighing less than 3000 g is increased significantly by smoking.

The harmful consequences of maternal cigarette smoking on the fetus are illustrated by its effect on the uteroplacental unit. Perinatal mortality is higher among offspring of smokers, the increases ranging from 20% among progeny of women who smoke less than a pack per day to almost 40% among offspring of those who smoke over one pack per day, with the excess mortality reflecting problems related to the uteroplacental system. Incidences of abruptio placentae, placenta previa, uterine bleeding and premature rupture of membranes are all increased (Fig. 8-7; see Chapter 12). These complications of smoking tend to occur at times when the fetus is not viable or is at great risk (i.e., 20–32 weeks of gestation).

Children born of cigarette-smoking mothers have been reported to be more susceptible to several respiratory diseases, including respiratory infections and otitis media.

Substantial evidence indicates that maternal cigarette smoking inflicts lasting harm on children and impairs physical, cognitive and emotional development. Thus, these children showed measurable deficits in physical growth, intellectual maturation and emotional development. In utero exposure to maternal cigarette smoking has been shown to increase severalfold the risk of certain types of attention deficit hyperactivity disorder (ADHD) in children. Deficits in cognitive and auditory function related to smoking during pregnancy may persist for years and are detectable well into adolescence. Boys appear to be generally more vulnerable than girls to many of the psychosocial problems resulting from perinatal exposure to maternal cigarette smoking.

Further, maternal smoking during pregnancy greatly increases (approximately fourfold in a recent study) the risk of sudden infant death syndrome (SIDS; see Chapter 6). This is thought to represent mainly the consequences of prenatal exposure to maternal smoking, since the increase in risk for SIDS if the father smokes, but not the mother, is much less (about 1.5-fold).

In the most comprehensive study to date, 17,000 children born during 1 week in Great Britain were studied at ages 7 and 11 years. Children of mothers who smoked 10 or more cigarettes a day during pregnancy were, on average, 1.0 cm shorter than children of nonsmoking mothers and 3–5 months

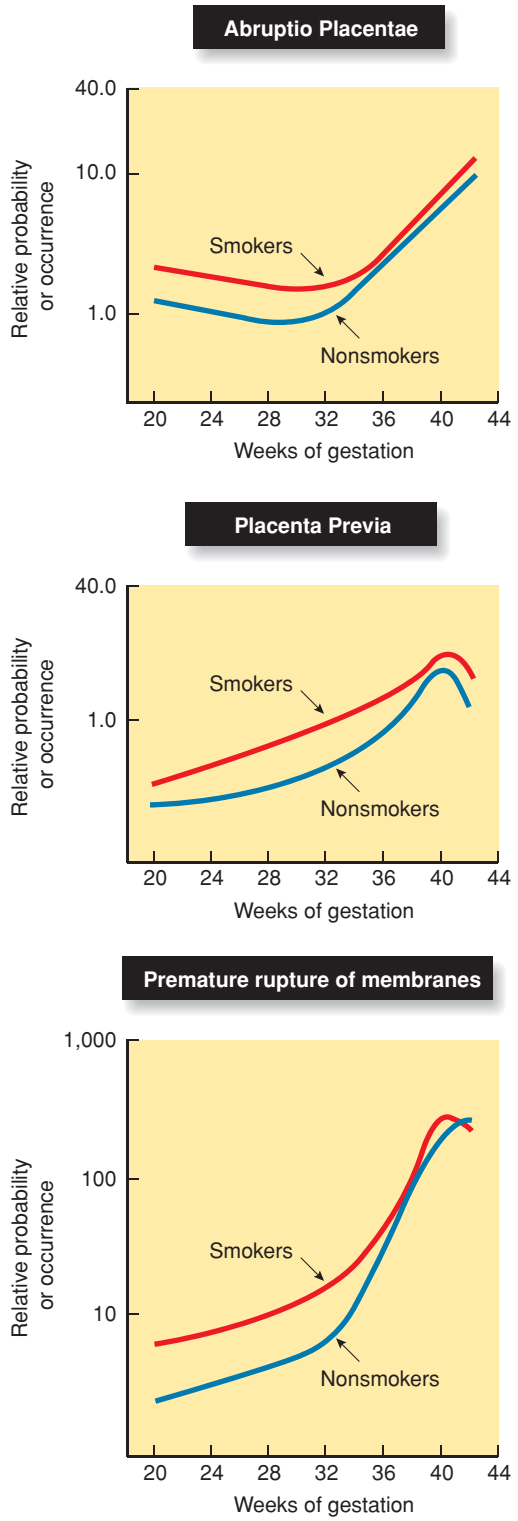

FIGURE 8-7. Effect of smoking on the incidence of abruptio placentae (*top*), placenta previa (*middle*) and the premature rupture of amniotic membranes (*bottom*). In each, the ordinate shows the probability of one of three complications of the third trimester of pregnancy. Note that it is a logarithmic scale. Smoking increases the probability of abruptio placentae and premature rupture of the amniotic membranes prior to 34 weeks of gestation, at which time the fetus is still premature. Smoking increases the risk of placenta previa up to 40 weeks of gestation.

behind in reading, mathematics and general intellectual ability. Moreover, the extent of the deficits was proportional to the number of cigarettes smoked during pregnancy.

Environmental Tobacco Smoke Is Harmful to Nonsmokers

Involuntary exposure to tobacco smoke in the environment—which is variably called second-hand smoke, passive smoking or environmental tobacco smoke (ETS)—is a risk factor for some diseases in nonsmokers (Table 8-1). ***Nonsmoking spouses of smokers have approximately a 20%–30% increased risk of lung cancer.*** The World Health Organization (WHO) and the U.S. Environmental Protection Agency classify ETS as a carcinogen and recognize that it is responsible for some lung cancers occurring in nonsmokers. Data also suggest that ETS is associated with an increased risk of breast cancer in premenopausal women who do not smoke. Data suggest other associations between ETS and human tumors—of the upper respiratory tract and elsewhere—but these connections are more tentative.

An increased incidence of respiratory illnesses and hospitalizations has been reported among infants whose parents smoke, and several studies have reported mild impairment of pulmonary function among children of smokers and exacerbation of preexisting asthma. Reduced indices of pulmonary function are also seen in children of smokers. ETS is associated with an increased risk for SIDS as well (see above).

The range of diseases significantly associated with ETS has been studied in many prospective and retrospective reports, and underlying pathophysiology has been investigated, and continues to be examined. These are illustrated in Fig. 8-8.

ETS, Cardiovascular Disease and Cerebrovascular Disease

There is a very strong connection between ETS and increased risk of coronary artery disease, acute coronary events and sudden death. Many reports substantiate this association, in addition to a considerable number of controlled physiologic studies that address mechanisms involved (see below). The magnitude of increased risk is in the range of 25%–30%, is dose dependent and is disproportionate to the level of smoke exposure, if compared to smokers.

A similar correlation exists between ETS and strokes. Many epidemiologic studies have documented increased incidence of cerebrovascular accidents in the context of ETS exposure. The impact, if any, of smoke-free environments on the incidence of ETS-related strokes remains to be established.

ETIOLOGIC FACTORS AND EPIDEMIOLOGY: The products of cigarette combustion to which active smokers expose passive smokers are not the same as those that active smokers breathe in. Some of the same toxins and carcinogens in mainstream smoke are the same as in ETS. However, unlike mainstream smoke, environmental smoke also includes products of combustion at the ends of lit cigarettes, where hotter temperatures generate higher levels of toxic and carcinogenic combustion products. These include nitrosated and nitrated hydrocarbons and aromatic and polycyclic

TABLE 8-1
HEALTH CONSEQUENCES OF ENVIRONMENTAL TOBACCO SMOKE

Cancer	During Childhood	Cardiac and Vascular	Respiratory and Other	During Pregnancy
Lung	New cases of asthma	Acute myocardial infarction	New cases of asthma	Stillbirth
Breast	Acute otitis media Pulmonary infections	Ischemic stroke Sudden cardiac death Angina	Pulmonary infections COPD Stroke	IUGR SIDS Neurologic and behavioral disorders Preterm delivery

COPD = chronic obstructive pulmonary disease; IUGR = intrauterine growth retardation; SIDS = sudden infant death syndrome.

compounds that do not characterize mainstream smoke. There is a documented exposure/risk relationship in ETS-related disease, the magnitude of which differs for men and women. In some studies, women exposed to second-hand smoke for extended periods (e.g., at home) suffer more from acute cardiac events (ACEs) due to ETS. Furthermore, ETS-related ACEs are significantly more likely to predispose to subsequent coronary events; again, the probabilities reflect levels of exposure to ETS.

PATHOPHYSIOLOGY: Although some observers have persisted in arguing otherwise, there is overwhelming pathophysiological mechanistic substantiation that ETS poses considerable danger to the heart and circulation (Table 8-2). The ability of the heart rate to adjust to changes in demand is compromised by short-term (5–60 minutes) exposure to ETS, as is the functionality of the microvasculature and the left ventricle. As a result, exercise tolerance is greatly diminished. Short exposures to sidestream smoke substantially impair antioxidant defenses and similarly hinder parasympathetic adaptive responses to fluctuating demand for cardiac output. Many of these observations have been made in healthy young adults and so point to ETS pathogenicity even in the absence of predisposing conditions.

Platelet and fibrin thrombi are stimulated. ETS also adds to atherogenic mechanisms involving vascular smooth muscle proliferation and oxidant and inflammatory injury to vascular endothelium. At the same time, reparative responses are undermined.

ETS is associated with increased body burden of oxidant stress and with systemic activation of inflammatory responses. Proinflammatory cytokines, circulating

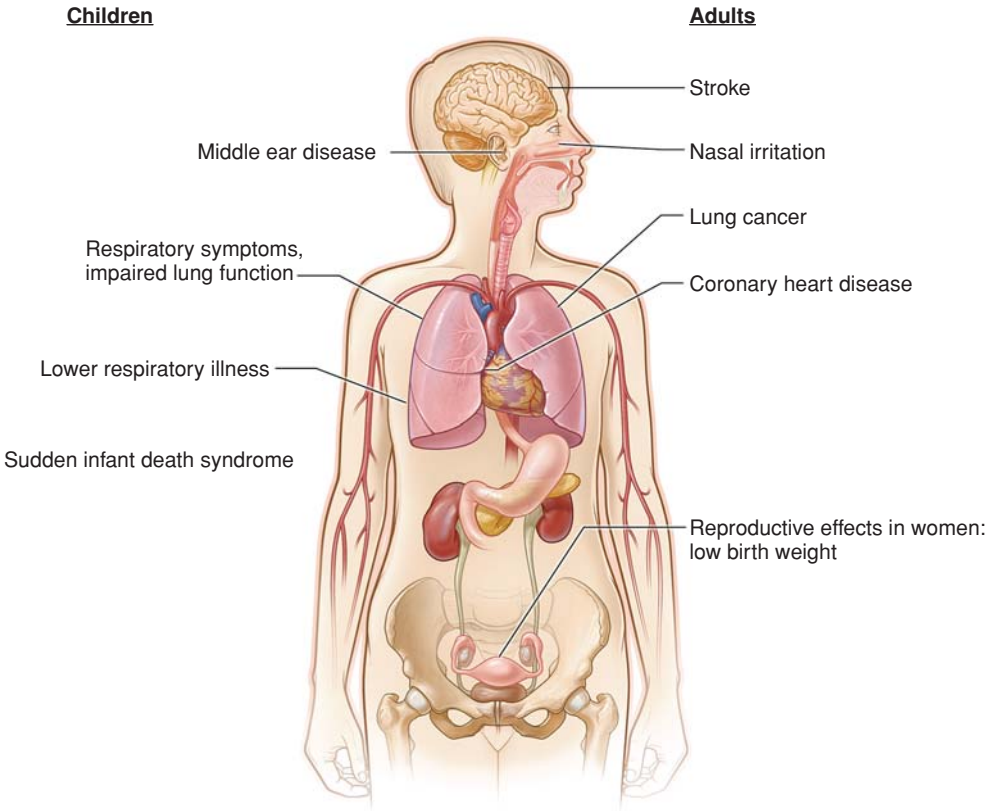

FIGURE 8-8. Complications of environmental tobacco smoke.

TABLE 8-2
EFFECTS OF ENVIRONMENTAL TOBACCO SMOKE ON THE HEART AND BLOOD

Magnification of atherogenesis
Higher levels of oxidant stress
Enhanced proliferation of arterial smooth muscle
Amplification of oxidation of LDL
Increased WBC adhesion to blood vessel walls
Higher levels of platelet aggregation
Impaired ability to adapt heart rate to fluctuations in demand
Depressed left ventricle function
Heightened inflammatory responses
Intensified platelet activation
Increased thrombogenesis
Poorer exercise tolerance
Reduced ability of arteries to dilate

LDL = low-density lipoprotein; WBC = white blood cell.

white blood cell count, biomarkers of inflammatory activation and indicators of activation of the adaptive immune system are all increased. At the same time, antioxidant defenses and other protective mechanisms are often impaired.

Studies of the consequences of outlawing smoking in public places illustrate the strongest links between ETS and acute coronary morbidity and mortality. In one report, the city of Helena, Montana, banned cigarette smoking in workplaces and public places. This ban was overturned by court order 6 months later. During the interval when the ban was in effect, the number of acute cardiac events leading to hospital admission decreased by 40%. When the ban on smoking was removed, hospital admissions for acute cardiac events rebounded almost to levels seen before the ban was instituted. Many subsequent studies corroborated these basic findings, although the magnitude of the decrease in acute coronary events differs from one study to the next. Both prospective and retrospective analyses have documented that lowering public exposure to ETS reduces acute coronary events by an average of about 15%.

ALCOHOLISM

Chronic alcoholism has been defined as regular intake of sufficient alcohol to injure a person socially, psychologically or physically. It is addiction to ethanol that features dependence and withdrawal symptoms and results in acute and chronic toxic effects of alcohol on the body. There are about 15–18 million alcoholics in the United States, about 1/10 of the population at risk. The proportion is even higher in some other countries. Certain ethnic groups, such as Native Americans and Eskimos, have high rates of alcoholism, while others, such as Chinese and Jews, are less afflicted. Alcoholism is more common in men, but the number of female alcoholics has been increasing.

Although there are no firm rules, for most people, daily consumption of more than 45 g alcohol should probably be discouraged and 100 g or more a day may be dangerous (10 g alcohol = 1 oz, or 30 mL, of 86 proof [43%] spirits).

The short-term effects of alcohol on the brain are familiar to most people, but the mechanism of inebriation is not understood. Like other anesthetic agents, alcohol is a central nervous system (CNS) depressant. However, it is such a weak anesthetic that it must be drunk by the glassful to exert any significant effect. In a normal person, characteristic behavioral changes can be detected at low alcohol concentrations (below 50 mg/dL). Levels above 80 mg/dL are usually associated with slower reaction times and gross incoordination and in American jurisdictions are considered legal evidence of intoxication while driving a motor vehicle. At levels above 300 mg/dL, most people become comatose, and at concentrations above 400 mg/dL, death from respiratory failure is common. In humans, the LD_{50} (median lethal dose) is about 5 g of alcohol per kilogram of body weight.

The situation is somewhat different in chronic alcoholics, who develop CNS tolerance to alcohol. Such individuals may easily tolerate blood alcohol levels of 100–200 mg/dL; and in fatal automobile accidents, blood levels of 500–600 mg/dL or more have been found by medical examiners. The mechanism underlying tolerance has not been established.

Acute alcohol intoxication is hardly a benign condition. Some 40% of all fatalities from motor vehicle accidents involve alcohol—currently about 14,000 deaths annually in the United States. Alcoholism is also a major contributor to fatal home accidents, death in fires and suicide.

Many chronic diseases associated with alcoholism were once attributed to malnutrition, and some alcoholics do suffer from nutritional deficiencies, such as thiamine deficiency (Wernicke encephalopathy) or folic acid deficiency (megaloblastic anemia). ***However, most alcoholics have adequate diets and most alcohol-related disorders should be attributed to the toxic effects of alcohol alone.*** The diseases associated with alcoholism are discussed in detail in chapters dealing with individual organs, and we restrict this discussion to the spectrum of disease (Fig. 8-9).

Alcohol Ingestion Affects Organs and Tissues

Liver

Alcoholic liver disease, the most common medical complication of alcoholism, has been known for thousands of years and accounts for a large proportion of cases of cirrhosis of the liver (Fig. 8-10) in industrialized countries. The nature of the alcoholic beverage is largely irrelevant; consumed in excess, beer, wine, whiskey, hard cider and so on all produce cirrhosis. Only the total dose of alcohol itself is relevant.

Pancreas

Both acute and chronic pancreatitis are complications of alcoholism, but they may be consequences of other disease processes as well (see Chapter 23). **Chronic calcifying pancreatitis,** on the other hand, is an unquestioned result of alcoholism and an important cause of incapacitating pain, pancreatic insufficiency and pancreatic stones.

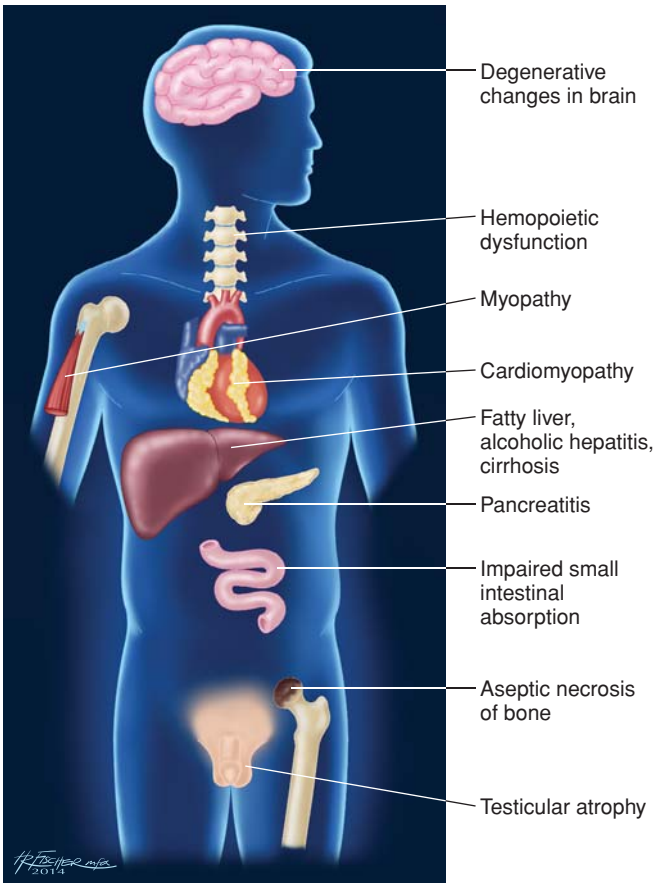

FIGURE 8-9. Complications of chronic alcohol abuse.

Heart

Alcohol-related heart disease was recognized over a century ago in Germany, where it was referred to as "beer-drinker's heart." This degenerative disease of the myocardium is a form of dilated cardiomyopathy, called **alcoholic cardiomyopathy,** and leads to low-output congestive heart failure (see Chapter 17). This cardiomyopathy clearly differs from the heart disease associated with thiamine deficiency (beriberi), a disorder characterized by high-output failure. Alcoholics' hearts seem also to be more susceptible to arrhythmias. Many cases of sudden death in alcoholics are probably caused by sudden, fatal arrhythmias.

In this context, moderate alcohol consumption, or "social drinking" (one to two drinks a day), provides significant protection against coronary artery disease (atherosclerosis) and its consequence, myocardial infarction. Similarly, compared with abstainers, social drinkers have a lower incidence of ischemic stroke.

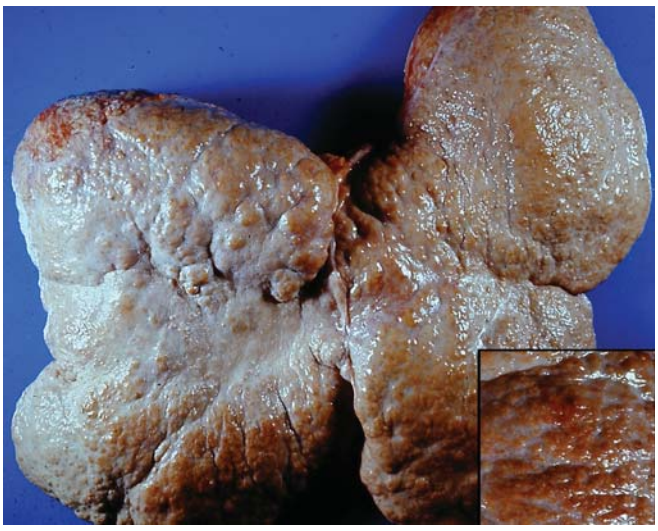

FIGURE 8-10. Cirrhosis of the liver in a chronic alcoholic. The surface displays innumerable small nodules of hepatocytes separated by interconnecting bands of fibrous tissue. These are highlighted in the higher magnification in the inset (lower right).

Skeletal Muscle

Muscle weakness, particularly of the proximal muscles, is common in alcoholics (see Chapter 31). A wide range of changes in skeletal muscle occurs in chronic alcoholics, varying from mild alterations in muscle fibers evident only by electron microscopy to severe, debilitating chronic myopathy, with degeneration of muscle fibers and diffuse fibrosis. Rarely, **acute alcoholic rhabdomyolysis**—necrosis of muscle fibers and release of myoglobin into the circulation—occurs. This sudden event can be fatal because of renal failure secondary to myoglobinuria.

Endocrine System

In male alcoholics, feminization and loss of libido and potency are common. Breasts become enlarged (gynecomastia), body hair is lost and a female distribution of pubic hair (female escutcheon) develops. Some of these changes can be attributed to impaired estrogen metabolism due to chronic liver disease, but many of the changes—particularly atrophy of the testes—occur even if there is no liver disease. Chronic alcoholism leads to lower levels of circulating testosterone because of a complex interference with the pituitary–gonadal axis, possibly complicated by accelerated hepatic metabolism of testosterone. Alcohol has a direct toxic effect on the testes; thus, male sexual impairment is one of the prices exacted by alcoholism.

Gastrointestinal Tract

Since the esophagus and stomach may be exposed to 10 M ethanol, it is not surprising that a direct toxic effect on the mucosa of these organs is common. Injury to the mucosa of both organs is potentiated by hypersecretion of gastric hydrochloric acid stimulated by ethanol. **Reflux esophagitis** may be particularly painful and peptic ulcers are also more common in alcoholics. Violent retching may lead to tears at the esophageal–gastric junction **(Mallory-Weiss syndrome),** sometimes severe enough to cause exsanguinating hemorrhage (see Chapter 19). Small intestine mucosal cells are also exposed to circulating alcohol, and a variety of absorptive abnormalities and ultrastructural changes have been demonstrated. Alcohol inhibits active transport of amino acids, thiamine and vitamin B_{12}.

Blood

Megaloblastic anemia is not uncommon in alcoholics and reflects a combination of dietary deficiency of folic acid

and the fact that alcohol is a weak folic acid antagonist in humans. Moreover, folate absorption by the small intestine may be decreased in alcoholics. In addition, chronic ethanol intoxication leads directly to an **increase in mean corpuscular volume of erythrocytes**. In the presence of alcoholic cirrhosis, the spleen is often enlarged by portal hypertension; in such cases, **hypersplenism** often causes **hemolytic anemia**. Transient **thrombocytopenia** is common after acute alcohol intoxication and may result in bleeding. Alcohol also interferes with platelet aggregation, thus contributing to bleeding.

Bone

Chronic alcoholics, particularly postmenopausal women, are at increased risk for **osteoporosis**. Although it is well established that alcohol, at least in vitro, inhibits osteoblast function, the precise mechanism responsible for accelerated bone loss is not understood. Interestingly, moderate alcohol intake seems to exert a protective effect against osteoporosis. Male alcoholics exhibit an unusually high incidence of **aseptic necrosis of the head of the femur**. The mechanism for this complication is also obscure.

Immune System

Alcoholics seem to be prone to many infections (particularly pneumonias) with organisms that are unusual in the general population, such as *Haemophilus influenzae.* Experimentally, a number of alcohol-induced effects on immune function have been reported.

Nervous System

General cortical atrophy of the brain is common in alcoholics and may reflect a toxic effect of alcohol (see Chapter 32). By contrast, most of the characteristic brain diseases in alcoholics are probably a result of nutritional deficiency.

- **Wernicke encephalopathy** is caused by thiamine deficiency and is characterized by mental confusion, ataxia, abnormal ocular motility and polyneuropathy, reflecting pathologic changes in the diencephalon and brainstem.
- **Korsakoff psychosis** is characterized by retrograde amnesia and confabulatory symptoms. It was once believed to be pathognomonic of chronic alcoholism but has also been seen in several organic mental syndromes and is considered nonspecific.
- **Alcoholic cerebellar degeneration** differs from other acquired or familial cerebellar degeneration by the uniformity of its manifestations. Progressive unsteadiness of gait, ataxia, incoordination and reduced deep tendon reflex activity are present.
- **Central pontine myelinolysis** is another characteristic change in the brain of alcoholics, apparently caused by electrolyte imbalance—usually after electrolyte therapy, after an alcoholic binge or during withdrawal. In this complication, a progressive weakness of bulbar muscles terminates in respiratory paralysis.
- **Amblyopia** (impaired vision) occurs occasionally in alcoholics. It may reflect alcohol-related decreases in tissue vitamin A, although other vitamin deficiencies may also be involved.
- **Polyneuropathy** is common in chronic alcoholics. It is usually associated with deficiencies of thiamine and other B vitamins, but a direct neurotoxic effect of ethanol may play a role. The most common complaints include numbness, paresthesias, pain, weakness and ataxia.

Fetal Alcohol Syndrome Results from Alcohol Abuse in Pregnancy

Infants born to mothers who consume excess alcohol during pregnancy may show a cluster of abnormalities that together constitute the fetal alcohol syndrome. These include growth retardation, microcephaly, facial dysmorphology, neurologic dysfunction and other congenital anomalies. About 6% of the offspring of alcoholic mothers are afflicted by the full syndrome. More often, exposure of the fetus to high concentrations of ethanol leads to less severe abnormalities, prominent among which are mental retardation, intrauterine growth retardation and minor dysmorphic features. Alcohol acts as an antagonist of *N*-methyl-D-aspartic acid (NMDA) and γ-aminobutyric acid (GABA)-mimetic neurotransmitters and can trigger neuron apoptosis. Fetal alcohol syndrome is discussed in greater detail in Chapter 6.

Alcohol Increases the Risk of Some Cancers

Cancers of the oral cavity, larynx and esophagus occur more often in alcoholics than in the general population. As most alcoholics are also smokers, the differential contributions of ethanol and cigarette smoke to these observed increases are not well defined. The risk of hepatocellular carcinoma is increased in patients with alcoholic cirrhosis. A number of reports have described increased incidence of breast cancer in alcoholic women, a subject that requires further study.

The Mechanisms by Which Alcohol Injures Tissues Are Not Understood

The pathogenesis of ethanol-induced organ damage remains obscure. In a number of experimental settings, ethanol and its metabolites have been shown to have harmful effects on cells. Among these are changes in redox potential (NAD/NADH ratio). In addition, ethanol may lead to formation of unusual compounds such as the first metabolite of ethanol oxidation, acetaldehyde, protein adducts, fatty acid ethyl esters and phosphatidyl ethanol. It also increases production of reactive oxygen species (ROS; see Chapter 1) and tends to intercalate between phospholipids within biological membranes and so disorders them. Moreover, ethanol has pleiotropic effects on cellular signaling and may promote apoptosis under some circumstances. The relationship of this effect to cell injury requires further study.

DRUG ABUSE

Drug abuse has been defined as "the use of any substance in a manner that deviates from the accepted medical, social or legal patterns within a given society." For the most part, drug abuse involves agents that are used to alter mood and perception. These include (1) derivatives of opium (heroin, morphine); (2) depressants (barbiturates, tranquilizers, alcohol); (3) stimulants (cocaine, amphetamines), marijuana and psychedelic drugs (PCP, lysergic acid diethylamide [LSD]); and (4) inhalants (amyl nitrite, organic solvents such as those in glue). Use of illicit drugs is estimated to cause about 17,000 deaths a year in the United States.

Illicit Drugs Are Responsible for Many Pathologic Syndromes

Heroin

Heroin is a common illicit opiate used to induce euphoria. It is often taken intravenously and in the usual dosage is effective for about 5 hours. Overdoses are characterized by hypothermia, bradycardia and respiratory depression. Other opiates that are subject to abuse include morphine and Dilaudid, but these have been largely replaced by oxycodone and fentanyl. Oxycodone, usually combined with acetaminophen, is an opiate alkaloid with both stimulant and analgesic properties. The strongest effect is achieved by intravenous administration. Fentanyl is an opiate similar to morphine but is up to 100 times more potent. Its illicit use involves injection or oral intake, and it is associated with a high risk of addiction.

Cocaine

Cocaine is an alkaloid derived from South American coca leaves. The freebase form of cocaine is hard and is far more potent than coca leaves. It may be taken by sniffing, smoking, intravenous injection or orally. An even more potent form of cocaine ("crack") is generally smoked. It is hard and is then "cracked" into smaller pieces that are smoked. The half-life of cocaine in the blood is about 1 hour.

Cocaine users report extreme euphoria and heightened sensitivity to a variety of stimuli. However, with addiction, paranoid states and conspicuous emotional lability occur. The mechanism of action of cocaine is related to its interference with the reuptake of the neurotransmitter dopamine.

Cocaine overdose leads to anxiety and delirium and occasionally to seizures. Cardiac arrhythmias and other effects on the heart may cause sudden death in otherwise apparently healthy people. Chronic abuse of cocaine is associated with the occasional development of a characteristic dilated cardiomyopathy, which may be fatal.

Amphetamines

Amphetamines, mainly methamphetamine, are sympathomimetic and resemble cocaine in their effects, although they have a longer duration of action. Methamphetamines are most commonly used as "crystal meth," which is easily produced by hydrogenation of ephedrine or pseudoephedrine. Methamphetamine is often made in home laboratories and is a major public health problem in the United States. The most serious complications of the abuse of amphetamines are seizures, cardiac arrhythmias and hyperthermia. Amphetamine use has been reported to lead to vasculitis of the CNS, and both subarachnoid and intracerebral hemorrhages have been described.

Hallucinogens

Hallucinogens are a group of chemically unrelated drugs that alter perception and sensory experience.

Phencyclidine (PCP) is an anesthetic agent that has psychedelic or hallucinogenic effects. As a recreational drug, it is known as "angel dust" and is taken orally, intranasally or by smoking. The anesthetic properties of phencyclidine effect diminished capacity to perceive pain and, therefore, may lead to self-injury and trauma. Other than the behavioral effects, PCP commonly produces tachycardia and hypertension. High doses result in deep coma, seizures and even decerebrate posturing.

LSD is a hallucinogenic drug whose popularity peaked in the late 1960s and is little used today. It causes perceptual distortion of the senses, interference with logical thought, alteration of time perception and a sense of depersonalization. "Bad trips" are characterized by anxiety and panic and objectively by sympathomimetic effects that include tachycardia, hypertension and hyperthermia. Large overdoses cause coma, convulsions and respiratory arrest.

Organic Solvents

The recreational inhalation of organic solvents is widespread, particularly among adolescents. Various commercial preparations such as fingernail polish, glues, plastic cements and lighter fluid are all sniffed. Among the active ingredients are benzene, carbon tetrachloride, acetone, xylene and toluene. However, many of these compounds are also industrial solvents and reagents and so chronic low-level occupational exposure occurs. These compounds are all CNS depressants, although early effects (e.g., with xylene) may be excitatory. Acute intoxication with organic solvents resembles inebriation with alcohol. Large doses produce nausea and vomiting, hallucinations and eventually coma. Respiratory depression and death may follow. Chronic exposure to, or abuse of, organic solvents may result in damage to the brain, kidneys, liver, lungs and hematopoietic system. Benzene, for example, is a bone marrow toxin and has been associated with the development of acute myelogenous leukemia.

Intravenous Drug Abuse Has Many Medical Complications

Apart from reactions related to pharmacologic or physiologic effects of substance abuse, the most common complications (15% of directly drug-related deaths) are caused by introducing infectious organisms by a parenteral route. Most occur at the site of injection: cutaneous abscesses, cellulitis and ulcers (Fig. 8-11). When these heal, "track marks" persist and these areas may be hypopigmented or hyperpigmented.

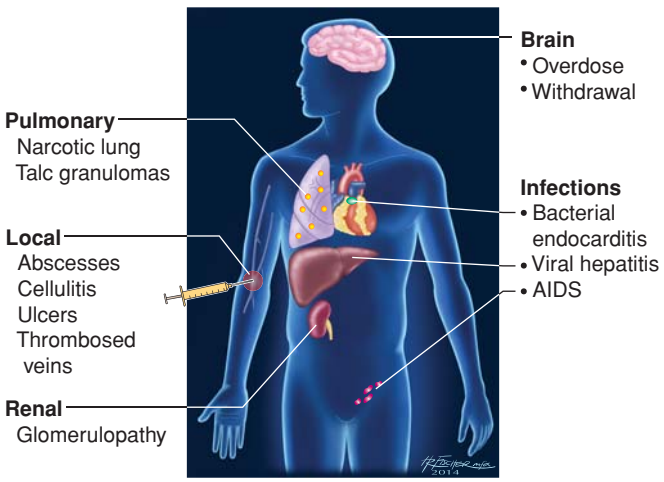

FIGURE 8-11. Complications of intravenous drug abuse.

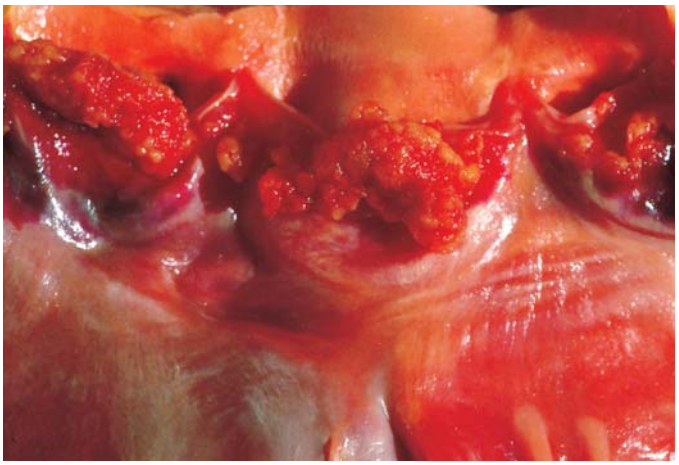

FIGURE 8-12. Bacterial endocarditis. The aortic valve of an intravenous drug abuser displays adherent vegetations.

Thrombophlebitis of the veins draining sites of injection is common. Intravenous introduction of bacteria may lead to septic complications in internal organs. Bacterial endocarditis, often involving *Staphylococcus aureus*, occurs on both sides of the heart (Fig. 8-12) and may cause pulmonary, renal and intracranial abscesses; meningitis; osteomyelitis; and mycotic aneurysms (Fig. 8-13).

Intravenous drug abusers are at very high risk for AIDS, as well as hepatitis B and C. These people may also suffer from the complications of viral hepatitis, such as chronic active hepatitis, necrotizing angiitis and glomerulonephritis. A focal glomerulosclerosis ("heroin nephropathy") is characterized by immune complexes and has been ascribed to an immune reaction to impurities that contaminate illicit drugs.

Intravenous injection of talc, which is used to dilute pure drug, is associated with the appearance of foreign body granulomas in the lung (Fig. 8-14). These may be severe enough to lead to interstitial pulmonary fibrosis.

FIGURE 8-13. Brain abscess. Cross-section of the brain from an intravenous drug abuser shows two encapsulated cavities.

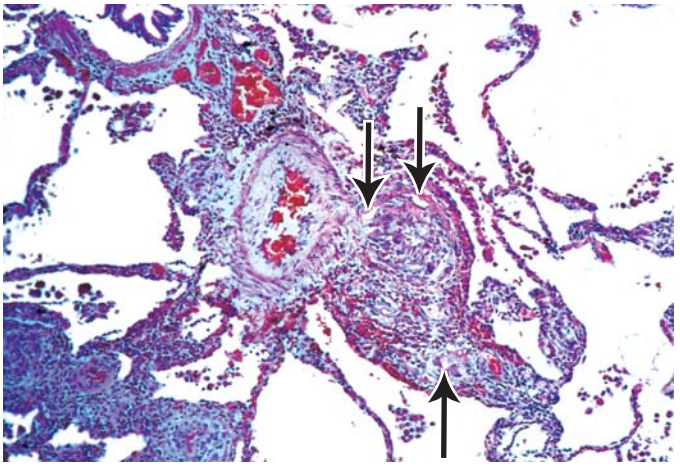

FIGURE 8-14. Talc granulomas in the lung. A section of lung from an intravenous drug abuser viewed under polarized light reveals a granuloma adjacent to a pulmonary artery. The refractile material (*arrows*) is talc that was used to dilute the drug prior to its intravenous injection.

Drug Addiction in Pregnant Women Poses Risks for the Fetus

Maternal drug use may cause addiction of newborn infants, who often exhibit a full-blown withdrawal syndrome. Moreover, the appearance of the drug withdrawal syndrome in the fetus during labor may result in excessive fetal movements and increased oxygen demand, a situation that increases the risk of intrapartum hypoxia and meconium aspiration. If labor occurs when maternal drug levels are high, the infant is often born with respiratory depression. Mothers who are addicted to drugs experience higher rates of toxemia of pregnancy and premature labor.

Maternal use of illicit drugs during pregnancy may injure the developing fetus in other ways. Thus, pregnant women who use cocaine more commonly experience placental abruption and premature labor. Infants born to such mothers are prone to be low birth weight, to have one of an array of CNS and other anomalies and to show impaired brain function after birth. Maternal addiction to heroin carries a number of risks of abnormalities of pregnancy and premature birth. It is also associated with a large number of postnatal problems (in addition to heroin withdrawal), including SIDS, neonatal respiratory distress syndrome and developmental retardation. Maternal abuse of other substances (e.g., amphetamines and hallucinogens) also leads to variably severe fetal and postnatal disorders.

IATROGENIC DRUG INJURY

Iatrogenic drug injury refers to the unintended side effects of therapeutic or diagnostic drugs prescribed by physicians. Adverse reactions to pharmaceuticals are surprisingly common. They are seen in 2%–5% of patients hospitalized on medical services; of these reactions, 2%–12% are fatal. The typical hospitalized patient is given about 10 different medications and some receive five times as many. The risk of an adverse reaction increases proportionately with the number of different drugs; for example, the risk of injury is at least 40% when more than 15 drugs are administered.

FIGURE 8-15. Erythema multiforme secondary to sulfonamide therapy.

Because they are so ubiquitously prescribed, drugs represent a significant environmental hazard. Untoward effects of drugs result from (1) overdose, (2) exaggerated physiologic responses, (3) a genetic predisposition, (4) hypersensitivity, (5) interactions with other drugs and (6) other unknown factors. The characteristic pathologic changes associated with drug reactions are treated in chapters dealing with specific organs. An example of a drug reaction is illustrated in Fig. 8-15.

SEX HORMONES

Oral Contraceptives Carry a Small Risk of Complications

Orally administered hormonal contraceptives (OCs) are now the most commonly used method of birth control in industrialized countries. Current formulations are combinations of synthetic estrogens and steroids with progesterone-like activity. They act either by inhibiting the gonadotropin surge at midcycle, thus preventing ovulation, or by preventing implantation by altering the phase of the endometrium. Most complications of oral contraceptives involve either the vasculature or reproductive organs (Fig. 8-16).

Vascular Complications

Deep vein thrombosis is a recognized complication of oral contraceptive use, the risk being increased two to three times. As a consequence, the risk of thromboembolism is correspondingly increased. Obesity and smoking magnify the risk of venous thrombosis attendant to OCs, as do coexisting disorders that increase clotting (thrombophilia).

The risk of arterial thrombotic events in women taking oral contraceptives is also increased. Thus, both myocardial infarction and thrombotic stroke are reported to be increased in some studies.

Neoplastic Complications

Tumors of several of the female reproductive organs, especially ovary, endometrium and breast, are strongly influenced by female hormones. Repeated epidemiologic studies indicate that OC use decreases risk of ovarian and endometrial cancers by about half, presumably because of suppression of the production of pituitary gonadotropins.

There is a small increase in the frequency of breast cancers in OC users. This applies mainly to nonfamilial breast cancers and to women currently taking OCs. The increased risk appears to endure for about 10 years following cessation of OC administration.

Squamous carcinoma of the cervix in women positive for human papilloma virus (HPV) may be somewhat increased in association with long-term (>5 years) OC use.

Benign liver adenomas are rare hepatic neoplasms that are significantly increased in incidence among women who use OCs. The risk of these tumors increases conspicuously with the duration of use, particularly after 5 years.

Several small studies have suggested a small increased risk of **hepatocellular carcinoma** among women using OCs. Fortunately, this cancer is rare in young women without chronic viral hepatitis.

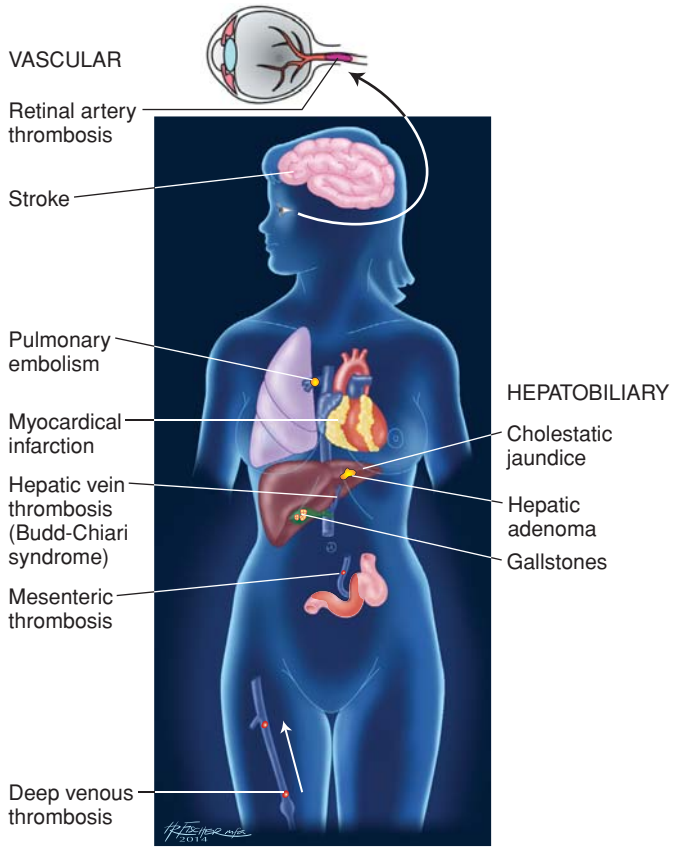

FIGURE 8-16. Complications of oral contraceptives.

Other Complications

For reasons unknown, oral contraceptives may induce an increased pigmentation of the malar eminences, called **chloasma,** which is accentuated by sunlight and persists for a long time after the contraceptives are discontinued.

Cholelithiasis is more frequent (twofold increase) in women who have used OCs for 4 years or less, but its incidence becomes lower than normal after that period of time. Thus, OCs accelerate gallstone formation but do not increase its overall incidence.

Benefits of Oral Contraceptives

In considering the potential side effects of the use of oral contraceptive agents, it is important to recognize that certain benefits accrue. In addition to a significant reduction in the risk of ovarian and endometrial cancers, the use of these agents decreases the risk of pelvic inflammatory disease, uterine leiomyomas, endometriosis and fibrocystic disease of the breast.

The Risks of Postmenopausal Hormone Replacement Therapy Depend on the Formulation, Age at Which Treatment Begins and Duration of Treatment

Hormone replacement (HR) preparations come in many varieties, the most common being oral estrogen only and oral combined estrogen plus progestogen combinations. These are given to women for diverse reasons, including to alleviate distressing symptoms of menopause, protect from osteoporosis and, more recently, protect from cardiovascular, cerebrovascular and CNS diseases that occur in older women. There is evidence of the effectiveness of these preparations in decreasing the incidence of bone fractures and mitigating many of the problems relating to hormone deficits.

However, there are significant risks associated with hormonal replacement following menopause. Estrogen-only and estrogen–progestogen combinations are associated with a slightly increased risk of venous thromboembolism. This increased risk is most common in the first year of HR and declines thereafter, even with continued HR. With the cessation of treatment, the risk of deep vein thrombosis and embolism declines to that in women who never received hormone replacement.

Because many tumors are hormonally sensitive, it has seemed logical that HR would increase the risk of developing tumors, particularly of the breast, endometrium and ovaries. Current data support the conclusion that there is a significantly increased risk of breast cancer in women receiving combined estrogen–progestogen formulations, while there is a slightly increased risk, or none at all, in those receiving estrogens alone. The converse appears to be true for endometrial and ovarian cancers.

There appears to be little overall benefit of either type of preparation in protecting from cardiovascular or cerebrovascular deaths. Women who begin HR more than 6 years after menopause have been reported to have a somewhat higher risk of developing Alzheimer disease, although those who initiate HR during that period appear not to be at risk.

Other Forms of Hormone Replacement

There are scant data regarding the risks of other forms of hormone replacement therapy. Androgen production in men declines with age, resulting in loss of muscle mass, increased adiposity and other problems. However, testosterone replacement therapy for age-related decline in muscular strength, sexual performance and other parameters remains controversial. Although prostate cancer in men is often hormonally sensitive, there are few studies reporting the incidence of prostate or other cancers in men receiving androgen replacement treatments.

Growth hormone (GH) replacement is used in people who lack adequate GH. Although many tumors require GH for their growth, there is no evidence that people who receive GH replacement treatment are more susceptible to developing tumors than other people of their age. GH is being suggested as providing a possible benefit in older people with age-related decreases in skeletal muscle mass. To date, there is little evidence of adverse consequences, although the question of GH-induced insulin resistance remains.

ENVIRONMENTAL CHEMICALS

Awareness of potential hazards posed by harmful chemicals in the environment is not new. In the 12th century Maimonides wrote:

> Comparing the air of cities to the air of deserts is like comparing waters that are befouled and turbid to waters that are fine and pure. In the city, because of the height of its buildings, the narrowness of its streets and all that pours forth from its inhabitants, the air becomes stagnant, turbid, thick, misty and foggy.…Wherever the air is altered…men develop dullness of understanding, failure of intelligence and defects of memory.

Humans are surrounded by, breathe in and consume many chemicals that are added to, or appear as contaminants in, foods, water and air. Several important mechanisms govern the effect of toxic agents, including the toxin's absorption, distribution, metabolism and excretion. Absorption (whether via pulmonary, gastrointestinal or cutaneous routes) depends largely on the chemical in question. Thus, the insecticides chlordane and heptachlor are lipid soluble and so rapidly absorbed and stored in body fat. In contrast, the water-soluble herbicide paraquat is readily eliminated.

The storage, distribution and excretion of chemicals control their concentrations in the organism at any given time. Agents stored in adipose tissue may exert prolonged low-level effects, while more water-soluble materials that are easily excreted by the kidney usually have a shorter duration of action.

Among the most important chemical hazards to which humans are exposed are environmental dusts and carcinogens. Inhalation of mineral and organic dusts occurs primarily in occupational settings (e.g., mining, industrial manufacturing, farming) and occasionally as a result of unusual situations (e.g., bird fanciers, pituitary snuff inhalation). Inhaling mineral dusts leads to pulmonary diseases known as **pneumoconioses,** while organic dusts may produce **hypersensitivity pneumonitis**. Pneumoconioses were formerly common, but control of dust exposure

TABLE 8-3
INCREASED MORBIDITY AND MORTALITY AS A FUNCTION OF PARTICULATE AIR POLLUTION (RESULTS OF REPRESENTATIVE STUDIES)

Type of Exposure	Health Consequence	Relative Increase in Incidence of Death and Disease (%)
Acute	Cardiovascular death	0.68[a]
	Ischemic cardiac disease	0.7[a]
	Heart failure	0.8[a]
	Acute attacks of asthma (children)	1.2[a]
	Acute attacks of asthma (adults)	1.1[a]
	Total lung (including asthma and COPD)	0.9[a]
	Acute myocardial infarction	4.5[b]
	Acute myocardial infarction	48[c]
Chronic	Cardiovascular death	12–76[d]
	Atherosclerosis	4[d]
	Venous thromboembolism	70[e]

[a]Per every 10 $\mu g/m^3$ increase in PM_{10}, 1 day before the event.
[b]Per every 10 $\mu g/m^3$ increase in $PM_{2.5}$ acutely.
[c]Per every 25 $\mu g/m^3$ increase in $PM_{2.5}$ acutely.
[d]Per every 10 $\mu g/m^3$ increase in $PM_{2.5}$.
[e]Per every 10 $\mu g/m^3$ increase in PM_{10}.

in the workplace through modifications of manufacturing techniques, improvements in air handling and use of masks has substantially reduced the incidence of these diseases. Because of their importance, pneumoconioses and hypersensitivity pneumonitis are discussed in detail in Chapter 18.

Chemical carcinogens are ubiquitous in the environment. Their potential for causing disease has elicited widespread concern. In particular, exposure to carcinogens in the workplace has been associated epidemiologically with a number of cancers (Table 8-3), which are reviewed in Chapter 5.

Toxic Effects Differ from Hypersensitivity Responses

Many substances predictably elicit disease in a variety of animal species in a dose-dependent manner, with a regular time delay and a reproducible pattern of target organ responses. Furthermore, the morphologic changes in injured tissues are constant and reproducible. By contrast, the actions of other agents are unpredictable, showing (1) great variability in their ability to produce disease, (2) irregular lag times before injury is apparent, (3) no dose dependency and (4) lack of reproducibility. Generally, **predictable dose-response reactions** reflect direct actions of a compound or its metabolite on a tissue—a "toxic" effect. The second, **unpredictable type of reaction** is believed to reflect "hypersensitivity," whether involving an immunologic response or other type of idiosyncratic side effect.

Chemical Toxicity May Follow Occupational Exposure

Beginning with the industrial revolution, there has been an exponential rise in the number of chemicals manufactured and a corresponding increase in the risk of human exposure. In any consideration of this topic, one must differentiate between acute poisoning and chronic toxicity. One must also distinguish industrial and accidental exposure from that which is likely to occur in the general environment. The lack of adequate quantitative exposure data in humans and the difficulties involved in assessing long-term risks of low-level exposures have led to use of data derived from animal studies to assess toxicities and risks in humans. Such projections can be hazardous because of (1) species differences in sensitivity, (2) differing routes of administration, (3) species-to-species variations in metabolic pathways by which some compounds are modified and (4) extrapolation from very high levels needed to show an effect in a short experimental time frame in animals to low-level exposures over years in humans. These considerations necessarily complicate the need to understand and quantify the potential for human toxicity of a plethora of chemicals.

Except for certain hypersensitivity reactions in susceptible people, acute poisoning by environmental chemicals does not pose a significant threat to the general population. Concentrations necessary to cause acute functional disorders or structural damage occur mainly in the workplace or because of uncommon accidents.

Accidental mass poisonings with the pesticides endrin and parathion have led to as many as 100 deaths in a single event, but long-term sequelae among the survivors have been difficult to document. The experimental literature dealing with the short- and long-term toxicity of industrial chemicals is voluminous and complicated and often contradictory. For this reason we largely restrict the following discussion to documented effects in humans.

Volatile Organic Solvents and Vapors

Volatile organic solvents and vapors are widely used in industry in many capacities. With few exceptions, exposures to these compounds are industrial or accidental and represent short-term dangers rather than long-term toxicity. For the most part, exposure to solvents is by inhalation rather than by ingestion.

- **Chloroform ($CHCl_3$) and carbon tetrachloride (CCl_4):** These solvents are CNS depressants (anesthetics) and impair the heart and blood vessels, but are better known as hepatotoxins. With both, but classically with carbon tetrachloride, large doses lead to acute hepatic necrosis, fatty liver and liver failure. Long-term exposure to carbon tetrachloride does not pertain to humans, as each exposure to it causes recognizable clinical liver injury, so that continued exposure would not be permitted.
- **Trichloroethylene (C_2HCl_3):** A ubiquitous industrial solvent, trichloroethylene in high concentrations depresses the CNS, but hepatotoxicity is minimal. There is no evidence for disease in humans, even after ordinary long-term industrial exposure.

- **Methanol (CH_3OH):** Because methanol, unlike ethanol, is not taxed, it is used by some impoverished alcoholics as a substitute for ethanol or by unscrupulous merchants as an adulterant of alcoholic beverages, especially in impoverished areas. In methanol poisoning, inebriation similar to that produced by ethanol is succeeded by gastrointestinal symptoms, visual dysfunction, seizures, coma and death. The major toxicity of methanol is believed to arise from its metabolism, first to formaldehyde and then to formic acid. Metabolic acidosis is common after methanol ingestion. The most characteristic lesion of methanol toxicity is necrosis of retinal ganglion cells and subsequent degeneration of the optic nerve, leading to blindness. Severe poisoning may lead to lesions in the putamen and globus pallidus.
- **Ethylene glycol ($HOCH_2CH_2OH$):** Because of its low vapor pressure, toxicity of ethylene glycol chiefly results from ingestion. It is commonly used in antifreeze and has been drunk by chronic alcoholics as a substitute for ethanol for many years. Poisoning with this compound came into prominence when it was used to adulterate wines, owing to its sweet taste and solubility. The toxicity of ethylene glycol is chiefly due to its metabolites, particularly oxalic acid, and occurs within minutes of ingestion. Metabolic acidosis, CNS depression, nausea and vomiting and hypocalcemia-related cardiotoxicity are seen. Oxalate crystals in renal tubules and oxaluria are often noted and may cause renal failure.
- **Gasoline and kerosene:** These fuels are mixtures of aliphatic hydrocarbons and branched, unsaturated and aromatic hydrocarbons. Chronic exposure is by inhalation. Despite prolonged exposure to gasoline by gas station attendants, auto mechanics and so forth, there is no evidence that inhalation of gasoline over the long term is particularly injurious. Acutely, gasoline is an irritant, but really only causes systemic problems if inhaled in very high concentrations. Increased use of kerosene for home heating has led to accidental poisoning of children.
- **Benzene (C_6H_6):** The prototypic aromatic hydrocarbon is benzene, which must be distinguished from benzine, a mixture of aliphatic hydrocarbons. Benzene is one of the most widely used chemicals in industrial processes, being a starting point for innumerable syntheses and a solvent. It is also a constituent of fuels, accounting for as much as 3% of gasoline. Virtually all cases of acute and chronic benzene toxicity have occurred as industrial exposures (e.g., in shoemakers and workers in shoe manufacturing, occupations that at one time were associated with heavy exposure to benzene-based glues).

  Acute benzene poisoning primarily affects the CNS and death results from respiratory failure. However, it is the long-term effects of benzene exposure that have attracted the most attention. In these cases, the bone marrow is the principal target. Patients who develop hematologic abnormalities characteristically exhibit **hypoplasia** or **aplasia of the bone marrow** and **pancytopenia. Aplastic anemia** usually is seen while the workers are still exposed to high concentrations of benzene. In a substantial proportion of cases of benzene-induced anemias, **myelodysplastic syndromes, acute myeloblastic leukemia, erythroleukemia** or **multiple myeloma** develops during continuing exposure to benzene or after a variable latent period following removal of the worker from the hazardous environment. Some cases of acute leukemia have occurred without a prior history of aplastic anemia. Although instances of chronic myeloid and chronic lymphocytic leukemia have been reported, a cause-and-effect relationship with benzene exposure is less convincing than that with cases of acute leukemia. Overall, the risk of leukemia is increased 60-fold in workers exposed to the highest atmospheric concentrations of benzene. It deserves mention that both gasoline and tobacco smoke contain benzene, and both contribute to increased benzene levels in the urban atmosphere. The consequent contribution of such benzene concentrations to hematologic diseases is speculative.

  The toxic effects of benzene are related to its metabolites, which are the consequence of cytochrome P450 degradation of the parent compound. The closely related compounds toluene and xylenes, also widely used as solvents, have not been incriminated as a cause of hematologic abnormalities, possibly because they are metabolized via different pathways.

Agricultural Chemicals

Pesticides, fungicides, herbicides, fumigants and organic fertilizers are crucial to the productivity of modern agriculture. However, many of these chemicals persist in soil and water and may pose a potential long-term hazard. Acute poisoning with very large concentrations of any of these chemicals has already been mentioned above. It is clear that exposure to industrial concentrations or inadvertently contaminated food can cause severe acute illness. Children are particularly susceptible and may ingest home gardening preparations.

Organochlorine pesticides, such as DDT (dichlorodiphenyltrichloroethane), chlordane and others, have caused concern because they accumulate in soils and in human tissues and break down very slowly. High levels of any such pesticide can be harmful to humans in acute exposures, but the side effects of chronic contact with the materials and their buildup are of greatest interest. Many of these compounds function as weak estrogens, but no harmful effects related to this activity have been documented. Some of these compounds, such as aldrin and dieldrin, have been associated with tumor development, but the acute toxicity of most organochlorine insecticides relates to inhibition of CNS GABA responses.

Symptoms of acute toxicity are often related to the mode of action of the toxin. For example, organophosphate insecticides, which have largely replaced organochlorine compounds, are acetylcholinesterase inhibitors that are readily absorbed through the skin. Thus, acute toxicity in humans mainly involves neuromuscular disorders such as visual disturbances, dyspnea, mucous hypersecretion and bronchoconstriction. Death may come from respiratory failure. In the United States, 30–40 people die annually of acute pesticide poisoning. Long-term exposure to substantial concentrations produces symptoms similar to those of acute exposure.

Human exposure to herbicides is not infrequent. Among the best known of these is paraquat. Occupational paraquat exposure is usually via the skin, although toxicity from ingestion and inhalation are documented. The compound is very corrosive and causes burns or ulcers of whatever it contacts. It is transported actively to the lung, where it can damage the pulmonary epithelium, causing edema and even respiratory failure. High-level exposures may lead to death from cardiovascular collapse, while when lower doses are involved, pulmonary fibrosis may ultimately lead to death.

Aromatic Halogenated Hydrocarbons

The halogenated aromatic hydrocarbons that have received considerable attention include (1) the polychlorinated biphenyls (PCBs); (2) chlorophenols (pentachlorophenol, used as a wood preservative); (3) hexachlorophene, previously used as an antibacterial agent in soaps; and (4) the dioxin TCDD (2,3,7,8-tetrachlorodibenzo-p-dioxin), a byproduct of the synthesis of herbicides and hexachlorophene and, therefore, a contaminant of these preparations that has not been produced intentionally. In 1976, an industrial accident in Seveso, Italy, exposed many people to extremely high concentrations of TCDD. As of 2009, small increases in incidences of breast and lymphoid/hematologic cancers are reported, but these results remain inconclusive. Chronic exposure to PCBs and TCDD does not appear to produce demonstrable toxicity. Serious questions have been raised regarding the danger of long-term exposure to dioxin, and there is now a consensus that at the very least this compound is far more carcinogenic in rodents than in humans. The problem of the presence of PCBs in the environment resembles that of agricultural chemicals: long-term animal toxicity is well documented, but there are no significant increases in the incidence of cancer or other diseases in workers exposed to PCBs. The same situation pertains to hexachlorophene and pentachlorophenol.

Cyanide

Prussic acid (HCN) is the classic murderer's tool in detective fiction, where the smell of bitter almonds (*Prunus amygdalus*) betrays the crime. Cyanide blocks cellular respiration by reversibly binding to mitochondrial cytochrome oxidase, the terminal acceptor in the electron transport chain, which is responsible for reducing molecular oxygen to water. The pathologic consequences are similar to those produced by any acute global anoxia.

Air Pollution Is a Major Cause of Death

The WHO has determined that air pollution is responsible for 8 million lives lost worldwide annually.[2] The most important air pollutants are those generated by combustion of fossil fuels, industrial and agricultural processes and so forth. The principal contributors to human disease among these are particulates, especially carbon particles. In addition, noxious and irritant gasses **sulfur dioxide** (SO_2), **oxides of nitrogen,** CO and **ozone** are important constituents of polluted air.

Carbon Particulates

Considerable evidence implicates carbon **particulates** in urban air and certain industrial settings as responsible for substantial human morbidity and mortality. Although the composition and sources of particulate matter vary widely, exhaust from diesel fuel combustion is the single largest source of carbon particles in urban air.

[2]Estimated 4.3 million deaths from household air pollution and 3.7 million deaths from ambient air pollution for 2012. These deaths include acute lower respiratory disease, chronic obstructive lung disease, ischemic heart disease, stroke and lung cancer, according to WHO, March 24, 2014.

Particulates vary in size, composition and origin. They generally fall into three categories, according to their aerodynamic diameter (AD): those between 2.5 μm and 10 μm (PM_{10}) are considered coarse particulates; those under 2.5 μm in AD are fine, designated $PM_{2.5}$; and the smallest are $PM_{0.1}$, which are less than 0.1 μm (or 100 nm), ultrafine particles.

The ability of PM to cause disease (see below) is a function of the toxic and carcinogenic combustion products they carry. While polycyclic aromatics (PAHs) were once thought to be the most potent of these, it is now clear that nitrated compounds (nitroarenes) are even more pathogenic. When these chemicals, bound to carbon particles, are breathed in, their disposition is a function of where the particles localize. Carbon particles have different abilities to deliver these toxic chemicals and have different pathogenetic properties based on their size (Fig. 8-17). PM_{10}s mostly settle in the conducting airways of the tracheobronchial tree. Fine particles ($PM_{2.5}$) penetrate more deeply into the lungs because of their smaller size. These find their way to small terminal airways and alveoli. Ultrafine particles ($PM_{0.1}$, <100 nm) penetrate very deeply. They have a high surface area–to–mass ratio (which allows for greater potential delivery of noxious components). These can traverse alveolar walls, pass through alveolar capillaries, enter the bloodstream and disseminate throughout the body (Fig. 8-17).

Many epidemiologic studies establish that both short-term and extended exposures to particulate air pollutants are associated with morbidity and increased mortality. The latter is evident as both

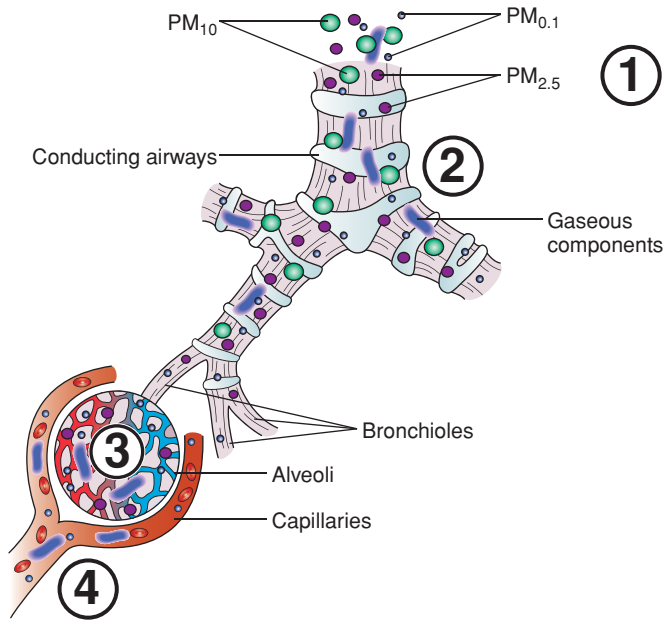

FIGURE 8-17. Fate of inspired pollutant particles. 1. Urban and industrial atmospheric pollution includes gasses and particulate carbon (PM) of various sizes. PM_{10} species (coarse particles) have aerodynamic diameter (AD) between 2.5 μm and 10 μm. $PM_{2.5}$ (fine particles) have AD less than 2.5 μm; and ultrafine particles ($PM_{0.1}$) have AD less than 0.1 μm. **2.** PM_{10} are largely trapped by mucus and cilia in conducting airways. Smaller particles and gasses pass through these airways. **3.** $PM_{2.5}$ deposit in terminal conducting airways and alveoli, where they are commonly engulfed by macrophages and elicit inflammatory responses. **4.** Ultrafine particles ($PM_{0.1}$) and gasses may pass through alveolar walls to enter the capillary circulation and then disseminate throughout the body. $PM_{0.1}$ particles may also deposit in alveolar walls.

TABLE 8-4
CANCERS ASSOCIATED WITH EXPOSURE TO OCCUPATIONAL CARCINOGENS

Agent or Occupation	Site of Cancer
Arsenic	Lung cancer
Asbestos	Mesothelioma (pleura and peritoneum) Lung cancer (in smokers)
Aromatic amines	Bladder cancer
Benzene	Leukemia, multiple myeloma
bis-(Chloromethyl)ether	Lung cancer
Chromium	Lung cancer
Furniture and shoe manufacturing	Nasal carcinoma
Hematite mining	Lung cancer
Nickel	Lung cancer, paranasal sinus cancer
Tars and oils	Cancers of lung, gastrointestinal tract, bladder and skin
Vinyl chloride	Angiosarcoma of liver

increased overall death rates and more deaths from cardiovascular diseases and cancer. Short- and long-term studies document excess mortality (Table 8-4) and dose-response relationships between particulate concentrations and sizes on the one hand, and both disease and death from cerebrovascular, peripheral vascular, cardiopulmonary and neoplastic causes on the other.

Short-term exposure to particulates. Studies of short-term human exposure examine transient spikes in ambient air pollution occur and, together with particle sizes, are correlated with morbidities and mortality. In such analyses, particulate concentrations correlate with disease and death that involve cardiac, vascular, thrombotic and short-term autonomic nervous system abnormalities (see Fig. 8-18). Daily death rates increase between 0.2% and 0.6% per 10 $\mu g/m^3$ elevation in PM_{10}. Outcomes include acute myocardial infarction, thromboembolism, ischemic stroke, arrhythmias and other related cardiac and vascular diseases.

In addition, short-term exposure to particulates has a strong impact on respiratory illnesses. Documented associations include acute exacerbations of preexisting asthma in children and adults, as well as increased hospital admissions for people who have chronic obstructive pulmonary disease (COPD; see Chapter 18). Particulates measured in these studies were principally PM_{10} and $PM_{2.5}$.

Extended exposure to particulates. Longer-term studies document associations between PM_{10} and $PM_{2.5}$ levels and, for example, lung cancer and more protracted indices of cardiovascular disease. For example, a large study conducted under the auspices of the American Cancer Society showed an average 13% increased risk of lung cancer for each 10-$\mu g/m^3$ increase in $PM_{2.5}$. Increased levels of larger particulates also correlated with higher rates of lung cancer. Other cancers have been linked as well to occupational exposure to diesel fumes, including bladder tumors and lymphomas.

In addition to neoplastic diseases, long-term studies of the toxicity of particulate pollution have shown increases in, or acceleration of, atherosclerosis and atherogenesis. These nonrespiratory consequences of particulates tend to reflect the ability of ultrafine particles to enter the systemic blood circulation (see below).

PATHOPHYSIOLOGY: The principal mechanisms by which carbon particle pollution exerts these effects appear to relate to inflammation and oxidative stress (Fig. 8-18). Carbon particles are phagocytosed by alveolar macrophages and endothelial cells, thus delivering their toxic and irritative cargoes into cells where they can alter intracellular oxidant concentrations and modify DNA structure. Generalized inflammatory activity is elevated due to delivery of oxidant chemicals, particularly by $PM_{0.1}$ particles.

Lung-related oxidant stress is a product of chemicals bound to larger particles ($PM_{2.5}$, PM_{10}). Postulated mechanisms mediating these pathologies triggered by both short- and longer-term exposures to high levels of particulates are illustrated in Fig. 8-18. Inflammation-mediated activation of clotting, which in this setting often accompanies inhibition of fibrinolysis, plays a large role in these phenomena. For example, ROS facilitate platelet aggregation and fibrin formation at nearby atherosclerotic plaques. Resultant inflammatory cell infiltration can destabilize such plaques and lead to acute cardiac events.

In utero exposure affects developing infants. Intrauterine growth retardation (IUGR) is more common if mothers are exposed to high levels of particulates (PM_{10}, $PM_{2.5}$). Also, increased formation of PAH–DNA adducts occurs in babies born following this kind of exposure. Such adducts are more abundant in newborns who were exposed in utero than in their mothers. This finding suggests that gestating human embryos are more susceptible to chemical DNA alterations than are adults.

MOLECULAR PATHOGENESIS: Genetic polymorphisms—particularly relating to genes encoding antioxidant enzymes—are likely to affect susceptibility to, and development of, diseases related to air pollution. A cohort of asthmatic children in Mexico City, whose disease exacerbations correlated with levels of fine particulates, was found to have mutations in glutathione S-transferase, an enzyme that metabolizes a variety of toxins and that can detoxify reactive oxygen species. Treating these children with antioxidant vitamins C and E led to clinical improvement. Patients with mutations in *GSTP1* and *GSTM1* genes have much higher levels of immunoglobulin E (IgE) and release more histamine in response to allergen challenge during exposure to diesel exhaust.

Mutant forms of other antioxidant enzymes render people increasingly susceptible to airway disease caused by airborne particulates. Among these enzymes is heme oxygenase-1 (*HMOX1*) and NAD(P)H:quinone

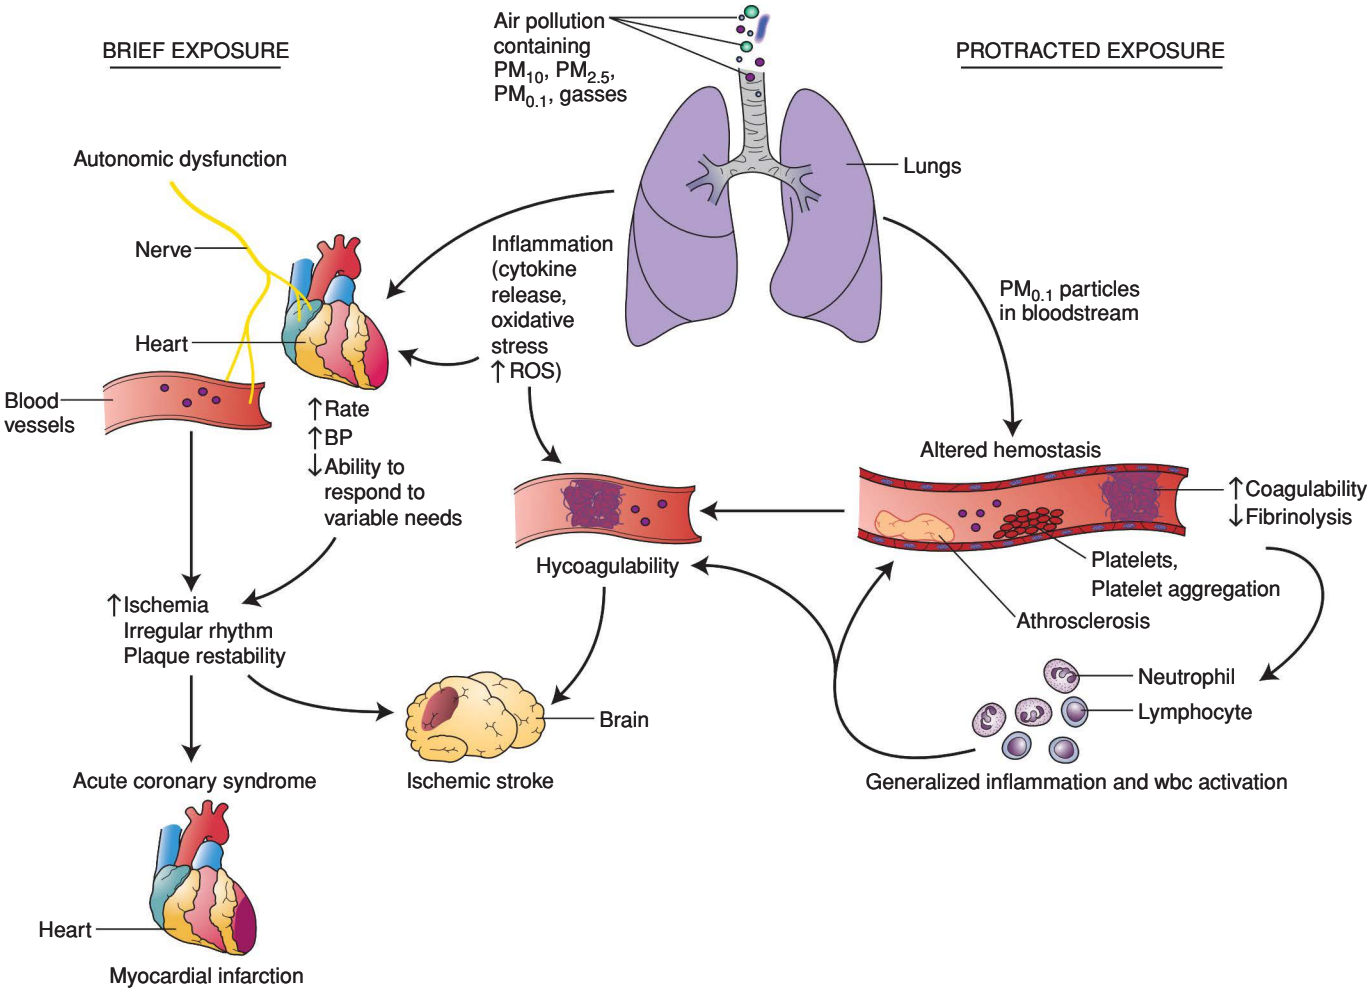

FIGURE 8-18. Pathophysiology relating to cardiovascular and thrombotic consequences of particulate air pollution. These are divided into the consequences of short-term exposure and more extended exposure to particulate air pollution. Carbon particles, especially fine and ultrafine particles, carry toxic and oxidant chemical products of combustion to the distal lungs and the circulation (hence, to blood vessels and the entire body). These affect autonomic responses, elicit inflammation and alter the balance of thrombotic and thrombolytic activities and thus impair hemostasis. The likely pathophysiologic mechanisms mediating the consequences of these derangements after both immediate exposure and protracted exposure are indicated.

oxidoreductase (*NQO1*). Polymorphisms in inflammation-related genes *TLR2* and *TLR4*, encoding toll-like receptors (see Chapters 2 and 4), may also affect the pathogenicity of carbon particulates.

Gasses Associated with Air Pollution

Sulfur Dioxide

Sulfur dioxide **(SO_2)** is highly irritative and may be oxidized to sulfuric acid. SO_2 mainly derives from burning fossil fuels. Acute exposure leads to bronchoconstriction and respiratory tract inflammation. Chronic experimental exposure to high levels of SO_2 may lead to a chronic bronchitis-like syndrome, but it is not clear that there are significant sequelae of human exposure to the concentrations of SO_2 normally found in smog.

Oxides of Nitrogen

Nitrogen oxides are generally written NOx, because they are a mixture of several compounds. They, as well, are derived from burning fossil fuels, especially in generating electricity. These gases are oxidants and respiratory irritants that induce airway hyperreactivity in acute exposure settings. Adverse effects attributable to chronic atmospheric levels of NOx have not been demonstrated. Tropospheric **ozone** (i.e., ozone near the ground as opposed to in the upper atmosphere) is largely produced by the action of sunlight on NO_2, especially on warm, sunny days. It is a strong oxidant that causes both respiratory (cough, dyspnea) and nonrespiratory (nausea, headache) symptoms on acute exposure. Chronic exposure to ozone in smog is reported to lead to deterioration in pulmonary function and is associated with a slight but significant increase in mortality.

Carbon Monoxide

Carbon monoxide **(CO)** is an odorless and nonirritating gas that results from incomplete combustion of organic substances. Its affinity for hemoglobin is 240 times more than that of oxygen. CO binding to hemoglobin forms carboxyhemoglobin and also increases the affinity of remaining heme moieties for oxygen. Thus, oxygen does not dissociate from such hemoglobin in the tissues as readily

as it should. As a result, hypoxia in CO poisoning is even greater than can be attributed to loss of oxygen-carrying capacity alone.

Atmospheric CO is derived principally from automobile exhaust and does not pose a health problem. Carboxyhemoglobin concentrations under 10% are common in smokers and ordinarily do not produce symptoms. Indoor combustion, however, particularly from space heaters, can generate much higher concentrations of CO, which can be hazardous. Concentrations up to 30% usually cause only headache and mild exertional dyspnea. Higher levels of carboxyhemoglobin lead to confusion and lethargy. Above 50%, coma and convulsions ensue. Levels greater than 60% are usually fatal. In fatal CO poisoning, a characteristic cherry-red color is imparted to the skin by the carboxyhemoglobin in the superficial capillaries. Recovery from severe CO poisoning may be associated with brain damage, which may be manifested as subtle intellectual deficits, memory loss or extrapyramidal symptoms (e.g., parkinsonism). Treatment of acute CO poisoning, as in people who attempt suicide or are trapped in fires, consists principally of the administration of 100% oxygen.

Harmful effects of long-term exposure to low levels of CO have been difficult to substantiate. However, in patients with ischemic heart disease, concentrations of carboxyhemoglobin below 5%–8% (often found in smokers) may accelerate the onset of exertional angina and cause changes in electrocardiograms.

Metals

Metals are an important group of environmental chemicals that have caused disease in humans from ancient times to the present.

Lead

Lead is a ubiquitous heavy metal that is common in the environment of industrialized countries. Before widespread awareness of chronic exposure to lead in the 1950s and 1960s, the classic symptoms of lead poisoning were commonly encountered in children and adults. In the United States, lead poisoning was primarily a pediatric problem related to pica—the habit of chewing on cribs, toys, furniture and woodwork—and eating painted plaster and fallen paint flakes. Most dwellings built before 1940 had lead-containing paint (up to 40% of dry weight) on interior and exterior walls. Children living in dilapidated older homes heavily coated with flaking paint were at significant risk for chronic lead poisoning. To these sources of lead was added a heavy burden of atmospheric lead in the form of dust derived from the combustion of lead-containing gasoline. Children and adults living near point sources of environmental lead contamination, such as smelters, were exposed to even higher levels of lead.

In adults, occupational exposure to lead occurred primarily among those engaged in lead smelting, which releases metal fumes and deposits lead oxide dust in the area. Lead oxide is a constituent of battery grids and an occupational exposure to lead is a hazard in the manufacture and recycling of automobile batteries. Accidental poisonings occasionally occurred from pottery that had been improperly fired with a lead glaze, renovation of old residences heavily coated with lead paint, "moonshine" whiskey made in lead stills or "sniffing" lead-containing gasoline.

PATHOPHYSIOLOGY: Lead is absorbed through the lungs or, less often, the gastrointestinal tract. Once in the blood, it rapidly equilibrates with the plasma and erythrocytes and is excreted by the kidneys. A portion of blood lead remains freely diffusible. Lead crosses the blood-brain barrier readily, and concentrations in the brain, liver, kidneys and bone marrow are directly related to its toxic effects. It binds sulfhydryl groups and interferes with the activities of zinc (Zn)-dependent enzymes. As well, it interferes with enzymes involved in the synthesis of steroids and cell membranes.

By contrast, bones, teeth, nails and hair represent a tightly bound pool of lead that is not generally regarded as harmful. With chronic exposure, 90% of the total body lead burden is in the bones. During metaphyseal bone formation in children, lead and calcium are deposited to produce the increased bone densities ("lead lines") seen radiographically at the metaphysis, thus providing a simple method of detecting increased body stores of lead in children.

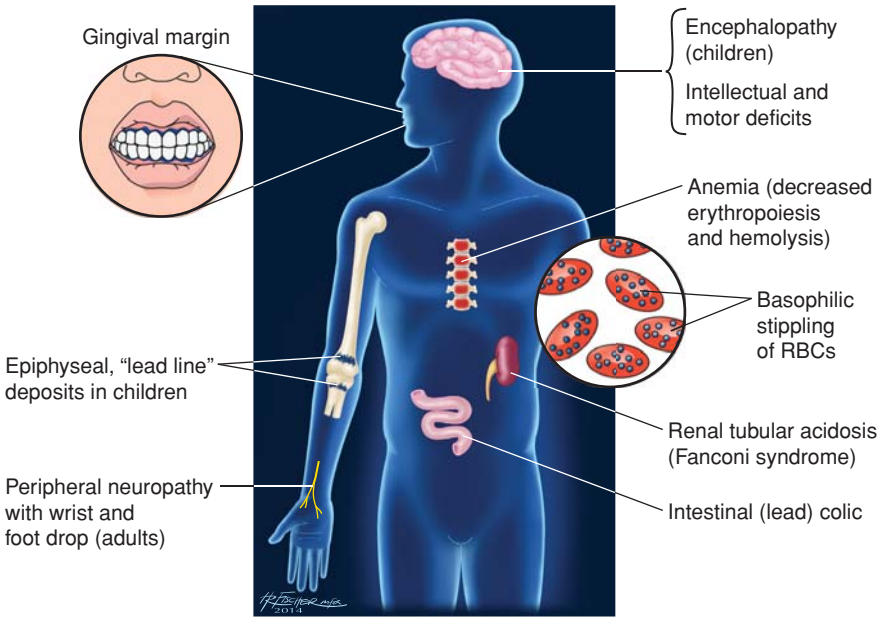
Anemia is a cardinal sign of lead intoxication. Lead disrupts heme synthesis in bone marrow erythroblasts by inhibiting δ-aminolevulinic acid dehydratase, the second enzyme in de novo synthesis of heme. It also inhibits ferrochelatase, which catalyzes the incorporation of ferrous iron into the porphyrin ring. The resulting inability to produce heme adequately causes a microcytic and hypochromic anemia like that seen in iron deficiency (see Chapter 26), in which heme synthesis is also impaired. The anemia of lead intoxication also entails prominent basophilic stippling of erythrocytes, reflecting clustering of ribosomes. Red blood cell life span is decreased; thus, lead intoxication leads to anemia due to ineffective hematopoiesis and accelerated erythrocyte turnover.

PATHOLOGY: Classic lead overexposure, which is rarely seen in the United States today, affects many organs, but its major toxicity involves dysfunction in (1) the nervous system, (2) the kidneys and (3) hematopoiesis (Fig. 8-19).

The brain is the target of lead toxicity in children; adults usually present with manifestation of peripheral neuropathy. Children with lead encephalopathy are typically irritable and ataxic. They may convulse or display altered states of consciousness, from drowsiness to frank coma. Children with blood lead levels above 80 μg/dL, but with concentrations lower than those in children with frank encephalopathy (120 μg/dL), exhibit mild CNS symptoms such as clumsiness, irritability and hyperactivity.

Lead encephalopathy is a condition in which the brain is edematous and displays flattened gyri and compressed ventricles. There may be herniation of the uncus and cerebellar tonsils. Microscopically, congestion, petechial hemorrhages and foci of neuronal necrosis are seen. A diffuse astrocytic proliferation in both the gray and white matter may accompany these changes. Vascular lesions in the brain are particularly prominent, with capillary dilation and proliferation.

Peripheral motor neuropathy is the most common manifestation of lead neurotoxicity in the adult, typically affecting



Gingival margin
Encephalopathy (children)
Intellectual and motor deficits
Anemia (decreased erythropoiesis and hemolysis)
Basophilic stippling of RBCs
Epiphyseal, "lead line" deposits in children
Renal tubular acidosis (Fanconi syndrome)
Peripheral neuropathy with wrist and foot drop (adults)
Intestinal (lead) colic

FIGURE 8-19. Complications of lead intoxication.

the radial and peroneal nerves and resulting in **wristdrop** and **footdrop,** respectively. Lead-induced neuropathy is probably also the basis of the paroxysms of gastrointestinal pain known as **lead colic**.

Lead nephropathy reflects the toxic effect of the metal on the proximal tubular cells of the kidney. The resulting dysfunction is characterized by aminoaciduria, glycosuria and hyperphosphaturia (Fanconi syndrome). Such functional alterations are accompanied by the formation of inclusion bodies in the nuclei of the proximal tubular cells. These inclusions are characteristic of lead nephropathy and are composed of a lead–protein complex containing more than 100 times the concentration of lead in the whole kidney.

Lead poisoning is treated with chelating agents such as ethylene diamine tetra-acetic acid (EDTA), either alone or in combination with dimercaprol (BAL). Both the hematologic and renal manifestations of lead intoxication are usually reversible; alterations in the CNS are generally irreversible.

Laboratory diagnosis is made by demonstrating high blood levels of lead and increased free erythrocyte protoporphyrin. Elevated urinary excretion of δ-aminolevulinic acid and decreased levels of aminolevulinic acid dehydratase in erythrocytes are confirmatory.

EFFECTS OF CHRONIC EXPOSURE TO LOW LEAD LEVELS: Owing to the removal of lead from gasoline, improvements in housing, substitution of titanium for lead in paints and control of industrial point sources, ambient levels of lead have fallen significantly: blood levels in the general population of the United States decreased from an average of 16 μg/dL in 1976 to 1.0 μg/dL in 2000. It has been established that cumulative exposure to lead is best measured in bone, rather than blood. The latter lead levels reflect more ongoing exposure. Thus, elevated bone levels of lead have been correlated with adult hypertension, while no relationship has been established with blood levels. The dramatic fall in mean blood lead levels has been accompanied by the near elimination of lead-related childhood fatalities and encephalopathy. However, low lead exposure in children, while not producing recognizable symptoms, may permanently decrease cognitive performance. The regulatory safe threshold for blood levels of lead in children has been progressively reduced and is now thought to be below 10 μg/dL.

Efforts to reduce environmental lead have led to decreases in the percentage of children in the United States with blood levels of 10 μg/dL of lead or more from 88% in the 1970s to 4.4% in the 1990s. However, high blood lead concentrations remain a problem among poor, mainly urban, children, and vigorous campaigns to address this situation are justified.

Mercury

Inorganic mercury has been used since prehistoric times and has been known to be an occupation-related hazard at least since the Middle Ages, but in recent years it has become recognized that organic mercury represents a greater risk to human health. Although mercury poisoning still occurs in some occupations, there has been increasing concern over the potential health hazards brought about by the contamination of many ecosystems following several well-known outbreaks of methylmercury poisoning. The most widely publicized episodes occurred in Japan, first in Minamata Bay in the 1950s and then in Niigata. In both cases, local inhabitants developed severe, chronic organic mercury intoxication. This poisoning was traced to the consumption of fish contaminated with mercury that had been discharged into the environment in the effluents from a fertilizer and a plastics factory. Children exposed in utero showed delayed developmental milestones and abnormal reflexes, despite the fact that fetal exposure was estimated to be 1/5 to 1/10 that in adults.

Mercury released into the environment may be bioconcentrated and enter the food chain. Bacteria in bays and oceans can convert inorganic mercury compounds from industrial wastes into highly neurotoxic organomercurials. These compounds are then transferred up the food chain and are eventually concentrated in the large predatory fish (e.g., tuna, pike) that make up a substantial part of the diet in many countries.

Although inorganic mercury is not efficiently absorbed in the gastrointestinal tract, organic mercurial compounds

are readily taken up because of their lipid solubility. Both inorganic and organic mercury are preferentially concentrated in the kidney and methylmercury also distributes to the brain. ***The kidney is the principal target of the toxicity of inorganic mercury, but the brain is damaged by organic mercurials.*** Claims that mercuric preservatives in vaccines cause autism or other neurologic complications have been proven false.

NEPHROTOXICITY: At one time, mercuric chloride was widely used as an antiseptic and acute mercuric chloride poisoning was much more common; the compound was ingested by accident or for suicidal purposes. Under such circumstances, **proximal tubular necrosis** was accompanied by oliguric renal failure. Mercurial diuretics were also widely prescribed in the past and chronic mercury nephrotoxicity was a not uncommon complication of their long-term use. Today, chronic mercurial nephrotoxicity is almost always a consequence of long-term industrial exposure. Proteinuria is common in chronic mercurial nephrotoxicity and there may be a nephrotic syndrome with more severe intoxication. Pathologically, there is a membranous glomerulonephritis with subepithelial electron-dense deposits, suggesting immune complex deposition.

NEUROTOXICITY: The neurologic effects of mercury are manifested as a constriction of visual fields, paresthesias, ataxia, dysarthria and hearing loss. Pathologically, there is cerebral and cerebellar atrophy. Microscopically, the cerebellum exhibits atrophy of the granular layer, without loss of Purkinje cells and spongy softenings in the visual cortex and other cortical regions.

Arsenic

The toxic properties of arsenic have been known for centuries. Arsenic-containing compounds have been widely used as insecticides, weed killers and wood preservatives. Arsenicals may also contaminate soil and leach into ground water as a result of naturally occurring arsenic-rich rock formations, from coal burning or from use of arsenical pesticides. As with mercury, there is evidence for the bioaccumulation of arsenic along the food chain.

Acute arsenic poisoning is almost always the result of accidental or homicidal ingestion. Death is due to **CNS toxicity**. Chronic arsenic intoxication affects many organ systems. It is characterized initially by such nonspecific symptoms as malaise and fatigue. Eventually, gastrointestinal, cardiovascular and hematologic dysfunction become evident. Both encephalopathy and peripheral neuropathy develop. The latter is characterized by paresthesias, motor palsies and painful neuritis. On epidemiologic grounds, **cancers of the skin, respiratory tract** and **gastrointestinal tract** have been attributed to industrial and agricultural exposure to arsenic. In some parts of the world, exposure of workers in rice paddies to arsenic in the ground water has been associated with skin cancers. Rare cases of hepatic angiosarcomas have been related to chronic arsenic exposure.

Cadmium

Cadmium is used in ever-increasing quantities in manufacturing alloys, producing rechargeable batteries and electroplating other metals (e.g., automobile parts and musical instruments). It is a plasticizer and a pigment. Cadmium oxide fumes are released in the course of welding steel parts previously plated with a cadmium anticorrosive. It accumulates in the human body, with a half-life of over 20 years, and since it is rarely recycled, the increase in industrial use of the metal is of concern. The main routes of exposure for the general population are ingestion and inhalation. Both plant- and animal-derived foodstuffs may contain substantial levels of cadmium.

Short-term cadmium inhalation irritates the respiratory tract, with pulmonary edema the most dangerous result. The lungs and the kidneys and, to a lesser extent, the skeletal and vascular systems are the principal target organs of chronic cadmium intoxication. Emphysema has been the major finding in the fatal cases of chronic cadmium pneumonitis. Although the confounding effects of smoking complicate interpretation of some of these studies, inhalation of cadmium does appear to lead to lung cancer. Proteinuria, which reflects tubular rather than glomerular damage, has been the most consistent finding in cadmium workers with renal damage.

Chromium

Chromium (Cr) is used extensively in several industries, including metal plating and some types of manufacturing. Although it occurs in any number of oxidation states, only Cr(III) and Cr(VI) are commonly used industrially. Its toxicity is usually a result of inhalation and the consequences of exposure depend on the solubility of the specific salt. Although acute intoxication is known, it is chronic exposure that is most problematic.

Cr(VI) is highly genotoxic. People who chronically inhale salts of hexavalent chromium have an increased risk of lung cancer and possibly other tumors as well. The less soluble chromate salts are generally more potent pulmonary carcinogens, particularly zinc chromate.

Nickel

Nickel is a widely used metal in electronics, coins, steel alloys, batteries and food processing. Dermatitis ("nickel itch"), the most frequent effect of exposure to nickel, may occur from direct contact with metals containing nickel, such as coins and costume jewelry. The dermatitis is a sensitization reaction; the body reacts to nickel-conjugated proteins formed following the penetration of the epidermis by nickel ions. Exposure to nickel, as to arsenic, increases the risk of development of specific types of cancer. Epidemiologic studies have demonstrated that workers who were occupationally exposed to nickel compounds have an increased incidence of lung cancer and cancer of the nasal cavities.

Iron

Iron-deficiency anemia is a common disease, particularly in premenopausal women. Oral iron preparations contain largely ferrous sulfate, the form absorbed by the gastrointestinal mucosa and then converted to the trivalent form. Acute ferrous sulfate poisoning from accidental ingestion occurs, mainly in children between the ages of 1 and 2 years. As little as 1–2 g of ferrous sulfate may be lethal, but most fatal cases follow ingestion of 3–10 g. Hemorrhagic gastritis and acute liver necrosis have been the most prominent findings at autopsy.

Long-term, excessive dietary intake of iron does not ordinarily lead to abnormal iron accumulation. South African Bantus have a significant incidence of iron overload, which has been attributed to a diet very high in iron,

largely derived from iron drums used to prepare homemade beer. The acidic pH of these brews readily solubilizes the iron and their low alcohol content allows large volumes to be consumed. A large proportion of the excess iron is in the liver, and there is a correlation between the degree of siderosis and the presence of cirrhosis. There is also a high incidence of diabetes and heart disease in this "Bantu siderosis."

However, some blacks have shown a similar syndrome, which now is attributed to a mutation in the gene for ferroportin (SLC4A1) that may predispose some people of African descent to iron overload (see Chapter 20).

Cobalt

Acute occupational inhalation of cobalt has led to acute respiratory distress syndrome (see Chapter 18). In addition, excessive intake of cobalt in beer that contained it to enhance foaming qualities was implicated in a degenerative disease of heart muscle (cardiomyopathy; see Chapter 17). When the cobalt was removed from the beer, no further cases of heart disease were reported.

Radioactive Elements

Elements whose radioactive isotopes are potentially hazardous include radium, strontium, uranium, plutonium, thorium and iodine. Chronic toxicities relate principally to radiation-induced carcinogenesis. The individual tumors reflect the organ localization of the elements and are discussed in the chapters that address specific organ pathology.

Biological Toxins Are Organisms and Their Nonviable Components

These toxins are mostly of microbial, algal, plant, protozoan, arthropod or mammalian origin. They include whole organisms, intact particulate or soluble products of those organisms (e.g., exotoxins) and fragments of organisms. Adverse reactions may result from inhalation, ingestion or other contact, and they may reflect infectious, hypersensitivity and toxic effects of those materials. This discussion addresses the latter. Infectious and hypersensitivity reactions to foreign matter are considered in Chapters 9 and 4, respectively, as well as individual organ-specific discussions (e.g., hypersensitivity pneumonitis in Chapter 18).

The toxic effects of microbial products are the best characterized of biological toxicities. **Organic dust toxic syndrome** (ODTS) is a systemic reaction to the direct toxicities of many, mainly fungal, toxins. It consists of flu-like symptoms (fever, malaise, etc.), often with a respiratory component (dyspnea, cough). Unlike hypersensitivity pneumonitis, ODTS appears to reflect cell death and the consequent acute inflammatory reaction. It is usually associated with toxins produced by many common fungi.

Aspergillus, Stachybotrys, Penicillium and *Fusarium* spp. are the most common culprits. These fungi are particularly abundant in water-damaged buildings and moist warm environments. Their mycotoxins include trichothecenes and β-1,3-glucans, which may elicit disease by ingestion and inhalational routes.

One particular toxin produced by *Aspergillus flavus* and *Aspergillus parasiticus,* called **aflatoxin,** is highly hepatotoxic and is recognized as a potent hepatocarcinogen. There are several known varieties of aflatoxin.

Bacterial endotoxins are lipopolysaccharides derived from Gram-negative bacterial cell walls. They are often complexed with proteins and phospholipids. Injected endotoxins are used experimentally to elicit inflammatory and febrile responses characterized by local or systemic macrophage activation. Inhaled, these compounds elicit profuse pulmonary inflammatory responses, involving release of inflammatory mediators (tumor necrosis factor-α [TNF-α], interleukin-1 [IL-1], etc.), causing fever, pneumonitis and pulmonary edema.

The subject of biological toxins is of considerable concern because of possible weaponization for use in biological warfare (see Chapter 9).

THERMAL REGULATORY DYSFUNCTION

Hypothermia Is a Decrease in Body Temperature below 35°C (95°F)

Hypothermia can result in systemic or focal injury, the latter exemplified by **trench foot** or **immersion foot.** In localized hypothermia of these types, actual tissue freezing does not occur. **Frostbite,** by contrast, involves the crystallization of tissue water.

Generalized Hypothermia

Hypothermia may occur in a number of settings, including immersion in cold water and exposure to extremely cold air temperatures, especially after taking agents that impair thermoregulation, such as alcohol and some drugs and pharmacologic agents. Perhaps the best-studied cause of hypothermia is cold water immersion. Acute immersion in water at 4°C–10°C (39.2°F–50°F) reduces central blood flow. Coupled with decreased core body temperature and cooling of the blood perfusing the brain, this results in mental confusion. Tetany makes swimming impossible. Furthermore, increased vagal discharge leads to premature ventricular contractions, ventricular arrhythmias and even fibrillation.

Attempting to increase heat production, the immersed body immediately responds by increasing muscle activity and oxygen consumption. However, there are limits to the sources of energy available for sustained warming. Within 30 minutes, heat loss exceeds heat production because of the combination of high direct conduction of heat from the whole skin surface and altered muscle tone caused by decreased arterial carbon dioxide and exhaustion. Core temperature then begins to fall. Peripheral vasoconstriction is another response to conserve heat. In addition, there is an increased sympathetic neural discharge, resulting in increased heart and basal metabolic rates and shivering. When the core temperature approaches 35°C, this activity may be three to six times above normal. Below 35°C, respiratory rate, heart rate and blood pressure decline because the functional reserve is reduced.

With prolonged cooling, a "cold-induced" diuresis results in increased blood viscosity. As a result, blood flow decreases and oxygen–hemoglobin association is less effective. Cardiac stroke volume decreases and peripheral vascular resistance increases as a direct result of both blood "sludging" and loss of plasma. The most important factor in causing death is cardiac arrhythmia or sudden

cardiac arrest. These observations have been confirmed and extended, largely because of the need to induce hypothermia in some patients undergoing open-heart surgery. In fact, with careful pharmacologic control, prolonged periods of lower body temperature can be achieved with no residual harm.

If hypothermia is prolonged, decreased body temperature alters cerebrovascular function. When body core temperature reaches 32°C (89.6°F), the person becomes lethargic, apathetic and withdrawn. A characteristic response is inappropriate behavior, including disrobing, even when cold. If temperature falls further, intermittent "stupor" and eventually coma supervene. If core temperature goes below 28°C (82.4°F), pulse and breathing weaken.

Although there are no specific morphologic changes in those who die from hypothermia, the skin shows red and purple discolorations, ears and hands swell and there is irregular vasoconstriction and vasodilation. Areas of cardiac myocytolysis are seen. Lungs may display pulmonary edema and intra-alveolar, intrabronchial and interstitial hemorrhage.

Focal Thermal Alterations

As discussed above, local reduction in tissue temperature, particularly in the skin, is associated with local vasoconstriction. Tissue water crystallizes if blood circulation is insufficient to counter persistent thermal loss. When freezing occurs slowly, ice crystals form within tissue cells and in the interstitial space. Concomitantly, electrolyte-rich gels are excluded. Injury to cellular organelles reflects the drastic changes in ion concentrations in the excluded volume. Denaturation of macromolecules and physical disruption of cellular membranes by the ice ensue. When freezing is rapid, a gel-like structure forms within the cell that lacks water crystalloids. This water-solid reduces the extent of mechanical and chemical injury. The most significant cellular damage apparently occurs on thawing, when mechanical disruption of membrane structures occurs, perhaps the result of transformation from a gel to a crystal.

The most biologically significant cell injury appears in the endothelial lining of the capillaries and venules, which alters small vessel permeability. This injury initiates extravasation of plasma, formation of localized edema and blisters and an inflammatory reaction. While frostbite results from the actual freezing of water, immersion foot (trench foot) is caused by a prolonged reduction in tissue temperature to a point not low enough to freeze tissue. This cooling causes cellular disruption. Endothelial cell damage leads to local thrombosis and changes caused by altered permeability are prominent. Vascular occlusion often leads to gangrene.

Hyperthermia Means an Increase in Body Temperature

Tissue responses to hyperthermia are similar in some respects to those caused by freezing injuries. In both instances, injury to the vascular endothelium results in altered vascular permeability, edema and blisters. The degree of injury depends on the extent of temperature elevation and how quickly it is reached. Small increases in body temperature increase the metabolic rate. However, above a certain limit, enzymes denature and other proteins precipitate and "melting" of lipid bilayers of cell membranes takes place.

Systemic Hyperthermia

Systemic hyperthermia, or **fever,** is an elevation of body core temperature. It occurs because of (1) increased heat production, (2) decreased elimination of heat from the body (reflecting an aberrant response of the thermal regulatory center) or (3) a disturbance of the thermal regulatory center itself. Hyperthermia can also occur because heat is conducted into the body faster than the system can clear it.

A body temperature above 42.5°C (108.5°F) leads to profound functional disturbances, including general vasodilation, inefficient cardiac function and altered respiration. Isolated heart–lung preparations fail at about the same temperature, suggesting an inherent limitation in the cardiovascular system and perhaps in the myocardial cells themselves. ***In general, systemic temperature elevations above 42°C (107.6°F) are not compatible with life.***

During infectious and inflammatory responses, several cytokines, including IL-1, IL-6 and TNF-α, interact with a portion of the hypothalamus at the roof of the third ventricle and apparently reset the body's "thermostat" to permit a higher body core temperature. There is also evidence that for mild pyrogens, parasympathetic activation may be involved.

Few, if any, defined pathologic changes are associated with fever alone. Physical findings include increased heart and respiratory rates, peripheral vasodilation and diaphoresis, all recognized mechanisms for thermal regulation. The CNS may respond with irritability, restlessness and (particularly in children) convulsions. Nocturnal temperature elevations with "night sweats" are a feature of pulmonary granulomatous infection (especially tuberculosis) and are also observed in lymphoproliferative diseases. Prolonged temperature elevation can produce wasting, principally because of an increased metabolic rate.

Malignant hyperthermia is a thermal alteration, accompanied by a hypermetabolic state and often by rhabdomyolysis (muscle necrosis), which occurs after anesthesia in susceptible people. This autosomal dominant disorder is associated with at least 70 different mutations in the gene for the sarcoplasmic reticulum ryanodine receptor (RYR1). A less common mutation causing malignant hyperthermia occurs in the gene for the α-subunit of the L-type voltage-gated calcium channel (CACNA1S). Muscle damage is caused by an abnormally high calcium concentration produced by accelerated release of Ca^{2+} through the mutant calcium release channel. After the introduction of treatment with dantrolene, which binds to the ryanodine receptor, mortality from malignant hyperthermia fell from 80% to less than 10%.

Heat stroke is a form of hyperthermia that occurs under conditions of very high ambient temperatures and is not mediated by endogenous pyrogens. It reflects impaired thermal regulatory cooling responses and characteristically occurs in infants, young children and the very aged. Often the disorder is associated with an underlying chronic illness and use of diuretics, tranquilizers that may affect the hypothalamic thermal regulatory center or drugs that inhibit perspiration. Another form of heat stroke is seen in healthy men during unusually vigorous exercise. Lactic acidosis, hypocalcemia and rhabdomyolysis may be severe problems, and almost 1/3

of patients with exertional heat stroke develop myoglobinuric acute renal failure. Heat stroke is not amenable to treatment with standard antipyretics, and only external cooling and fluid and electrolyte replacement are effective therapy.

Cutaneous Burns

Cutaneous burns are the most common form of localized hyperthermia. Both the elevated temperature and rate of temperature change are important in determining the tissue response. A temperature of 50°C (120°F) may be sustained for 10 minutes or more without cell death, while a temperature of 70°C (158°F) or higher for even several seconds causes necrosis of the entire epidermis.

Cutaneous burns have been separated into full-thickness (previously, third-degree) and partial thickness (previously, first- and second-degree) burns (Fig. 8-20).

- **Full-thickness burns** char both epidermis and dermis. Histologically, they are carbonized and cellular structure is lost.

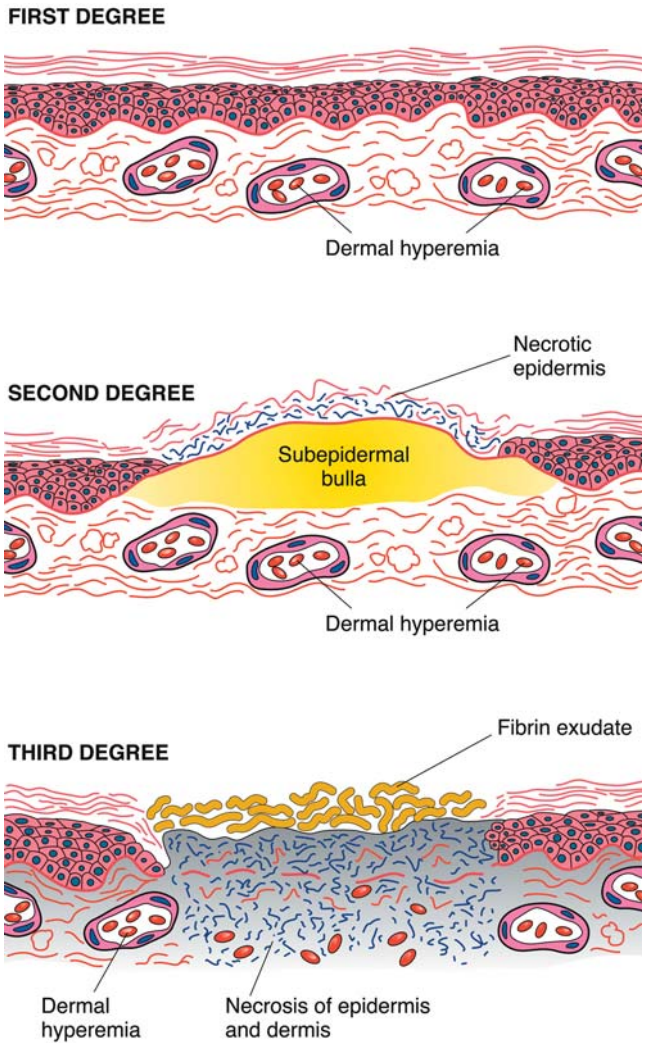


FIGURE 8-20. The pathology of cutaneous burns. A first-degree skin burn exhibits only dilation of the dermal blood vessels. In a second-degree burn, there is necrosis of the epidermis and subepidermal edema collects under the necrotic epidermis to form a bulla. In a third-degree burn, both the epidermis and dermis are necrotic.

Among the most important functions of the skin are fluid retention and protection from infectious agents. Not surprisingly, then, when skin is severely damaged, its ability to subserve these functions is compromised. One of the most serious systemic disturbances caused by extensive cutaneous burns is fluid loss. Patients with full-thickness burns can lose about 0.3 mL of body water/cm^2 of burned area per day. Resulting hemoconcentration and poor vascular perfusion of the skin and other viscera complicate the recovery of these patients. Many severely burned people, particularly those with more than 70% of their body surface involved with full-thickness burns, develop shock and acute tubular necrosis of the kidneys and mortality is very high. Severely burned patients who survive longer are at great risk of lethal surface infections and sepsis. Even normal skin saprophytes may cause infection of charred tissue and pose another difficulty for healing.

Healing of cutaneous burns is related to the extent of tissue destruction. Mild partial thickness burns, by definition, have little if any cell loss and healing requires only repair or replacement of injured endothelial cells. More severe partial thickness burns also heal without a scar because epidermal basal cells remain and are a source of regenerating cells for the epithelium. Full-thickness burns, in which the entire thickness of the epidermis is destroyed, pose a separate set of problems. If the skin appendages are spared, re-epithelialization can arise from them. Initially, islands of proliferation at the orifices of these glands grow and coalesce to cover the surface. Deeper burns that destroy the skin appendages require new epidermis to be grafted to the débrided area to establish a functional covering. Burned skin that is not replaced by a graft heals with dense scarring. Since this scar tissue lacks the elasticity of normal skin, contractures that limit motion may eventually result.

Inhalation Burns

People trapped in burning buildings and vehicles are exposed to air and aerosolized flammable materials heated to very high temperatures. Inhalation of these noxious fumes injures or destroys respiratory tract epithelium from the oral cavity to the alveoli. If a patient survives the acute episode, acute respiratory distress syndrome (ARDS), which itself may be fatal (see Chapter 18), may develop.

Electrical Burns

Electrical injury produces damage through (1) electrical dysfunction of cardiovascular conduction and the nervous system and (2) conversion of electrical energy to heat energy when the current encounters the resistance of the tissues. ***Because electrical energy can potentially disrupt the electrical system within the heart, it frequently causes death through ventricular fibrillation.*** The amount of current necessary for such a disruption depends in part on its pathway through the body and its ease in penetrating the skin. Someone who inadvertently touches a 120-V line in a living room may suffer burns on the hand because the skin that contacts the wire has substantial resistance to the flow of electrical current. If that resistance is decreased, as when a person inadvertently touches the same line in a bathtub, the lower resistance increases transmitted current, leading to disordered cardiac electrical activity.

FIGURE 8-21. Electrical burn of the skin. The victim was electrocuted after attempting to stop a fall from a ladder by grasping a high-voltage electrical line.

Electrical burns of the skin reflect the voltage, the area of electrical conductance and the duration of current flow (Fig. 8-21). Very–high-voltage current chars tissue and produces a third-degree burn. On the other hand, broad, moist surfaces exposed to the same flow exhibit less-severe change. With exposure to very–high-voltage currents, the force may be almost "explosive," in which case vaporization of tissue water produces extensive damage.

ALTITUDE-RELATED ILLNESSES

High-altitude illness is rare, in large part because mountain climbers tend to acclimate before extreme altitudes are achieved. However, there is an altitude limit beyond which human life cannot be sustained for prolonged periods. Communities in the Andes succeed at 4000 to 4300 meters (13,124 to 14,108 ft). Inhabitants adapt to the decreased pressure and availability of oxygen by developing elevated hematocrits and large "barrel" chests with increased lung volume. Even those who live in this zone do not survive at elevations above 5500 to 6000 meters (18,045 to 19,686 ft). Prolonged stays at this altitude result in weight loss, difficulty in sleeping and lethargy, perhaps because of the redirection of cellular energy simply for survival. For example, 75%–90% of the oxygen available at 6000 meters is used simply for the effort of inspiration.

The modifications induced by high altitude are related to decreased atmospheric pressure and consequent decreased oxygen availability. Unlike sea level, where activity does not change oxygen saturation, physical activity at these elevations leads to decreased partial pressure of arterial oxygen. At sea level, cardiac output limits exercise; at high altitudes, the diffusing capacity of the lung for oxygen seems to be the determinant.

Acclimation to chronic hypoxia at high altitudes results in a reduced ventilatory drive. Acclimated people exhibit increases in (1) capillaries per unit volume of brain, muscle and myocardium; (2) myoglobin within tissues; (3) mitochondria per cell; and (4) hematocrit. An increase in erythrocyte levels of 2′3′-diphosphoglycerate, which enhances oxygen delivery to tissues, occurs within hours, but polycythemia takes months. Some of the minor effects of high altitude are systemic edema, retinal hemorrhages and flatulence. The more serious nonfatal diseases are acute and chronic mountain sickness and high-altitude deterioration. Fatal **high-altitude pulmonary edema** and **high-altitude encephalopathy** may ensue.

- **High-altitude systemic edema:** This condition results from asymptomatic increases in vascular permeability, particularly in hands, face and feet and most often at elevations over 3000 meters. It is reflected only in weight gain; on return to lower altitude, diuresis causes the edema to disappear. This disorder may in part reflect endothelial cell responses to hypoxia and is twice as common in women as in men. A calcium channel blocker has been used as treatment.
- **High-altitude retinal hemorrhage:** A critical analysis by funduscopic examination revealed that 30%–60% of those sleeping above 5000 meters had retinal hemorrhages. The initial effect includes retinal vascular engorgement and tortuousness. Optic disc hyperemia is also noted and multiple flame-shaped hemorrhages subsequently occur. These changes are reversible.
- **High-altitude flatus:** Changes in external pressure and production of intestinal gas provide for expansion of intestinal luminal contents and lead to increased flatus at altitudes above 3500 meters. No medical disease attends these changes.
- **Acute mountain sickness:** This condition is rare below 2500 meters but occurs to some degree in nearly everyone at 3000 to 3600 meters. Initial presentation includes headache, lassitude, anorexia, weakness and difficulty sleeping. The underlying pathophysiology is in part related to hypoxia and shifts in plasma fluid to the interstitial space. Adaptation through increased respiratory rate causes some improvement. Descent to lower altitudes is certainly indicated. Chronic or subacute exacerbation of this disease also occurs, frequently at lower altitudes, and the symptoms may be severe. Prophylaxis with acetazolamide (a carbonic anhydrase inhibitor) or dexamethasone has been successful for acute mountain sickness.
- **High-altitude deterioration:** Generally occurring at very high elevations (5500 meters or more), high-altitude deterioration presents as a decrease in physical and mental performance. The combination of chronic hypoxia, inadequate fluid intake, inadequate nutrition, decreased plasma volume and hemoconcentration are aggravating factors.
- **High-altitude pulmonary edema and cerebral edema:** Serious high-altitude problems, including pulmonary edema and cerebral edema, can occur with a rapid ascent to heights over 2500 meters, particularly in susceptible people who have difficulty sleeping at higher altitudes. Tachycardia, right ventricular overload and marked reduction in arterial oxygen pressure occur, without changes in pH or carbon dioxide retention. A characteristic patchy pulmonary infiltrate is noted radiographically. Pulmonary hypertension is common in patients with high-altitude pulmonary edema. Hypoxic vasoconstriction and intravascular thrombosis have been proposed as causes of pulmonary hypertension. Eventually, cardiac output is decreased and systemic blood pressure falls. The precapillary arterioles become dilated, increasing capillary bed pressure and inducing interstitial and

alveolar edema. Autopsy findings include severe confluent pulmonary edema, proteinaceous alveolar exudates and hyaline membrane formation. Capillary obstruction by thrombi has been noted. A dilated heart and enlarged pulmonary arteries are commonly found.

- **High-altitude encephalopathy** is characterized by confusion, stupor and coma. Autopsies reveal cerebral edema and vascular congestion. A proposed mechanism is severe cerebral hypoxia, with inhibition of the sodium pump and resultant intracellular edema.

PHYSICAL INJURIES

The effect of mechanical trauma is related to (1) the force transmitted to the tissue, (2) the rate at which the transfer occurs, (3) the surface area to which the force is transferred and (4) the area of the body involved. The compressibility of the tissue adjacent to the transmitted force in part determines its effect. However, transmission of absorbed energy can produce alterations elsewhere in the body. Blows over a hollow viscus can rupture the organ because of compression of the fluid or gas it contains; organs nestled beneath the skin, such as the liver, can be easily ruptured. An impact directly over the heart can even disturb its electrical systems. However, a blow over a large muscle mass, such as the thigh or upper arm, is often less injurious than a direct blow to a poorly shielded bone, such as the anterior tibia. Furthermore, the distribution of the force is important.

A Contusion Is a Localized Mechanical Injury with Focal Hemorrhage

A force with sufficient energy may disrupt capillaries and venules within an organ by physical means alone. The result may be so limited that the only histologic change is hemorrhage in tissue spaces outside the vascular compartment. A discrete extravascular blood pool within the tissue is called a **hematoma**. Initially, the deoxygenated blood renders the area blue to blue-black, as in the classic "black eye." Macrophages ingest the erythrocytes, convert their hemoglobin to bilirubin and so change the color from blue to yellow. Both mobilization of the pigment by macrophages and further metabolism of bilirubin cause the yellow to fade to yellowish green and then to disappear.

An Abrasion Is a Skin Defect Caused by Crushes or Scrapes

The disruptive force may provide a portal of entry for microorganisms. The impact of the agent and its configuration are frequently seen in these wounds and are of special interest to the forensic pathologist.

A Laceration Is a Split or Tear of the Skin

Lacerations result from an impact stronger than that causing an abrasion and are usually the result of unidirectional displacement. When they have crushed margins, they are called **abraded lacerations**.

Wounds Are Mechanical Disruptions of Tissue Integrity

An incision is a deliberate opening in the skin by a cutting instrument (e.g., a surgeon's scalpel). Incisions have sharp edges and, importantly, spare no tissue to the depth of the wound. **Deep penetrating wounds** made by high-velocity projectiles, such as bullets, are often deceptive, because the energy of the missile as it passes through the body may be released at sites distant from the entrance itself. Bullets, because they rotate, produce a well-defined and usually round entrance wound (Fig. 8-22). Once the projectile enters the flesh, however, it may fragment, tumble, or actually explode, resulting in considerable tissue damage and a large, ragged exit wound.

ULTRAVIOLET LIGHT

Within the large spectrum of electromagnetic radiation emitted by the sun, exposure to ultraviolet (UV) light (100–400 nm) has a number of different effects on the human body. It can damage DNA and is a leading cause of cancer of the skin (see Chapter 5).

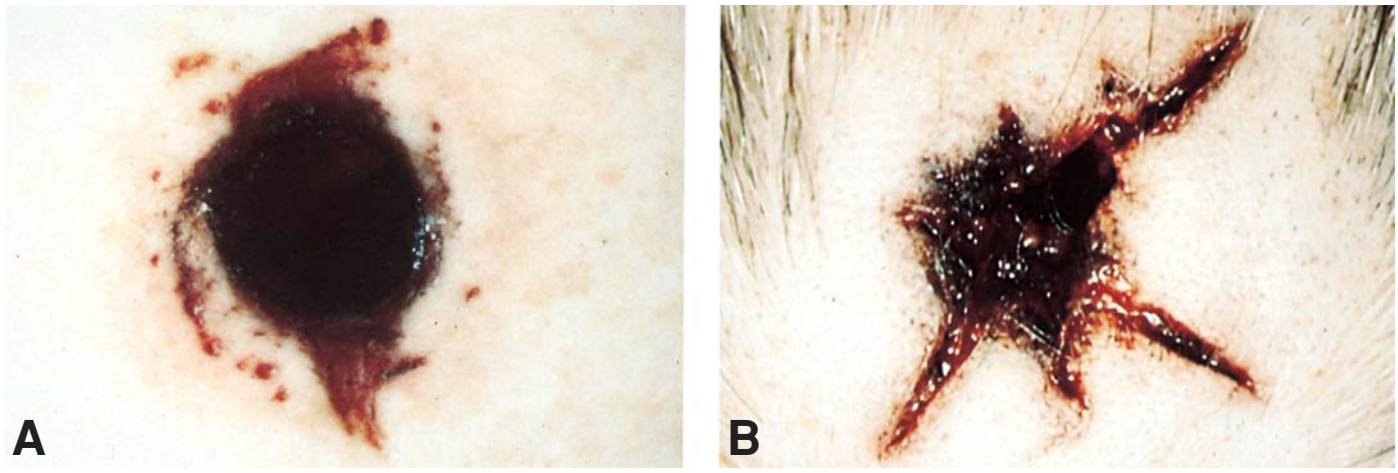

FIGURE 8-22. Bullet wounds. A. The entrance wound is sharply punched out. **B.** The exit wound is irregular with characteristic stellate lacerations.

UV radiation is also absorbed by photoreceptors in the skin, after which substances that suppress cell-mediated immunity may be released. As a consequence, both local and systemic immune functions may be modulated. Recent evidence suggests a beneficial effect of UV light on the severity of some autoimmune diseases, such as multiple sclerosis. Exposure to UV radiation also stimulates endogenous production of vitamin D in the skin (see below). UV wavelengths between 270 nm and 300 nm, called UVB, result in production of a precursor for vitamin D from a cholesterol derivative.

RADIATION

We can define radiation simply as emission of energy by one body, its transmission through an intervening medium and its absorption by another body. By this definition, radiation encompasses the entire electromagnetic spectrum and certain charged particles emitted by radioactive elements. Alpha particles and the beta particles of elements such as tritium (^{3}H) and carbon 14 (^{14}C) are of immense use scientifically and pose few hazards for humans. High-energy radiation, in the form of gamma or x-rays, mediates most of the biological effects discussed here. We do not consider the effects of ultraviolet radiation here; they are discussed in Chapters 5 and 28.

Radiation is quantitated in a number of ways:

- **A roentgen** is a measure of the emission of radiant energy from a source. This unit refers to the amount of ionization produced in air.
- **A rad** measures absorption of radiant energy, which is biologically the more important parameter. A rad defines the energy, expressed as ergs, absorbed by a tissue. One rad equals 100 ergs per gram of tissue.
- **A gray** (Gy) corresponds to 100 rads (1 joule/kg of tissue) and a centigray (cGy) is equivalent to 1 rad.
- **The rem** was introduced to describe the biological effect caused by a rad of high-energy radiation, since low-energy particles produce more biological damage than gamma or x-rays.
- **A sievert** (Sv) is the dose in gray multiplied by an appropriate quality factor Q, so that 1 Sv of radiation is roughly equivalent in biological effectiveness to 1 Gy of gamma rays.

For the purposes of this discussion of radiation-induced pathology, the rad, gray, rem and sievert are considered comparable.

PATHOPHYSIOLOGY: At the cellular level, radiation essentially has two effects: (1) a somatic effect, associated with acute cell killing; and (2) genetic damage. Radiation-induced cell death is believed to be caused by the acute effects of the radiolysis of water (see Chapter 1). The production of activated oxygen species may result in lipid peroxidation, membrane injury and possibly an interaction with macromolecules of the cell. Genetic damage to the cell caused indirectly by a reaction of DNA with oxygen radicals is expressed either as mutation or as reproductive failure. Both mutation and reproductive failure may lead to delayed cell death, and mutation is involved in development of radiation-induced neoplasia.

Different tissues are differently sensitive to radiation. The vulnerability of a tissue to radiation-induced damage depends on its proliferative rate, which in turn correlates with the natural life span of the constituent cells. For example, the intestine and the hematopoietic bone marrow are far more vulnerable than tissues such as bone and brain. Damage to the DNA of a long-lived, nonproliferating cell does not necessarily impair its function or viability because its reproductive and metabolic functions are separate properties. By contrast, short-lived, proliferating cells, such as intestinal crypt cells or hematopoietic precursors, must be rapidly replaced by division of precursor cells. If radiation-induced DNA damage precludes mitosis of these cells, the mature elements are not replaced and the tissue can no longer function.

It is important to distinguish between whole-body irradiation and localized irradiation. Except for unusual circumstances, as in the high-dose irradiation that precedes bone marrow transplantation, significant levels of whole-body irradiation result only from industrial accidents or from nuclear weapons explosions. By contrast, localized irradiation is an inevitable byproduct of any diagnostic radiologic procedure and it is the intended result of radiation therapy. Rapid somatic cell death occurs only with extremely high doses of radiation, well in excess of 10 Gy. It is morphologically indistinguishable from coagulative necrosis produced by other causes (see Chapter 1). By contrast, irreversible damage to the replicative capacity of cells requires far lower doses, possibly as few as 50 cGy.

Whole-Body Irradiation Injures Many Organs

Fortunately, there have been few instances of human disease caused by whole-body irradiation, and most of our information has been derived from studies of Japanese atom bomb survivors. Further information is now available from the study of the survivors of the much smaller sample of people exposed in the accident at the Chernobyl nuclear power plant in Ukraine in 1986.

Since comparable doses of radiant energy are transmitted to all organs in whole-body irradiation, development of the different acute radiation syndromes reflects the dissimilarities in vulnerability of the target tissues (Fig. 8-23).

- **300 cGy:** At this dose of whole-body radiation, a syndrome characterized by **hematopoietic failure** develops within 2 weeks. After initial depletion of circulating lymphocytes, a progressive decrease in formed elements of the blood eventually leads to bleeding, anemia and infection. The last is often the cause of death.
- **10 Gy:** In the vicinity of this dose, the main cause of death is related to the **gastrointestinal system**. Although gastrointestinal symptoms occur through the entire dose range of whole-body exposure, at higher levels, the entire epithelium of the gastrointestinal tract is destroyed within 3 days (i.e., the time of the normal life span of villous and crypt cells). As a result, fluid homeostasis of the bowel is disrupted and severe diarrhea and dehydration ensue. Moreover, the epithelial barrier to intestinal bacteria is breached; gut organisms invade

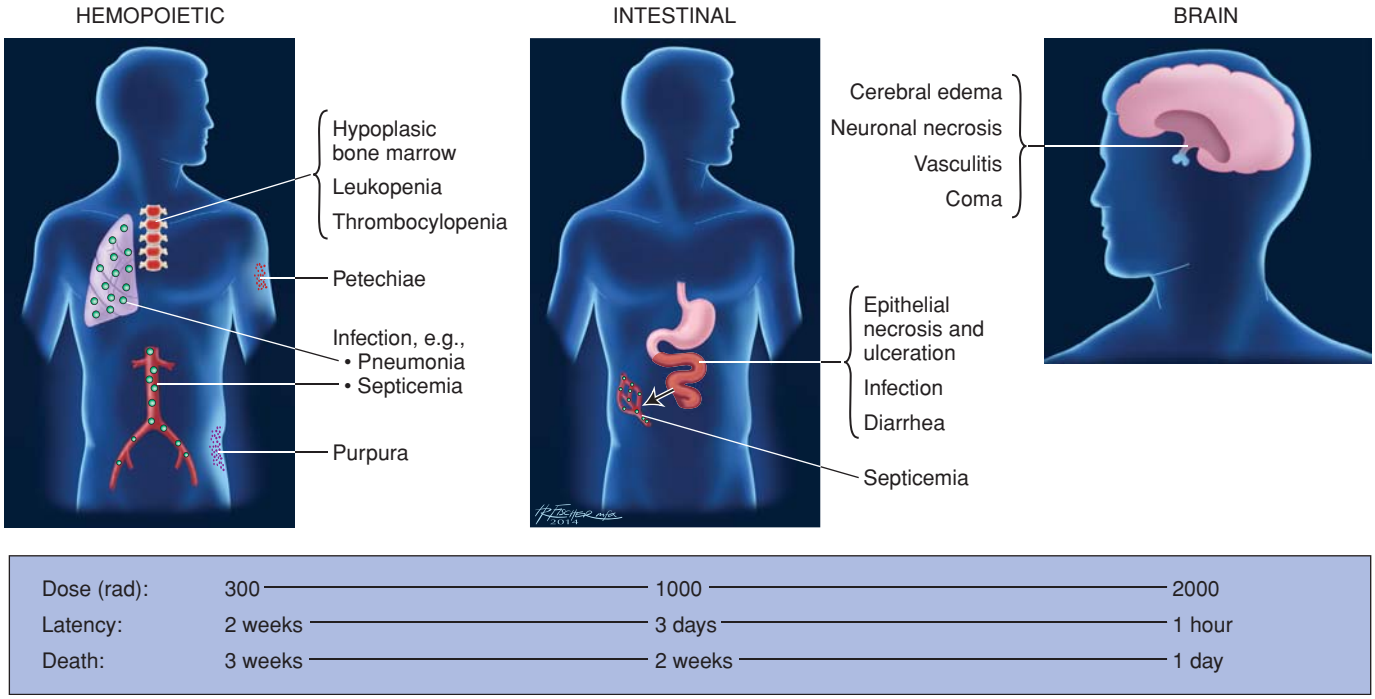

FIGURE 8-23. Acute radiation syndromes. At a dose of approximately 300 rads of whole-body radiation, a syndrome characterized by hematopoietic failure develops within 2 weeks. In the vicinity of 1000 rads, a gastrointestinal syndrome with a latency of only 3 days is seen. With doses of 2000 rads or more, disease of the central nervous system appears within 1 hour and death ensues rapidly.

and disseminate throughout the body. Septicemia and shock kill the victim.

- **20 Gy:** With whole-body doses of 20 Gy and above, CNS damage causes death within hours. In most cases, cerebral edema and loss of the integrity of the blood-brain barrier, owing to endothelial injury, predominate. With extreme doses, radiation necrosis of neurons can be expected. Convulsions, coma and death follow.

FETAL EFFECTS: The effects of whole-body irradiation on the human fetus have been documented in studies of Hiroshima nuclear bomb survivors. Pregnant women exposed to 25 cGy or more gave birth to infants with reduced head size, diminished overall growth and mental retardation.

In studies of the clinical status of children exposed to therapeutic doses of radiation between the 3rd and 20th weeks of gestation, growth retardation and microcephaly were observed. Other effects of irradiation in utero include hydrocephaly, microphthalmia, chorioretinitis, blindness, spina bifida, cleft palate, clubfeet and genital abnormalities. Data from experimental and human studies strongly suggest that major congenital malformations are highly unlikely at doses below 20 cGy after day 14 of pregnancy. However, lower doses may produce more-subtle effects, such as a decrease in mental capacity. ***To protect against such a possibility, the established maximum permissible dose of radiation to the fetus from exposure of the expectant mother is far below the known teratogenic dose.***

GENETIC EFFECTS: Most data on which predictions of human genetic effects are based are derived from experimental data and analysis of nuclear bomb survivors. ***After long-term follow-up, survivors of the nuclear detonations at Hiroshima and Nagasaki have shown no evidence of genetic damage in the form of either congenital abnormalities or heritable diseases in subsequent offspring or their descendants.*** In experimental animals, the risk of induced mutation per cGy is at most 0.5%–5% of the risk of spontaneous mutation (the spontaneous risk of mutation in humans is estimated to be 10% of live births). By extension, 20–200 cGy of radiation is necessary to double the spontaneous mutation rate. Consequently, the risk of genetic damage to future generations from radiation appears to be small.

AGING: There is to date no evidence that radiation exposure leads to premature aging. A mortality study of survivors of the nuclear bomb explosions in Japan did not show excess mortality beyond that attributable to neoplasia. Nor is there any evidence of acceleration in disease among the survivors in any part of the age range.

Localized Radiation Injury Complicates Radiation Therapy for Tumors

In the course of radiation therapy for malignant neoplasms, some normal tissue is inevitably irradiated. Although almost any organ can be damaged by radiation, the skin, lungs, heart, kidney, bladder and intestine are susceptible and difficult to shield (Fig. 8-24). Localized damage to the bone marrow is clearly of little functional consequence because of the immense reserve capacity of the hematopoietic system.

PATHOLOGY: Persistent damage to radiation-exposed tissue can be attributed to (1) compromise of the vascular supply and (2) a fibrotic repair reaction to acute necrosis and chronic ischemia. Radiation-induced tissue injury predominantly affects small arteries and arterioles. The endothelial cells are the most sensitive elements in the blood vessels and in the short term exhibit

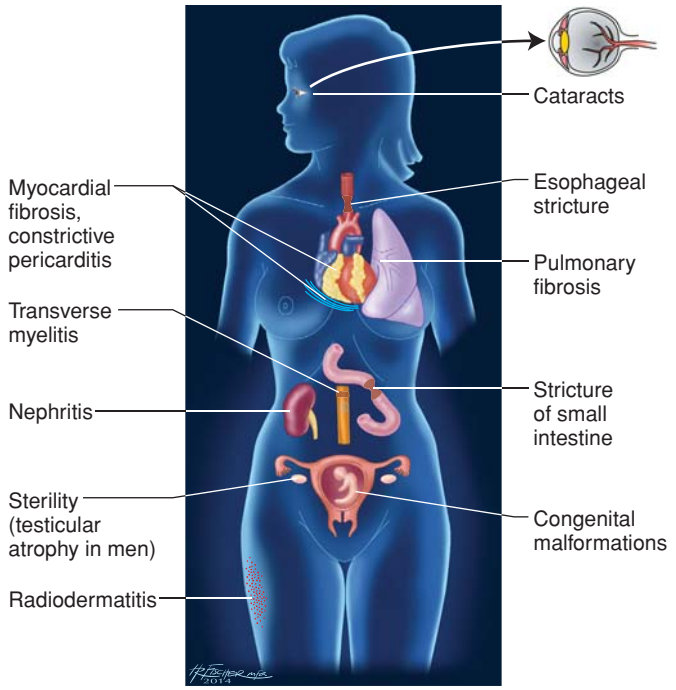

FIGURE 8-24. The nonneoplastic complications of radiation.

swelling and necrosis. With time, vascular walls become thickened by endothelial cell proliferation and subintimal deposition of collagen and other connective tissue elements. Striking vacuolization of intimal cells, so-called foam cells, is typical. Fragmentation of the internal elastic lamina, loss of smooth muscle cells, scarring in the media and fibrosis of the adventitia are seen in the small arteries. Bizarre fibroblasts with large hyperchromatic nuclei are common and probably reflect radiation-induced DNA damage.

CLINICAL FEATURES: Acute necrosis from radiation is represented by such disorders as **radiation pneumonitis, cystitis, dermatitis** and **diarrhea from enteritis**. Chronic disease is characterized by **interstitial fibrosis** in the heart and lungs, **strictures** in the esophagus and small intestine and **constrictive pericarditis**. Chronic **radiation nephritis,** which simulates malignant nephrosclerosis, is primarily a vascular disease that leads to severe hypertension and progressive renal insufficiency.

As radiation therapy inevitably traverses the skin, it often causes **radiation dermatitis**. The initial damage is evidenced by blood vessel dilation, recognized as **erythema**. Necrosis of the skin may follow and linger as **indolent ulcers** that do not heal because the epithelium is unable to regenerate. Impaired wound healing in irradiated tissues may pose serious problems for surgeons operating in those areas. **Poorly healed** or **dehisced wounds** or **persistent ulcers** often require full-thickness skin grafts. **Chronic radiation dermatitis** results from repair and revascularization of the skin and is characterized by atrophy, hyperkeratosis, telangiectasia and hyperpigmentation (Fig. 8-25).

The **gonads,** both testes and ovaries, are similar to other tissues in their dependence on continuous cell cycling and are exquisitely radiosensitive. Acute inhibition of mitosis in the testis results in necrosis of the germinal stem cells, the spermatogonia. The combination of radiation-induced vascular injury and direct damage to the germ cells leads to progressive atrophy of seminiferous tubules, peritubular fibrosis and loss of reproductive function. Interstitial and Sertoli cells do not cycle rapidly and so persist, thus preserving normal hormonal status. Comparable injury is seen in the irradiated ovary; the follicles become atretic and the organ eventually becomes fibrous and atrophic.

Cataracts (lenticular opacities) may be produced if the eye lies in the path of the radiation beam. **Transverse myelitis** and paraplegia occur when the spinal cord is unavoidably irradiated during treatment of certain thoracic or abdominal tumors. **Vascular damage in the cord** may bring about localized ischemia.

High Doses of Radiation Cause Cancer

The evidence that radiation can lead to cancer is incontrovertible and comes from many sources (Fig. 8-26). In the early part of the 20th century, scientists and radiologists tested their x-ray equipment by placing their hands in the path of the beam. As a result, they developed basal and squamous cell carcinomas of the exposed skin. In addition, early instruments were not properly shielded and the hazards associated with fluoroscopy were not appreciated. The radiologists of that era suffered an unusually high incidence of leukemia. This situation has been rectified with the use of modern shielding and protective equipment.

An unusual occupational exposure to radiation occurred among workers who painted radium-containing material onto watches to create luminous dials. These workers were in the habit of licking their paint brushes to produce a point, which led to their ingesting the radium. Since the

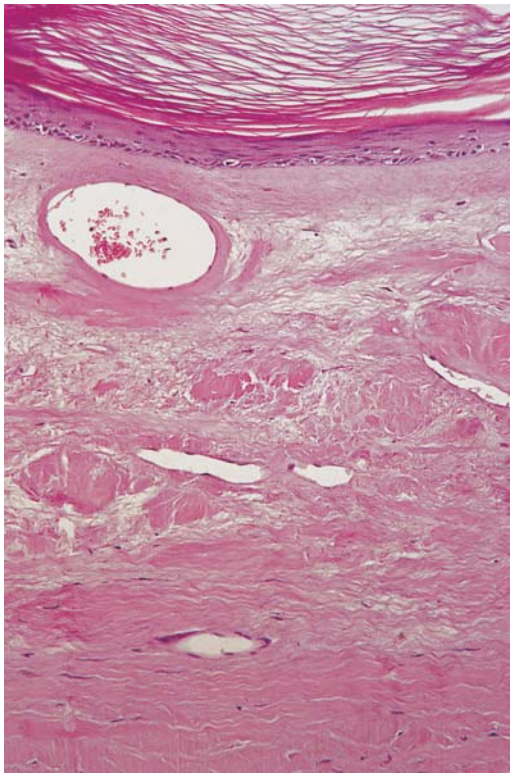

FIGURE 8-25. Chronic radiation dermatitis. The epidermis is atrophic. The dermis is densely fibrotic and contains dilated superficial blood vessels.

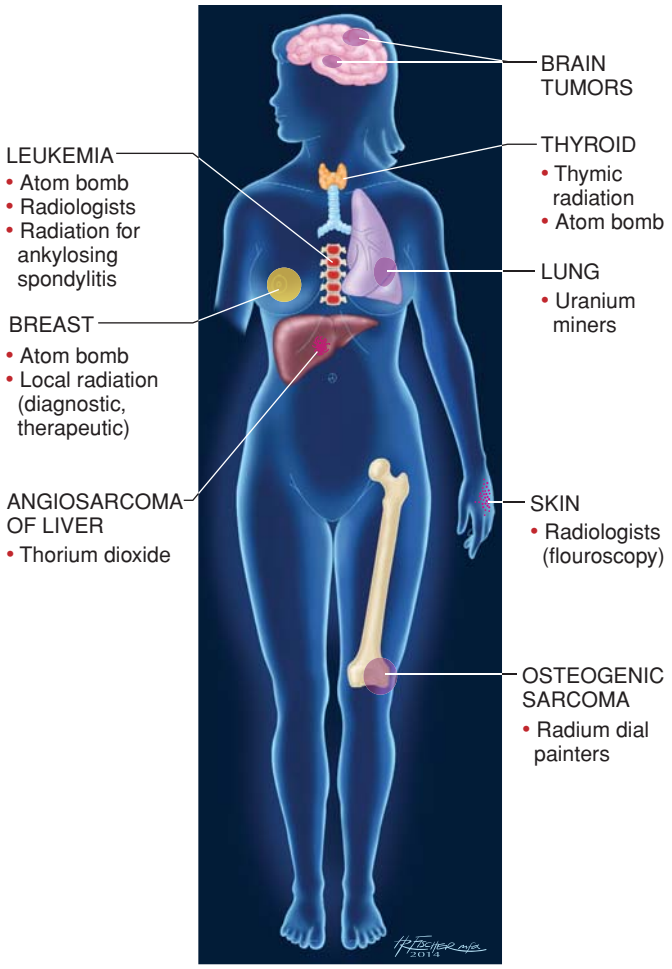

FIGURE 8-26. Radiation-induced cancers.

body handles radium as it does calcium, it subsequently localized in their bones, so they were exposed to a long-lived isotope that persisted in their bones indefinitely. These people experienced a high incidence of cancer of the bone and of the paranasal sinuses. Another example of occupational exposure to a radioactive element is the high rate of lung cancer in uranium miners who inhaled radioactive dust and radon gas. Most of these workers also smoked and evidence strongly favors a synergistic effect in lung carcinogenesis.

Iodine is concentrated by the thyroid. If radioactive iodine isotopes are inhaled or ingested, that gland will experience highly concentrated exposure to radioactivity. An explosive increase in the incidence of thyroid cancer among children in geographical areas contaminated by the nuclear catastrophe at Chernobyl in Ukraine in 1986 has been linked to release of radioactive iodine isotopes in that incident.

The risk of **solid tumors,** especially breast cancer, is particularly high among adult women who were treated with thoracic radiation for Hodgkin disease as children. Long-term survivors of childhood Hodgkin disease, who were treated with radiation therapy, have almost a 20-fold increased risk of developing a second neoplasm owing to the radiation. Another example of iatrogenic cancer resulted in Great Britain from widespread use of low-dose spinal irradiation to treat ankylosing spondylitis. These patients later developed aplastic anemia, acute myelogenous leukemia and other tumors with high frequency. An increase in brain tumors was found in people who had received cranial irradiation for tinea capitis infection of the scalp in childhood. Thorium dioxide (Thorotrast), a material avidly ingested by phagocytic cells, was used a few decades ago for radionuclide imaging. The persistence in the liver of a long-lived radioisotope resulted in development of hepatic angiosarcomas.

The survivors of the nuclear bomb explosions in Japan suffered from a number of cancers. They exhibited a more than 10-fold increase in the incidence of leukemia, which peaked 5–10 years after exposure, then declined to background rates. Two thirds were cases of acute leukemia; the remainder were of chronic myelogenous leukemia. Chronic lymphocytic leukemia, an uncommon disease in Japan, showed no increase in incidence. The risk of multiple myeloma increased five-fold and there was a small increment in the incidence of lymphoma. The frequency of solid tumors, although not as great as that for leukemia, was clearly increased for the breast, lung, thyroid, gastrointestinal tract and urinary tract. The development of malignant tumors, including leukemia, showed a dose-response relationship.

LOW-LEVEL RADIATION AND CANCER: Data from studies of cancer induction in animals, chromosomal damage in human cell cultures, malignant transformation of mammalian cells in vitro and populations exposed to radiation show that the estimates of risk at low radiation doses are very low. The data do not show that the risk of cancer from low-level radiation is zero. There is a general concern that gamma radiation is associated with increased risk of cancer at doses of 5–10 cGy. Although DNA damage appears to occur proportionately to the dose of gamma radiation, there is considerable uncertainty as to the extent to which DNA repair mechanisms may be protective at low radiation doses or dose rates.

RADON: The finding that some homes in the United States are contaminated with radon has elicited considerable public concern. Radon is a radioactive noble gas formed from the decay of uranium 238 (^{238}U), which is found in soil and rock formations. Radon is itself inert. Concern about the environmental hazards of radon focus on its radioactive decay products, which are called radon daughters. These include radioactive isotopes of bismuth, lead and polonium, which are chemically active and which bind to particulates and lung tissues. The half-life of the α-emitting isotope, ^{218}Po, is 103 years.

Previously, studies of the risk of radon gas were done in uranium miners and were not well controlled for smoking as an independent risk factor. More recent large-scale studies indicate that people who dwell in homes containing high concentrations of radon gas have an increased risk of developing lung cancer. The relative risk is by far the greatest for smokers and ex-smokers. However, recent studies also indicate that people who never smoked also have increased risk of lung cancer.

Microwave Radiation, Electromagnetic Fields and Ultrasound Are Not Ionizing

Microwaves, produced by ovens, radar and diathermy, are electromagnetic waves that penetrate tissue but do not produce ionization. Unlike x- and gamma radiation, absorption of microwave energy produces only heat. The activation

energy of radiofrequency and microwave radiation is too low to modify chemical bonds or alter DNA. Thus, exposure to microwave radiation under ordinary circumstances is highly unlikely to produce any injury. Moreover, a study of 20,000 radar technicians in the navy who were chronically exposed to high levels of microwave radiation failed to detect any increased incidence of cancer.

Controversy also surrounds possible carcinogenic—especially leukemogenic—effects of exposure to nonionizing electromagnetic fields, such as those encountered in the vicinity of high-voltage electric lines. Recent epidemiologic evidence has led to a consensus that exposure to electromagnetic fields does not raise the incidence of leukemia or other cancers.

Ultrasound, the vibrational waves in air above the audible range, produces mechanical compression but, again, no ionization. Highly focused and energetic ultrasound devices are used to disrupt tissue in vitro for chemical analysis and to clean various surfaces, including teeth. However, there is no reason to believe that diagnostic ultrasound or accidental exposure to any industrial device results in any measurable damage.

NUTRITIONAL DISORDERS

Protein-Calorie Malnutrition Reflects Starvation or Specific Deficiencies

Marasmus is the term used to denote a deficiency of calories from all sources. **Kwashiorkor** is a form of malnutrition in children caused by a diet deficient in protein alone.

Marasmus

Global starvation—that is, a deficiency of all elements of the diet—leads to marasmus. The condition is common throughout the nonindustrialized world, particularly when breast feeding is stopped and a child must subsist on a calorically inadequate diet. Pathologic changes are similar to those in starving adults and include decreased body weight, diminished subcutaneous fat, a protuberant abdomen, muscle wasting and a wrinkled face. In general, the child is a "shrunken old person." Wasting and increased lipofuscin pigment are seen in most visceral organs, especially the heart and the liver. No edema is present. Pulse, blood pressure and temperature are low; diarrhea is common. Since immune responses are impaired, the child suffers from numerous infections. An important consequence of marasmus is **growth failure**. If these children are not provided with adequate food in childhood, they will not reach their full potential stature as adults. Severe marasmus accompanied by iron-deficiency anemia in early childhood, when brain development is under way, may result in permanent intellectual deficits.

Kwashiorkor

Kwashiorkor (Fig. 8-27) results from a **deficiency of protein** in diets relatively high in carbohydrates. It is one of the most common diseases of infancy and childhood in the nonindustrialized world. Like marasmus, it usually occurs after an infant is weaned, when a protein-poor diet, consisting principally of staple carbohydrates, replaces mother's milk. There is generalized growth failure and muscle wasting, as

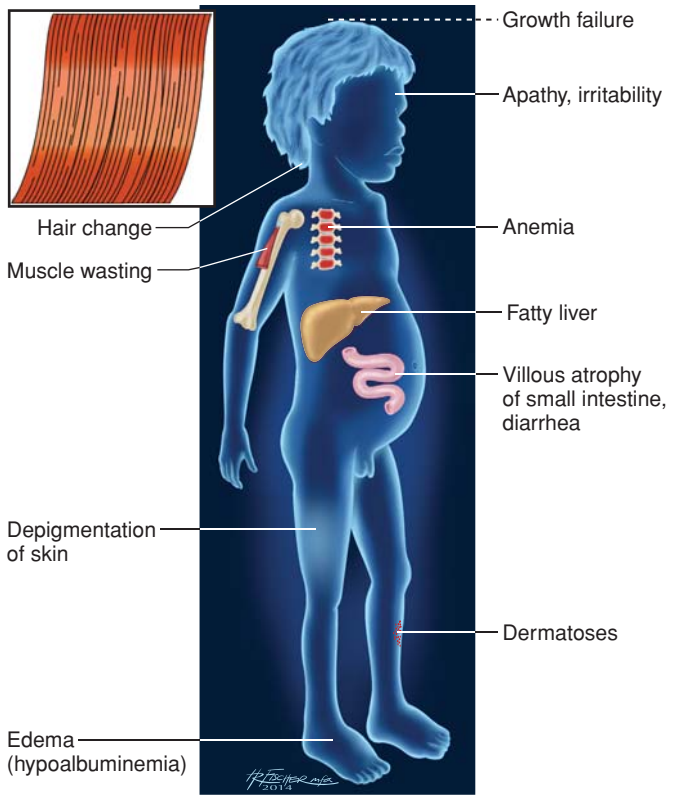

FIGURE 8-27. Complications of kwashiorkor.

in marasmus, but subcutaneous fat is normal, since caloric intake is adequate. Extreme apathy is notable, in contrast to children with marasmus, who may be alert. Also in contrast to marasmus, severe edema, hepatomegaly, depigmentation of the skin and dermatoses are usual. "Flaky paint" lesions of the skin on the face, extremities and perineum are dry and hyperkeratotic. Hair becomes a sandy or reddish color; a characteristic linear depigmentation of the hair ("flag sign") provides evidence of particularly severe periods of protein deficiency. The abdomen is distended because of flaccid abdominal muscles, hepatomegaly and ascites due to hypoalbuminemia. Along with general atrophy of the viscera, villous atrophy of the intestine may interfere with nutrient absorption. Diarrhea is common. Anemia is the rule, but it is not generally life-threatening. The nonspecific effects on growth, pulse, temperature and the immune system are similar to those in marasmus. It has been claimed in some studies that kwashiorkor not only impairs physical development but also stunts later intellectual growth.

PATHOLOGY: Microscopically, the liver in kwashiorkor is conspicuously fatty. Accumulation of lipid within the cytoplasm of the hepatocyte displaces the nucleus to the periphery of the cell. The adequacy of dietary carbohydrate provides lipid for the hepatocyte, but the inadequate protein stores do not permit synthesis of enough apoprotein carrier to transport the lipid from the liver cell. The changes, with the possible exception of mental retardation, are fully reversible when sufficient protein is made available. In fact, the fatty liver reverts to normal after early childhood, even if the diet remains deficient in protein. In any event, hepatic changes are not progressive and do not lead to chronic liver disease.

Vitamins Are Organic Catalysts That Are Both Required for Normal Metabolism and Available Only from Dietary Sources

Thus, vitamins in one species are not necessarily vitamins in another. For example, humans cannot synthesize ascorbic acid (vitamin C) and so require dietary ascorbate to prevent scurvy, but most lower animals can produce their own vitamin C and do not require it as a vitamin.

Vitamin A

Vitamin A is a fat-soluble substance that is important for skeletal maturation and maintenance of specialized epithelial linings and cell membrane structure. In addition, it is an important constituent of the photosensitive pigments in the retina. Vitamin A occurs naturally as **retinoids** or as a precursor, **β-carotene**. The source of the precursor—carotene—is in plants, principally leafy, green vegetables. Fish livers are a particularly rich source of vitamin A itself (retinoids).

Vitamin A appears to be important in immune function and nonimmune defense mechanisms. It has long been known that vitamin A deficiency is associated with poor resistance to infection. Administration of vitamin A to deficient people reduces all overall mortality. In addition, in underdeveloped countries, vitamin A supplementation to pregnant women and their children has reduced infant mortality.

Metabolism

β-Carotene is modified in the intestinal mucosa to retinoids, which are absorbed with chylomicrons. It is stored in the liver, where 90% of the body's vitamin A is located. At times when fat absorption is impaired (e.g., diarrhea), vitamin A absorption decreases.

Vitamin A Deficiency

Although vitamin A deficiency is uncommon in developed countries, it is a significant health problem in poorer regions of the world, including much of Africa, China and Southeast Asia.

PATHOLOGY: ***Deficiency of vitamin A results principally in squamous metaplasia, especially in glandular epithelium*** (Fig. 8-28). Thus, keratin debris blocks sweat and tear glands. Squamous metaplasia is common in the trachea and bronchi and bronchopneumonia is a frequent cause of death. The epithelia lining the renal pelvis, pancreatic ducts, uterus and salivary glands are also commonly affected. Epithelial changes in the renal pelvis may be associated with kidney stones. With further diminution of vitamin A stores, squamous metaplasia of conjunctival and tear duct epithelial cells occurs, which leads to **xerophthalmia,** dryness of the cornea and conjunctiva. The cornea becomes softened (**keratomalacia,** Fig. 8-29) and vulnerable to ulceration and bacterial infection, which may lead to blindness. **Follicular hyperkeratosis,** a skin disorder caused by occluded sebaceous glands, is also a feature of this disease.

CLINICAL FEATURES: The earliest sign of vitamin A deficiency often is diminished vision in dim light. Vitamin A is a necessary component in retinal rod pigment and is active in light transduction.

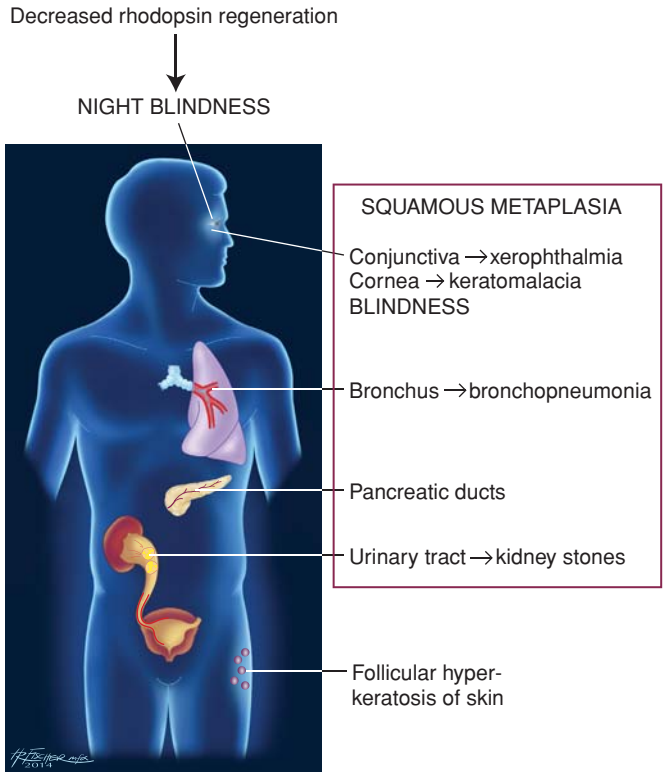

FIGURE 8-28. Complications of vitamin A deficiency.

Because vitamin A aldehyde, retinal, is constantly degraded in generating the light signal, a continuous supply of vitamin A is necessary for night vision.

Vitamin A Toxicity

Vitamin A poisoning is usually caused by overenthusiastic administration of vitamin supplements to children. Early Arctic explorers were said to have experienced vitamin A toxicity because they ate polar bear liver, which is particularly rich in the vitamin. Enlargement of the liver and spleen are common; microscopically, these organs show lipid-laden macrophages. In the liver, vitamin A is also present in hepatocytes, and prolonged hypervitaminosis A has been incriminated in rare cases of cirrhosis. Bone pain and neurologic

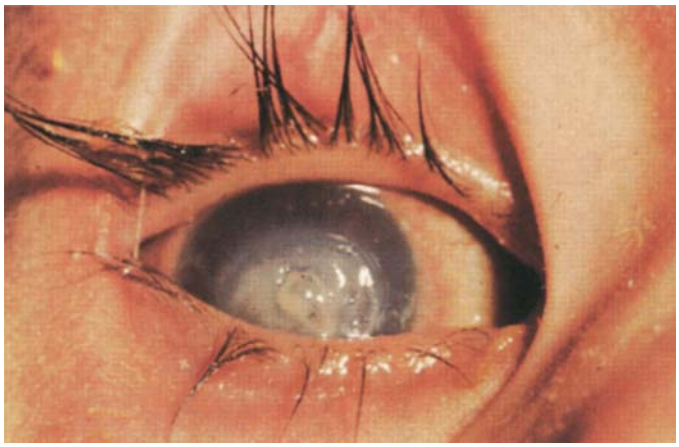

FIGURE 8-29. Keratomalacia in vitamin A deficiency.

TABLE 8-5
B VITAMINS

Vitamin	Biochemical Name
B_1	Thiamine
B_2	Riboflavin
B_3	Niacin
B_5	Pantothenic acid
B_6	Pyridoxine
B_7	Biotin
B_9	Folic acid
B_{12}	Cyanocobalamin

symptoms, such as hyperexcitability and headache, may be the presenting symptoms. Discontinuing the excess vitamin A consumption reverses all or most of the lesions. Excessive carotene intake is benign and simply stains the skin yellow, which may be mistaken for jaundice.

Synthetic derivatives of retinoic acid are now used pharmacologically to alleviate severe acne. Both retinoic acid and a high dietary intake of preformed vitamin A are particularly dangerous in pregnancy because they are potent teratogens. A number of clinical studies have reported that excess intake of vitamin A leads to reduced bone mineral density and consequently increases the incidence of bone fractures.

Vitamin B Complex

Vitamins in the B group of water-soluble vitamins are numbered 1 through 12, but only eight are distinct vitamins (Table 8-5).

Thiamine (B_1)

Thiamine was the active ingredient in the original description of vitamin B, which was defined as a water-soluble extract in rice polishings that cured beriberi (clinical thiamine deficiency). The vitamin is an essential cofactor in the activity of several enzymes crucial to energy metabolism, mainly in the tricarboxylic acid (Krebs) cycle. Thiamine deficiency was classically seen in the Orient, where the staple food was polished rice that had been deprived of its thiamine content by processing. With increased awareness of the disease and improved nutrition in some areas of Asia, the disorder is less common now than in previous generations. In Western countries, the disease occurs in alcoholics, neglected people with poor overall nutrition and food faddists. ***The cardinal symptoms of thiamine deficiency are polyneuropathy, edema and cardiac failure*** (Fig. 8-30). The deficiency syndrome is classically divided into **dry beriberi,** with symptoms referable to the neuromuscular system, and **wet beriberi,** in which manifestations of cardiac failure predominate.

Thiamine deficiency in chronic alcoholics may be manifested by CNS involvement, in the form of Wernicke syndrome, in which progressive **dementia, ataxia and ophthalmoplegia** (paralysis of the extraocular muscles) are

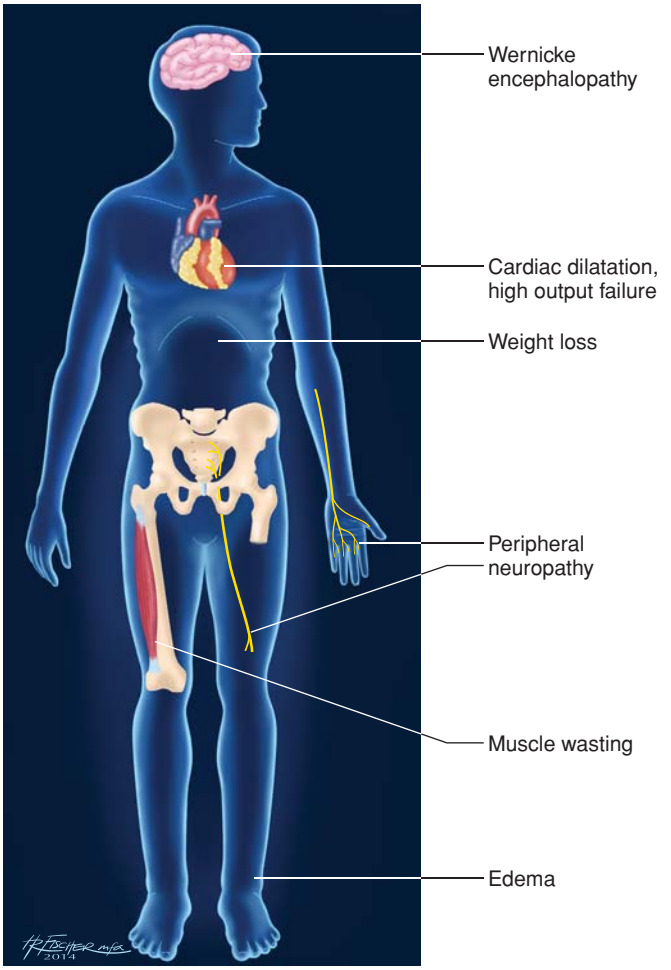

FIGURE 8-30. Complications of thiamine deficiency (beriberi).

prominent. Korsakoff syndrome, in which a thought disorder is conspicuous, at one time was attributed solely to thiamine deficiency but is now understood to be seen both in chronic alcoholics and in patients with other organic mental syndromes.

PATHOLOGY: Pathologic examination of the nervous system in thiamine deficiency has not defined a pathognomonic change in the peripheral nerves, given that similar or identical changes can be seen with other peripheral neuropathies. A characteristic alteration is myelin sheath degeneration, which often begins in the sciatic nerve, then involves other peripheral nerves and sometimes the spinal cord itself. In advanced cases, axon fragmentation may be seen.

The most striking lesions in Wernicke encephalopathy are found in the mamillary bodies and surrounding areas that abut on the third ventricle (see Chapter 32). Indeed, atrophy of the mamillary bodies can be visualized in alcoholics by computed tomography and magnetic resonance imaging. Microscopically, degeneration and loss of ganglion cells, rupture of small blood vessels and ring hemorrhages are seen in the brain.

The changes in the heart are also nonspecific. Grossly, the heart is flabby, dilated and increased in weight. The process may affect either the right or the left side of the heart or both. The microscopic changes are nondescript and include

edema, inconsistent fiber hypertrophy and occasional foci of fiber degeneration.

CLINICAL FEATURES: Patients with dry beriberi present with paresthesias, depressed reflexes and weakness and muscle atrophy in the extremities. Wet beriberi is characterized by generalized edema, a reflection of severe congestive failure. The basic lesion is uncontrolled, generalized vasodilation and significant peripheral arteriovenous shunting. This combination leads to a compensatory increase in cardiac output and eventually to a large dilated heart and congestive heart failure. In a patient without documented metabolic disease (e.g., hyperthyroidism), high output failure and generalized edema strongly suggest thiamine deficiency.

The most reliable diagnostic test for thiamine deficiency is an immediate and dramatic response to parenteral administration of thiamine. Measurements of thiamine in the blood and erythrocyte transketolase activity are also useful.

Riboflavin (B_2)

Riboflavin, a vitamin derived from many plant and animal sources, is important for synthesis of flavin nucleotides, which are important in electron transport and other reactions in which energy transfer is crucial. Riboflavin is converted within the body to flavin mononucleotides and dinucleotides. Clinical symptoms of riboflavin deficiency are uncommon; they are usually seen only in debilitated patients with a variety of diseases and in poorly nourished alcoholics.

Deficiencies of thiamine, riboflavin and niacin are unusual in industrialized countries because bread and cereals are fortified with these vitamins. Occasionally, a mild riboflavin deficiency is seen during pregnancy and lactation, or during a phase of rapid growth in childhood and adolescence, when increased demands are combined with moderate nutritional deprivation.

PATHOLOGY AND CLINICAL FEATURES: Riboflavin deficiency, when it occurs, is almost always seen in conjunction with deficiencies of other water-soluble vitamins. It is manifested principally by lesions of the facial skin and corneal epithelium. **Cheilosis,** a term used for fissures in the skin at the angles of the mouth, is a characteristic feature (Fig. 8-31). These cracks in the skin may be painful and often become infected.

Hyperkeratosis and a mild mononuclear infiltrate of the skin are noted. **Seborrheic dermatitis,** an inflammation of the skin that exhibits a greasy, scaling appearance, typically involves the cheeks and the areas behind the ears. The tongue is smooth and purplish (magenta), owing to mucosal atrophy. The most troubling lesion may be **corneal interstitial keratitis,** which is followed by opacification of the cornea and eventual ulceration. The localization of the lesions in riboflavin deficiency is not explained biochemically. There is no known toxicity from ingesting large amounts of riboflavin.

Niacin (B_3)

Niacin refers to nicotinic acid. Nicotinic acid is derived from dietary sources or biosynthesized from tryptophan. In the body, nicotinic acid is converted to nicotinamide, which plays a major role in formation of NAD. This compound and its phosphorylated derivative, NADP, are

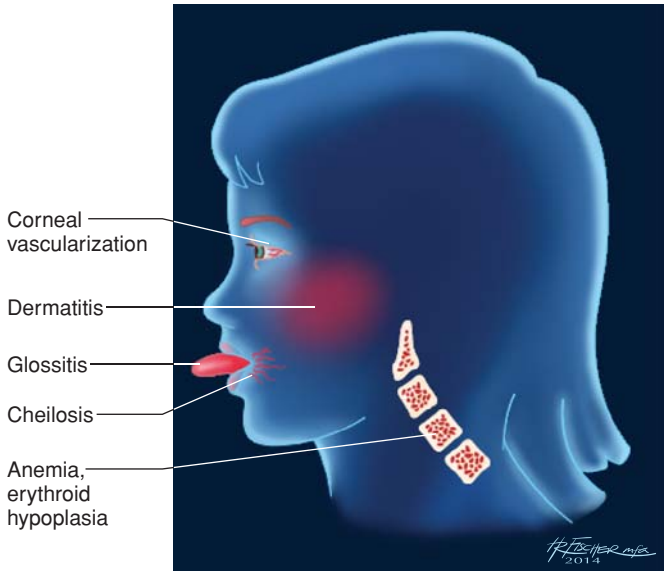

FIGURE 8-31. Complications of riboflavin deficiency.

important in intermediary metabolism and an extensive variety of oxidation–reduction reactions. Animal protein, as found in meat, eggs and milk, is high in tryptophan and is therefore a good source of endogenously synthesized niacin. Niacin itself is available in many types of grain. **Pellagra** is the term for clinical niacin deficiency. It is uncommon today.

ETIOLOGIC FACTORS: Pellagra is seen principally in patients who have been weakened by other diseases and in malnourished alcoholics. Food faddists who do not eat sufficient protein may suffer a deficiency of tryptophan, which in combination with a lack of exogenous niacin may result in mild pellagra. Malabsorption of tryptophan, as in Hartnup disease, or excessive use of tryptophan for serotonin synthesis in the carcinoid syndrome may also lead to mild symptoms of pellagra. Deficiencies of pyridoxine and riboflavin increase the requirement for dietary niacin because both of these cofactors are required for biosynthesis of niacin from tryptophan. Pellagra is particularly prevalent in areas where corn (maize) is the staple food, because the niacin in corn is chemically bound and thus poorly available. Corn is also a poor source of tryptophan.

PATHOLOGY: Pellagra (Ital., "rough skin") is characterized by the three "Ds" of niacin deficiency: **dermatitis, diarrhea** and **dementia** (Fig. 8-32). Areas exposed to light, such as the face and the hands, and those subjected to pressure, such as the knees and the elbows, exhibit a rough, scaly dermatitis (Fig. 8-33). The involvement of the hands leads to so-called glove dermatitis. The lesions are discrete and show areas of pigmentation and of depigmentation. Microscopically, hyperkeratosis, vascularization and chronic inflammation of the skin are characteristic. Subcutaneous fibrosis and scarring may be seen in late stages. Similar lesions are found in the mucous membranes of the mouth and vagina. In the mouth, inflammation and edema lead to a large, red tongue, which in the chronic stage is fissured and is likened to raw meat. Chronic, watery diarrhea is

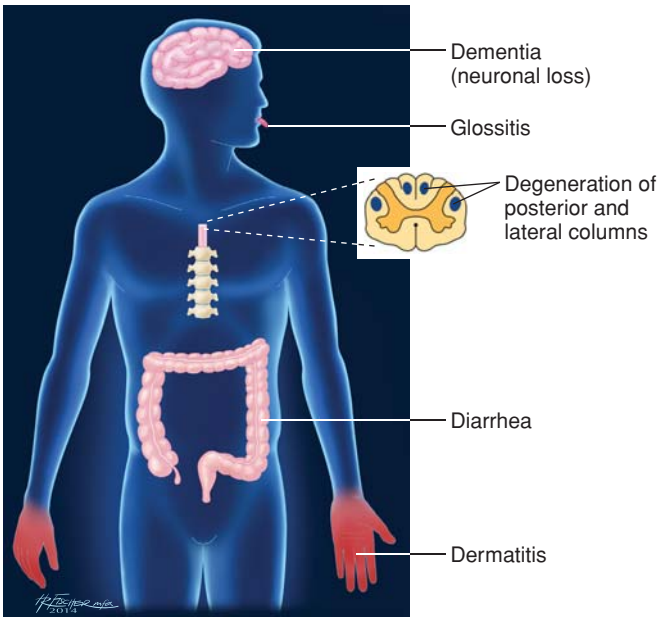

FIGURE 8-32. Complications of niacin deficiency (pellagra).

typical for the disease, presumably due to mucosal atrophy and ulceration in the entire gastrointestinal tract, particularly in the colon. The dementia, characterized by aberrant ideation bordering on psychosis, is represented in the brain by degeneration of ganglion cells in the cortex. Myelin degeneration of tracts in the spinal cord resembles the subacute combined degeneration of vitamin B_{12} deficiency. Severe long-standing pellagra adds another **"D,"** namely, death.

FIGURE 8-33. Pellagra. Dermatitis in sun-exposed areas of the arms and around the neck in this elderly woman is shown.

In pharmacologic doses, niacin supplements decrease levels of low-density lipoprotein (LDL) cholesterol and increase levels of high-density lipoprotein (HDL) cholesterol, thus providing a useful adjunct in preventing atherosclerosis.

Pantothenic Acid (B_5)

Pantothenic acid serves as a component of coenzyme A (CoA) and is an essential cofactor in the biosynthesis of fatty acids and certain peptides. Major sources of pantothenic acid include beef, chicken, liver, eggs, grains and a number of vegetables.

Deficiency of pantothenic acid is distinctly uncommon, except in severe malnutrition. The syndrome is characterized by behavioral, neurologic and gastrointestinal disturbances.

There are no known adverse effects of overconsumption of pantothenic acid.

Pyridoxine (B_6)

Vitamin B_6 activity is found in three related, naturally occurring compounds: pyridoxine, pyridoxal and pyridoxamine. For convenience, they are grouped under the heading pyridoxine. These compounds are widely distributed in vegetable and animal foods. Vitamin B_6 functions as a coenzyme in numerous metabolic pathways, including those related to amino acids, lipids, methylation and decarboxylation, gluconeogenesis, heme and neurotransmitters. Some studies also suggest a role for vitamin B_6 in maintaining normal B- and T-cell immune function.

EPIDEMIOLOGY: Population studies have incriminated low levels of pyridoxine in increasing risk of atherosclerosis, but the mechanisms for this effect remain obscure. Low blood levels of vitamin B_6 have also been correlated with a number of conditions such as aging, impaired renal function and inflammatory conditions. The relevance of these correlations merits further study.

A recent analysis of prospective studies suggests a 20% lower risk of colorectal cancer when comparing people with high versus low intake of vitamin B_6. The report found that low blood levels of the active form of vitamin B_6, namely, pyridoxal 5-phosphate, correlated with increased risk of developing colorectal cancer.

In the United States, it is estimated that vitamin B_6 intake is inadequate for about 20% of men over age 50 years and for 40% of women in the same age group.

ETIOLOGIC FACTORS: Pyridoxine is converted to pyridoxal phosphate, a coenzyme for many enzymes, including transaminases and carboxylases. Pyridoxine deficiency is rarely caused by an inadequate diet, although infants who have been fed poorly prepared powdered formula in which pyridoxine was destroyed during preparation have suffered convulsions. A higher demand for the vitamin, as may occur in pregnancy, may lead to a secondary deficiency state. Of particular concern is the deficiency of pyridoxine that follows prolonged medication with a number of drugs, particularly isoniazid, cycloserine and penicillamine. A deficiency state is also occasionally reported in alcoholics.

CLINICAL FEATURES: There are no clinical manifestations of pyridoxine deficiency that can be considered characteristic or pathognomonic. The

usual dermatologic complications of other B vitamin deficiencies occur with pyridoxine deficiency. ***The primary expression of the disease is in the CNS, a feature consistent with the role of this vitamin in the formation of pyridoxal-dependent decarboxylase of the neurotransmitter GABA.*** In infants and children, diarrhea, anemia and seizures have occurred.

Conditions are encountered in which there is no clinical or biochemical evidence of pyridoxine deficiency, yet large (pharmacologic) doses of the vitamin are useful in treating the disorder. Such diseases are called pyridoxine-dependency syndromes and include anemia, convulsions and homocystinuria caused by cystathionine synthetase deficiency.

Pyridoxine-responsive anemia is hypochromic and microcytic and therefore can be confused with iron-deficiency anemia. Unlike iron-deficiency anemia, however, pyridoxine-responsive anemia is characterized by saturation of iron stores and increased saturation of transferrin. Thus, administration of iron may simply make pyridoxine-responsive anemia worse. By definition, the anemia responds well to massive doses of pyridoxine.

Biotin (B_7)

Most biotin is found in meats and cereals, where it is largely bound to protein. Biotin is an obligatory cofactor for five carboxylases that participate in intermediary metabolism, including the Krebs cycle.

ETIOLOGIC FACTORS: **Biotin deficiency** is reported in people who consume large amounts of raw eggs, in those with prolonged malabsorption syndrome and in children with severe protein-calorie malnutrition. Chronic administration of anticonvulsant drugs can also lead to biotin depletion.

CLINICAL FEATURES: Symptoms of biotin deficiency include seborrheic and eczematous skin rash. In adults, neurologic symptoms include lethargy, hallucinations and paresthesias. In infants, hypotonia and developmental delay have been reported.

There are no known adverse consequences of high-dose biotin administration.

Folic Acid (B_9)

Folic acid is a heterocyclic derivative of glutamic acid and serves as a methyl group donor, especially in nucleotide synthesis. Folate, together with vitamin B_{12} (see below), is a key cofactor in methylation reactions. One of the key reactions in question is the conversion of homocysteine to methionine, which is needed to generate S-adenosylmethionine (SAM). SAM is a key methyl donor in the synthesis of neurotransmitters (norepinephrine to epinephrine), phospholipids (phosphatidylethanolamine to phosphatidylcholine), methylated nucleotides and histones. Folate also is critical in the generation of purine nucleotides and the conversion of uracil to thymidine. The latter reaction is important for understanding the consequences of folate deficiency in causing megaloblastic anemia.

FOLATE DEFICIENCY: Folic acid and vitamin B_{12} (see below) both participate in the pathway to produce methionine (see above), and the extent of the role of SAM in diverse biochemical reactions explains the extent of the overlap between the manifestations of deficiencies of these two vitamins (e.g., megaloblastic anemia; see Chapter 26). The distinction between deficiencies of these two B vitamins was elucidated by Herbert, who, in 1962, developed megaloblastic anemia following a self-imposed experimental diet lacking only folate.

Folate is present in almost all foods, including meat, dairy products, seafood, cereals and vegetables. Deficiency is thus usually a consequence of a generally poor diet, as is seen in some alcoholics, rather than a diet deficient in any single constituent. Malabsorption syndromes may also result in folate deficiency. Because the settings in which folate deficiency occurs affect many nutrients, isolated folate deficiency is rare.

Folate supplements given during early pregnancy have been shown to decrease the incidence of fetal neural tube defects. This effect is not clearly related to a folate deficiency and may be a pharmacologic benefit. Because neural tube formation occurs before many women know they are pregnant, fortification of cereal and grain products with folic acid has been mandated in the United States since 1998.

Cyanocobalamin (B_{12})

Deficiency of vitamin B_{12} is almost always seen in cases of pernicious anemia and results from the lack of secretion of intrinsic factor in the stomach (see Chapter 19), which prevents absorption of the vitamin in the ileum.

ETIOLOGIC FACTORS: Since vitamin B_{12} is found in almost all animal protein, including meat, milk and eggs, dietary deficiency is seen only in rare cases of extreme vegetarianism and then only after many years of a restricted diet. Parasitization of the small intestine by the fish tapeworm *Diphyllobothrium latum* (from undercooked fish) may lead to vitamin B_{12} deficiency because the parasite absorbs the vitamin in the gut lumen.

CLINICAL FEATURES: Deficiency of vitamin B_{12} is associated with megaloblastic anemia. In addition, pernicious anemia is complicated by a neurologic condition called subacute combined degeneration of the spinal cord. Comprehensive discussions of vitamin B_{12} deficiency are found in Chapters 26 and 32.

Choline

Choline is an amine that is found in many foods, especially wheat products, peanuts, soybeans, fish and meat. It is incorporated principally into membrane phospholipids and is the major dietary source of methyl groups. Choline is necessary for lipid signaling, transport and metabolism, and for cholinergic neurotransmission. It is also important in reactions involving transfer of methyl groups. Because there is an endogenous pathway for choline biosynthesis, it was not considered to be an essential human nutrient. Recently, however, choline deficiency syndromes have been identified and adequate dietary levels are now established.

Experimentally, a choline-deficient diet led to evidence of liver and muscle damage. Patients maintained on total parenteral nutrition due to short bowel syndrome often develop liver disease, some of which can be prevented by choline supplementation.

Vitamin C (Ascorbic Acid)

The effects of vitamin C deficiency, namely, **scurvy,** were described 5000 years ago in Egyptian hieroglyphs and were mentioned by Hippocrates in 500 BC.

PATHOPHYSIOLOGY: Ascorbic acid is a water-soluble vitamin that is a powerful biological reducing agent involved in many oxidation/reduction reactions and in proton transfer. It is important for chondroitin sulfate synthesis and for proline hydroxylation to form the hydroxyproline of collagen. Ascorbic acid serves many other important functions: it prevents oxidation of tetrahydrofolate and augments absorption of iron from the gut. Without vitamin C, biosynthesis of certain neurotransmitters is impaired, leading to, for example, a reduction in dopamine β-hydroxylase activity. Wound healing and immune functions also involve ascorbic acid. The best dietary sources of vitamin C are citrus fruits, green vegetables and tomatoes.

Scurvy is the clinical vitamin C deficiency state. The first demonstration of the need for this vitamin was the remarkable effect of lime in preventing scurvy among 18th-century British sailors. The distribution of limes in the British navy led to the name "limey" for the seamen. Scurvy is uncommon in the Western world, but is often noted in nonindustrialized countries in which other forms of malnutrition are prevalent. In industrialized countries, scurvy is now a disease of people afflicted with chronic diseases who do not eat well, the neglected aged and malnourished alcoholics. The stress of cold, heat, fever or trauma (accidental or surgical) leads to an increased requirement for vitamin C. Children who are fed only milk for the first year of life develop scurvy, as do alcoholics. Mild depression of ascorbic acid levels also occurs in other conditions, including cigarette smoking, tuberculosis, rheumatic fever and many debilitating disorders. About 3% of the body's ascorbic acid is catabolized per day.

PATHOLOGY: ***Most of the events associated with vitamin C deficiency are caused by formation of abnormal collagen that lacks tensile strength*** (Fig. 8-34). Within 1–3 months, subperiosteal hemorrhages lead to pain in bones and joints. Petechial hemorrhages, ecchymoses and purpura are common, particularly after mild trauma or at pressure points. Perifollicular hemorrhages in the skin are particularly typical of

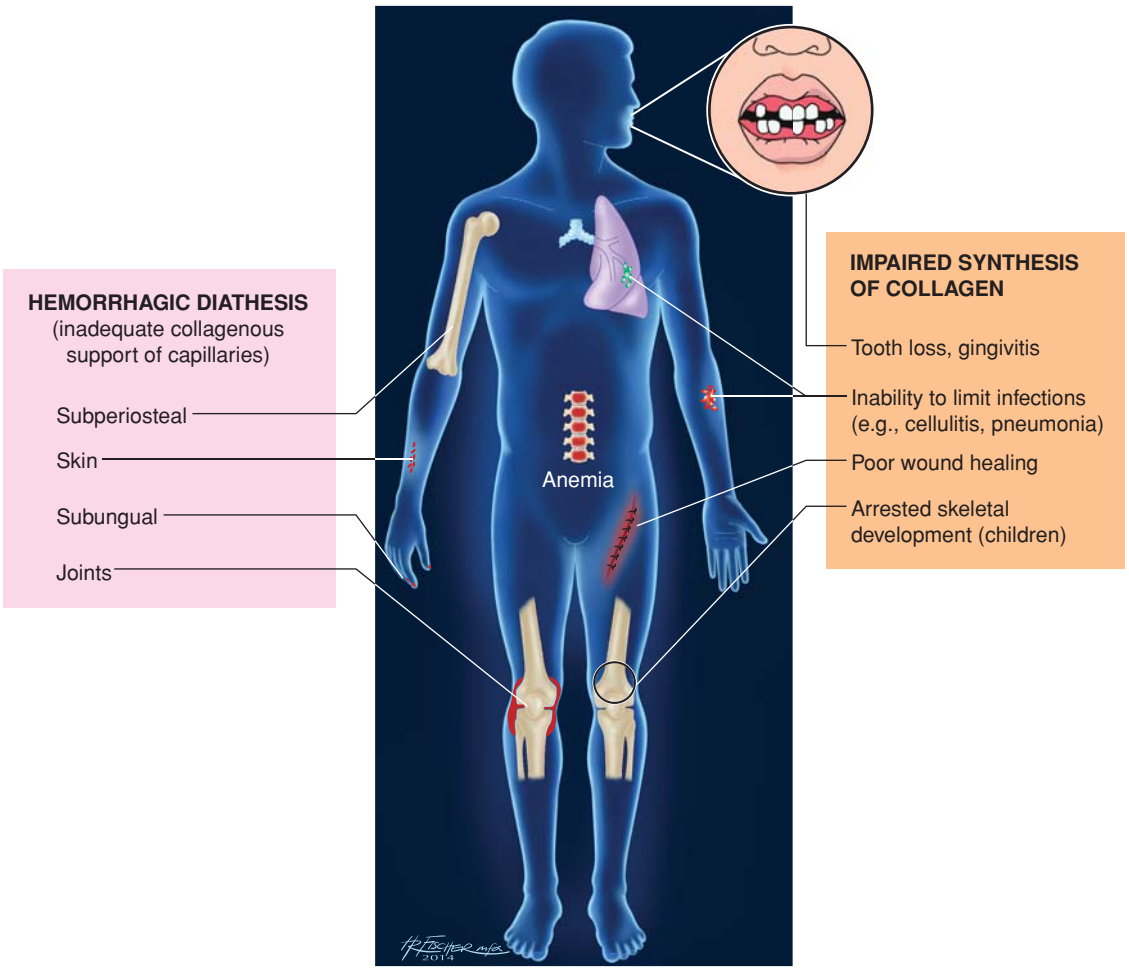

FIGURE 8-34. Complications of vitamin C deficiency (scurvy).

scurvy. In advanced cases, swollen, bleeding gums are a classic finding. Alveolar bone resorption results in loss of teeth. Wound healing is poor and dehiscence of previously healed wounds occurs. Anemia may result from prolonged bleeding, impaired iron absorption or associated folic acid deficiency.

In children, vitamin C deficiency leads to growth failure and collagen-rich structures such as teeth, bones and blood vessels develop abnormally. Effects on developing bone are conspicuous and relate principally to impaired function of osteoblasts (see Chapter 30). In addition to poor wound healing, scorbutic patients have difficulty walling off infections to form abscesses, so that infections spread more easily. The diagnosis of scurvy is confirmed by finding low levels of ascorbic acid in the serum.

While the claims that ascorbic acid may help to prevent upper respiratory infections lack substantiation, ingestion of large amounts of vitamin C is not known to be harmful.

Vitamin D

Some 500,000,000 years ago, vitamin D first appeared on Earth in ocean-dwelling phytoplankton, in which it may have functioned to absorb ultraviolet irradiation or act as a photochemical signal. During evolution, terrestrial vertebrates became dependent on vitamin D for the sustenance of their bony skeletons.

Vitamin D is a fat-soluble steroid hormone found in two forms: vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol), both of which have equal biological potency in humans. Vitamin D_3 is produced in the skin and vitamin D_2 is derived from plant ergosterol. The vitamin is absorbed in the jejunum along with fats and is transported in the blood bound to an α-globulin (vitamin D–binding protein). ***To achieve biological potency, vitamin D must be hydroxylated to active metabolites in the liver and kidney. The active form of the vitamin promotes calcium and phosphate absorption from the small intestine and may directly influence mineralization of bone.***

The discovery of nuclear receptors for 1,25(OH)2-vitamin D in various tissues not related to calcium metabolism has led to a search for pharmacologic applications of this vitamin. It may have uses in the treatment of psoriasis, hypertension, possibly certain cancers and multiple sclerosis.

Vitamin D Deficiency

ETIOLOGIC FACTORS: ***In children, vitamin D deficiency causes rickets; in adults, osteomalacia occurs.*** Vitamin D deficiency results from (1) insufficient dietary vitamin D, (2) insufficient production of vitamin D in the skin because of limited sunlight exposure, (3) inadequate absorption of vitamin D from the diet (as in the fat malabsorption syndromes) or (4) abnormal conversion of vitamin D to its bioactive metabolites. The last occurs in liver disease and chronic renal failure.

CLINICAL FEATURES: The bone lesions of vitamin D deficiency in children (rickets) have been recognized for centuries and were common in the Western industrialized world until recently. It was a disease that affected the urban poor to a much greater extent than their rural counterparts. A partial explanation for this difference lies in the greater exposure of rural residents to sunlight. Addition of vitamin D to milk and many processed foods, administration of vitamin preparations to young children and generally improved levels of nutrition have made rickets a curiosity in industrialized countries. See Chapter 26 for more details.

Hypervitaminosis D

The most common cause of excess vitamin D is the inordinate consumption of vitamin preparations. Abnormal conversion of vitamin D to biologically active metabolites is occasionally seen in granulomatous diseases such as sarcoidosis. In cases of calcium malabsorption, when the underlying disease is corrected, the sensitivity of target tissues to vitamin D may be increased.

PATHOLOGY: The initial response to excess vitamin D is **hypercalcemia,** which leads to nonspecific symptoms such as weakness and headaches. Increased renal calcium excretion results in **nephrolithiasis** or **nephrocalcinosis. Ectopic calcification** in other organs, such as blood vessels, heart and lungs, may be seen. Infants are particularly susceptible to excess vitamin D, and if the condition is not corrected, they may develop premature arteriosclerosis, supravalvular aortic stenosis and renal acidosis.

Vitamin E

Vitamin E is an antioxidant that (experimentally at least) protects membrane phospholipids against lipid peroxidation by free radicals formed by cellular metabolism. The activity of this fat-soluble vitamin is found in a number of dietary constituents, principally in α-tocopherol. Corn and soy beans are particularly rich in vitamin E.

Dietary deficiency of vitamin E can occur in children as a result of mutations in the α-tocopherol transfer protein and in adults with various malabsorption syndromes. The deficiency may present clinically as spinocerebellar ataxia, skeletal myopathy and pigmented retinopathy.

In premature infants, hemolytic anemia, thrombocytosis and edema have been associated with vitamin E deficiency. Vitamin E therapy has been reported to improve hemolytic anemia in premature newborns and may reduce the severity but not the incidence of retrolental fibroplasia. Vitamin E is reported to retard development of cirrhosis in infants with congenital biliary atresia. A number of interesting experimental effects are produced by vitamin E, such as inhibition of (1) platelet aggregation, (2) conversion of dietary nitrites to carcinogenic nitrosamines and (3) prostaglandin synthesis. Protection against toxins that exert their activity through production of free radical oxygen species has also been shown. The applicability of these results to humans requires further study.

Attempts to use vitamin E as a pharmacologic agent to prevent cancer and coronary artery disease have been unsuccessful.

Vitamin K

Vitamin K, a fat-soluble material, occurs in two forms: vitamin K_1, from plants, and vitamin K_2, which is principally synthesized by the normal intestinal bacteria. Green leafy vegetables are rich in vitamin K and liver and dairy products contain smaller amounts.

PATHOPHYSIOLOGY: Dietary deficiency is very uncommon in the United States; most cases are associated with other disorders. However, inadequate dietary intake of vitamin K does occasionally occur in conjunction with chronic illness associated with anorexia.

Vitamin K deficiency is common in severe fat malabsorption, as seen in sprue and biliary tract obstruction. Destruction of intestinal flora by antibiotics may also result in vitamin K deficiency. Newborn infants frequently exhibit vitamin K deficiency because the vitamin is not transported well across the placenta and the sterile gut of the newborn does not have bacteria to produce it. Vitamin K confers **calcium-binding properties to certain proteins and is important for the activity of four clotting factors: prothrombin, factor VII, factor IX and factor X. Deficiency of vitamin K can be serious, because it can lead to catastrophic bleeding. Parenteral vitamin K therapy is rapidly effective.**

Amino Acids

Of the 20 amino acids in human proteins, no pathways exist for the synthesis of eight, and possibly nine (the additional amino acid being histidine). These amino acids are required in the diet and are considered to be **essential amino acids**. Another nine amino acids can be synthesized in the human body from simple precursors or from other amino acids. These are called **nonessential amino acids**. Finally, two amino acids (cysteine, tyrosine) are conditionally dispensable because their synthesis is limited under certain conditions or when adequate quantities of precursors are not available. Table 8-6 lists the 20 amino acids and the extent to which they must be acquired in the diet.

Deficiency of essential amino acids is manifest as protein deficiency (kwashiorkor; see above).

TABLE 8-6
AMINO ACIDS

Amino Acid	Nature of Requirement
Alanine (A)	Nonessential
Arginine (R)	Nonessential
Asparagine (N)	Nonessential
Aspartic acid (D)	Nonessential
Cysteine (C)	Conditionally essential
Glutamic acid (E)	Nonessential
Glutamine (Q)	Nonessential
Glycine (G)	Nonessential
Histidine (H)	Conditionally essential
Isoleucine (I)	Essential
Leucine (L)	Essential
Lysine (K)	Essential
Methionine (M)	Essential
Phenylalanine (F)	Essential
Proline (P)	Nonessential
Serine (S)	Nonessential
Threonine (T)	Essential
Tryptophan (W)	Essential
Tyrosine (Y)	Conditionally essential
Valine (V)	Essential

Increasing Use of Vitamins

Recent years have witnessed an explosion of interest in potential pharmacologic uses of vitamins, unrelated to treating dietary or other deficiencies. Consequently, many people are consuming certain vitamins in doses that far exceed what is needed to prevent deficiency diseases. It is likely that studies of such people will provide information regarding both the potential beneficial and toxic effects of large doses of vitamins.

Essential Trace Minerals Are Mostly Components of Enzymes and Cofactors

Essential trace minerals include iron, copper, iodine, zinc, cobalt, selenium, manganese, nickel, chromium, tin, molybdenum, vanadium, silicon and fluorine. Dietary deficiencies of these minerals are clinically important in the case of iron and iodine. These are discussed in Chapters 26 and 27, which deal with blood and endocrine diseases, respectively.

Chronic zinc deficiency has been reported in Iran and Egypt to result in hypogonadal dwarfism in boys. The children usually are those who eat clay, a substance that may bind zinc, but a deficiency in dietary protein is usually also present. An inherited disorder of zinc metabolism, acrodermatitis enteropathica, which is a chronic form of zinc deficiency, is characterized by diarrhea, rash, hair loss, muscle wasting and mental irritability. Similar symptoms are seen in acute zinc deficiency associated with total parenteral nutrition. Zinc deficiency is also seen in diseases that cause malabsorption, such as Crohn disease, celiac disease, cirrhosis and alcoholism.

Dietary copper deficiency is rare but may occur in certain inherited disorders, in malabsorption syndromes and during total parenteral nutrition. The most common result is microcytic anemia, although megaloblastic changes have also been described.

Manganese deficiency has been described and causes poor growth, skeletal abnormalities, reproductive impairment, ataxia and convulsions. **Industrial exposure to manganese** causes symptoms closely related to those of parkinsonism.

Agents of Biowarfare

The Toll of Infectious Diseases

Perhaps the greatest scourge to mankind is the diverse group of disorders collectively known as infectious diseases. They have caused more pain, suffering, disability and premature death than any other category of diseases in history. Bacterial and viral diarrheas, bacterial pneumonias, tuberculosis, measles, malaria, hepatitis B, pertussis and tetanus kill more people each year than all cancers and cardiovascular diseases (Table 9-1). The impact of infectious diseases is greatest in less developed countries, where millions of people, mostly children younger than 5 years of age, die of treatable or preventable infectious diseases. Even in the developed countries of Europe and North America, the mortality, morbidity and loss of economic productivity from infectious diseases is enormous. It is estimated that smallpox alone claimed between 300 million and 500 million human lives during the 20th century alone. Although smallpox has been eradicated from the natural environment, a multitude of other infectious agents continue to claim millions of lives each year. Infectious diseases such as tuberculosis, malaria, childhood diarrhea and acquired immunodeficiency syndrome (AIDS) continue to ravage the developing world, taking millions of lives each year. Even in industrialized nations, the morbidity and mortality from infectious disease is still substantial. In the United States, sepsis alone is responsible for an estimated 200,000 deaths per year (see Chapter 12).

Past accomplishments of individuals illustrate the contributions that can be made in this area to the alleviation of

TABLE 9-1
SOURCES OF GLOBAL DEATHS

human suffering: Edward Jenner's use of cowpox (vaccinia) virus in 1798 to immunize against smallpox; John Snow's removal of the Broad Street pump handle, which ended the 1854 cholera outbreak in London; and the discovery in 1843 by Oliver Wendell Holmes, Sr., that simply washing hands between patients could dramatically reduce the incidence of puerperal postpartum fever.

All these discoveries were made before an intelligible theory of causation of these illnesses existed. That theory arrived with the work of Koch, Pasteur, Lister and Ehrlich, who established the field of microbiology. This feat led directly to identification of agents responsible for many infectious diseases, establishment of effective standards of antisepsis and, eventually, the discovery and development of antibiotics to treat common bacterial, fungal, helminthic and protozoal diseases.

By the 1970s, it seemed that infectious diseases would become medical curiosities owing to the development of antibiotics, improved sanitation and immunization. It is instructive that in 1970, the Surgeon General of the United States declared, "The time has come for us to close the book on infectious disease." The fact that we had not conquered infectious diseases and that, in fact, tremendous problems were lurking was illustrated by the discovery of Legionnaires disease in 1976. The end of our naive expectations that infectious diseases were conquered came in 1981, with the first reports of human immunodeficiency virus-1 (HIV-1)/AIDS. Since then, many other infections have emerged (see below), for which we currently have little treatment and no cures: Ebola virus, severe acute respiratory syndrome (SARS), drug-resistant tuberculosis, pandemic strains of influenza virus, carbapenem-resistant Enterobacteriaceae (CRE) and others. The recent concern over these and other infectious diseases underscores the facts that the potential for future infectious threats to human existence is real, animal reservoirs of microbes that can be transmitted to humans are bottomless and vigilance can never be relaxed. Finally, the possibility that people may seek to use infectious agents as weapons of warfare should dispel any complacency that we are safe from these pathogens.

Infectious Diseases Feature Tissue Damage from an Invading Transmissible Agent

Infectious diseases represent many of the familiar taxa: bacteria, fungi, protozoa and various parasitic worms. Yet some infectious agents do not qualify as completely independent organisms. Viruses cannot replicate by themselves and are obligate intracellular parasites that hijack the replicative machinery of susceptible cells. Likewise, prions, the class of proteinaceous infectious agents, lack nucleic acids and clearly represent a different infectious disease paradigm.

There is great diversity in how various infectious diseases are acquired. Many of these maladies, such as influenza, syphilis and tuberculosis, are contagious (i.e., transmissible from person to person). Yet many infectious diseases, such as legionellosis, histoplasmosis and toxoplasmosis, are not contagious but are rather acquired from the environment. *Legionella* bacteria normally replicate in aquatic amebas but can infect humans via aerosolized water or through microaspiration of contaminated water. Other infectious agents come from many diverse sources: animals, insects, soil, air, inanimate objects and the endogenous microbial flora of the human body.

Perhaps the greatest paradox is that certain retroviruses have actually been incorporated into the human genome and are passed from generation to generation. Their function is unclear but their possible activation during placentation has led to speculation that such endogenous retroviruses may have allowed placental mammals to evolve.

INFECTIVITY AND VIRULENCE

Virulence is the complex of properties that allows an organism to establish infection and to cause disease or death. The organism must (1) gain access to the body, (2) avoid multiple host defenses, (3) accommodate to growth in the human milieu and (4) parasitize human resources.

Virulence reflects both the structures inherent to the offending microbe and the interplay of those factors with host defense mechanisms.

HOST DEFENSE MECHANISMS

The means by which the body prevents or contains infections are known as defense mechanisms (Table 9-2). There are major anatomic barriers to infection—the skin and the aerodynamic filtration system of the upper airway—that prevent most organisms from ever penetrating the body. The mucociliary blanket of the airways is also an essential defense, expelling organisms that gain access to the respiratory system. Microbial flora normally resident in the gastrointestinal tract and in various body orifices compete with outside organisms, preventing them from gaining sufficient nutrients or binding sites in the host. The body's orifices are also protected by secretions that possess antimicrobial properties, both nonspecific (e.g., lysozyme and interferon) and specific (secretory immunoglobulin A [IgA]). In addition, gastric acid and bile chemically destroy many ingested organisms.

Heritable Differences in Host Membrane Receptors May Determine Whether an Infection Occurs

The first step in infection is often a highly specific interaction of a binding molecule on an infecting organism with a receptor molecule on the host. If the host lacks a suitable receptor, the organism cannot attach to the target. Thus, *Plasmodium vivax,* one of the organisms that cause human malaria, infects human erythrocytes by using Duffy blood group determinants on the cell surface as receptors. Many people, particularly blacks, lack these determinants and are not susceptible to infection with *P. vivax.* As a result, *P. vivax* malaria is absent from much of Africa. Similar racial or geographic differences in susceptibility are apparent for many infectious agents, including *Coccidioides immitis* and *Coccidioides posadasii,* which are 14 times more common in blacks and 175 times more frequent in Filipinos than in whites.

Age Is Important in Predicting Susceptibility to Many Infections

The effect of age on the outcome of exposure to many infectious agents is well illustrated by infections of the fetus. Some organisms produce more severe disease in utero than in children or adults. Infections of the fetus with cytomegalovirus (CMV), rubella virus, parvovirus B19 and *Toxoplasma gondii* interfere with fetal development. Normally, the fetus is protected by maternal IgG (generated by a specific previous infection) that passively crosses the placenta. In acute infection of a pregnant woman who lacks neutralizing antibody, certain pathogens may cross the placenta. These infections are usually subclinical or produce minimal disease in the mother. Depending on the organism and timing of exposure, fetal infection can produce minimal damage, major congenital abnormalities or death.

Age also affects the course of common illnesses, such as the diverse viral and bacterial diarrheas. In older children and adults, these infections cause discomfort and inconvenience, but rarely severe disease. The outcome can be different in children under 3 years of age, who cannot compensate for rapid volume loss resulting from profuse diarrhea. The World Health Organization (WHO) estimates that acute diarrheal diseases remain the second leading cause of death in children under 5 years of age and kill 1.5 million children yearly.

Other examples include infection with *Mycobacterium tuberculosis,* which produces severe, disseminated tuberculosis in children under the age of 3 years. By contrast, older people tend to fare much better.

Maturity, however, is not always an advantage in infections. Epstein-Barr virus (EBV) is more likely to cause symptomatic infections in adolescents and adults than in younger children. Varicella-zoster virus causes chickenpox in children but produces more severe disease in adults, who are more likely to develop viral pneumonia.

The elderly fare more poorly with almost all infections than younger persons. Common respiratory illnesses such as influenza and pneumococcal pneumonia are more often fatal in those older than 65. An example of the susceptibility of the aged to infectious disease occurred during the 2002–2003 outbreak of the newly emergent SARS coronavirus. The case fatality rate was less than 1% for people younger than 24 years, but was greater than 50% for those over 65 years.

Human Behavior Often Controls Exposure to Infectious Agents

The link between behavior and infection is probably most obvious for sexually transmitted diseases. Syphilis, gonorrhea, urogenital chlamydial infections, AIDS and a number of other infectious diseases are transmitted primarily by sexual contact.

Other aspects of behavior also influence the risk of acquiring infections. Humans contract brucellosis and Q fever, which are primarily bacterial diseases of domesticated farm animals, by close contact with infected animals or their secretions. These infections occur in farmers, herders, meat processors and, in the case of brucellosis, people who drink unpasteurized milk. Transmission of a number of parasitic diseases is strongly affected by behavior. Schistosomiasis is acquired when water-borne parasite larvae penetrate the skin of a susceptible host. It is primarily a disease of farmers who work in fields irrigated by infected water. The larvae of hookworm and *Strongyloides stercoralis* live in humid soil and penetrate the skin of the feet in people who walk barefoot. Shoes are probably the single most important factor in limiting infection with soil-transmitted nematodes. Anisakiasis and diphyllobothriasis are helminthic diseases acquired by eating incompletely cooked fish. Toxoplasmosis is a protozoan infection transmitted from animals to humans by ingestion of incompletely cooked, infected meat or by exposure to infected cat feces. Botulism, a food poisoning caused by a bacterial toxin, is contracted by ingestion of improperly canned food that contains the toxin.

As humans change their behavior, they open up new possibilities for infectious diseases. Although the agent of Legionnaires disease is common in the environment, aerosols generated by cooling plants, faucets and humidifiers provide the means for causing human infections. Traditional behaviors are not necessarily health promoting.

People with Compromised Defenses Are More Likely to Contract Infections and to Have More Severe Infections

Disruption or absence of any of the complex host defenses results in increased numbers and severity of infections. Damage to epithelial surfaces by trauma or burns can lead to invasive bacterial or fungal infections. Injury to the airway mucociliary apparatus, as in smoking or influenza, impairs clearance of inhaled microorganisms and gives rise to an increased incidence of bacterial pneumonia. Congenital absence of certain complement components prevents formation of a fully functional membrane attack complex and permits disseminated, and often recurrent, *Neisseria* infections (see Chapter 2). Diseases such as diabetes mellitus and the use of chemotherapeutic drugs and corticosteroids may interfere with neutrophil production or function and increase the likelihood and severity of infections with bacteria or fungi.

Compromised hosts are often attacked by organisms that are innocuous to normal people. For example, patients deficient in neutrophils frequently develop life-threatening bloodstream infections with commensal microorganisms that normally populate the skin and gastrointestinal tract. Such organisms that mainly cause disease in hosts with impaired defenses are **opportunistic pathogens**.

Viral Infections: Introduction

Viruses range from 20 to 300 nm and consist of RNA or DNA surrounded by a protein shell. Some are also enveloped in lipid membranes. ***Viruses do not metabolize or reproduce independently. They are obligate intracellular parasites and require living cells in order to replicate.*** After invading cells, they divert intracellular biosynthetic and metabolic pathways to synthesizing virus-encoded nucleic acids and proteins.

Viruses often cause disease by killing infected cells, but many do not. For example, rotavirus, a common cause of diarrhea, interferes with the function of infected enterocytes without immediately killing them. It prevents enterocytes from synthesizing proteins that transport molecules from the intestinal lumen, thus causing diarrhea.

Viruses may also promote release of chemical mediators that elicit inflammatory or immunologic responses. The symptoms of the common cold are due to release of bradykinin from infected cells. Other viruses cause cells to proliferate and form tumors. Human papillomaviruses (HPVs), for instance, cause squamous cell proliferative lesions, which include common warts (see Chapter 5).

Some viruses infect and persist in cells without interfering with cellular functions, a process known as **latency**. Latent viruses may emerge to produce disease years after a primary infection. Opportunistic infections may reflect reactivation of latent virus infections. CMV and herpes simplex viruses are commonly present as latent agents and emerge in people with impaired cell-mediated immunity.

Finally, some viruses may reside within cells, either by integrating into their genomes or by remaining episomal. Such viruses can cause those cells to generate tumors. EBV causes endemic Burkitt lymphoma in Africa and other tumors in different settings. Human T-cell leukemia virus-1 (HTLV-1; see Chapter 5) causes a form of T-cell leukemia/lymphoma.

This section is divided into diseases caused by RNA viruses and those caused by DNA viruses. This division reflects fundamental differences in the biology of these agents. Some viruses with highly organ-specific tropisms are not described in detail, but rather are addressed in those chapters that deal with the organs that are principally affected.

Viral Infections: RNA Viruses

RNA viruses generally follow different paths to causing disease than do most DNA viruses. They need different enzymes for their infectious cycles, and many aspects of their biology do not have correlates among DNA viruses. One of the key differences between some RNA viruses and many DNA viruses is that the polymerases of some important pathogenic RNA viruses (e.g., HIV-1, hepatitis C virus [HCV]) do not proofread the strand being synthesized. This has two important consequences. First, the mutation rate—and thus the plasticity of these viruses in circumventing therapies—is very high. Second, a greater proportion of daughter virions is inactive.

RESPIRATORY VIRUSES

The Common Cold Is the Most Common Viral Disease

The common cold (coryza) is an acute, self-limited upper respiratory tract disorder caused by infection with a variety

of RNA viruses, including over 110 distinct rhinoviruses and several coronaviruses. Colds are frequent and worldwide in distribution. They spread from person to person via infected secretions. Infection is more likely during winter months in temperate areas and during the rainy seasons in the tropics, when spread is facilitated by indoor crowding. In the United States, children usually suffer six to eight colds per year and adults two to three. Overall, rhinoviruses cause up to 40% of all colds, coronaviruses 20%, and respiratory syncytial virus (RSV) 10%.

Rhinoviruses and coronaviruses have a tropism for respiratory epithelium and optimally reproduce at temperatures well below 37°C (98.6°F). Thus, infection remains confined to the cooler passages of the upper airway. The viruses infect the nasal respiratory epithelial cells, causing increased mucus production and edema. Infected cells release chemical mediators, such as bradykinin, which produce most of the symptoms associated with colds, namely, increased mucus production, nasal congestion and eustachian tube obstruction. Resulting stasis may predispose to secondary bacterial infection and lead to bacterial sinusitis and otitis media. Rhinoviruses and coronaviruses do not destroy respiratory epithelium and produce no visible alterations. Clinically, the common cold is characterized by rhinorrhea, pharyngitis, cough and low-grade fever. Symptoms last about a week.

Influenza May Predispose to Bacterial Pneumonia

Influenza is an acute, usually self-limited, infection of upper and lower airways, caused by influenza virus. These viruses are enveloped and contain single-stranded RNA.

EPIDEMIOLOGY: There are three distinct types of influenza virus—A, B and C—that cause human disease. Influenza A is by far the most common and causes the most severe disease. Ten million to 40 million cases of influenza occur annually in the United States, often accounting for over 40,000 deaths. Influenza is highly contagious, and epidemics frequently spread around the world. New strains emerge regularly, often from animal hosts in parts of the world, largely the far east, where humans and animals, especially fowl, live in close contact. Influenza strains are identified by their type (A, B, C), serotype of their hemagglutinin (H) and neuraminidase (virus subtype), geographic site of origin, strain number and year of isolation (Fig. 9-1). Thus, the avian influenza virus ("bird flu") strain that emerged in 2003 and still continues to spread around the globe is designated A(H5N1). In 2009, a novel influenza A virus, designated H1N1 ("swine flu"), emerged in Veracruz, Mexico, and swiftly spread globally as a pandemic infection. The virulence of the H1N1 strain was underscored by the 10,000 deaths it caused in the United States alone within 7 months of its initial identification and 300,000 identified deaths worldwide by the end of the pandemic in 2009. This strain of influenza A virus has produced significant mortality in infected children and pregnant women. In 2013, a newly emergent and virulent strain of avian flu virus, H7N9, was identified in China. Because epidemic influenza virus antigens change so often, herd immunity that develops during one epidemic rarely protects against the next one.

MOLECULAR PATHOGENESIS: Influenza spreads from person to person by virus-containing respiratory droplets and secretions. When it reaches the respiratory epithelial cell surface, a viral glycoprotein (hemagglutinin) that binds to sialic acid residues on human respiratory epithelium and the virus binds and enters the cell. Once inside, the virus directs the cell to produce progeny viruses and causes cell death. Infection usually involves both the upper and lower airways. Destruction of ciliated epithelium cripples mucociliary clearance, predisposing to bacterial pneumonia, especially with *Staphylococcus aureus* and *Streptococcus pneumoniae.*

PATHOLOGY: Influenza virus causes necrosis and desquamation of ciliated respiratory tract epithelium and a predominantly lymphocytic inflammatory infiltrate. Extension of infection to the lungs leads to necrosis, sloughing of alveolar lining cells and the histologic appearance of viral pneumonitis.

CLINICAL FEATURES: Rapid onset of fever, chills, myalgia, headaches, weakness and nonproductive cough are characteristic. Symptoms may be primarily those of an upper respiratory infection or those of tracheitis, bronchitis and pneumonia. Epidemics are accompanied by deaths from both influenza and its complications, particularly in the elderly and people with underlying cardiopulmonary disease. Prevention by killed viral vaccines specific to epidemic strains is 75% effective.

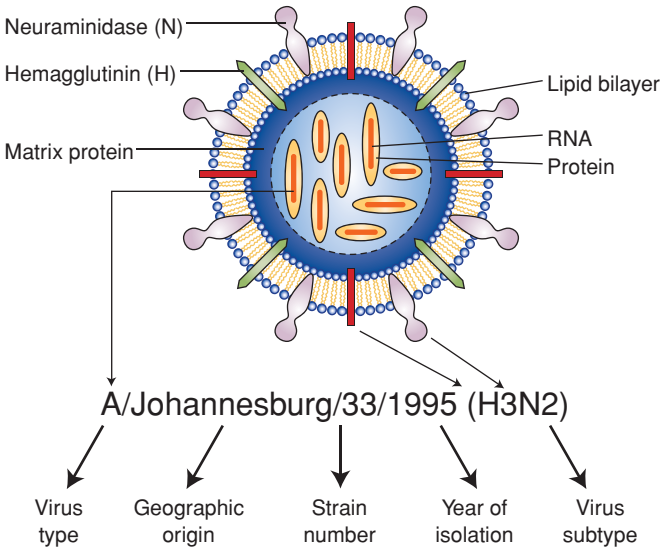

FIGURE 9-1. Nomenclature of influenza virus strains. The virus type (A, B or C) is based on nucleoprotein characteristics encoded by the NP gene of the virus. The H classification is based on the hemagglutinin (most commonly H1, H2 or H3, also H5) encoded by the HA gene. The N classification is based on the type of neuraminidase (N1 or N2) encoded by the NA gene.

Parainfluenza Virus Is Associated with Croup

The parainfluenza viruses cause acute upper and lower respiratory tract infections, particularly in young children. The four serotypes of these enveloped, single-stranded RNA viruses belong to the paramyxovirus family. They are the most common cause of croup (laryngotracheobronchitis), which is characterized by stridor on inspiration and a "barking" cough.

EPIDEMIOLOGY: Croup is common in children under the age of 3 years and is characterized by subglottic swelling, airway compression and respiratory distress. The virus spreads from person to person via infectious respiratory aerosols and secretions. Infection is highly contagious; disease is present worldwide. The parainfluenza viruses are isolated from 10% of young children with acute respiratory tract illnesses. While not as well known as influenza virus among the general population, parainfluenza virus infection is the second leading cause of hospitalization of children under 5 years of age for respiratory illness.

PATHOLOGY: Parainfluenza viruses infect and kill ciliated respiratory epithelial cells and elicit an inflammatory response. In very young children, this process frequently extends into the lower respiratory tract, causing bronchiolitis and pneumonitis. In young children, where the trachea is narrow and the larynx is small, the local edema of laryngotracheitis compresses the upper airway enough to obstruct breathing and cause croup. Parainfluenza infection is associated with fever, hoarseness and cough. A barking cough is characteristic, as is inspiratory stridor. In older children and adults, symptoms are usually mild.

Respiratory Syncytial Virus Causes Bronchiolitis in Infants

EPIDEMIOLOGY: RSV belongs to the same family, Paramyxoviridae, as parainfluenza virus. It spreads rapidly from child to child in respiratory aerosols and secretions, particularly in daycare centers, hospitals and other settings where small children are confined. The virus, which is present worldwide, is highly contagious. In the United States, 60% of infants are infected during their first RSV season, and nearly all will be infected by 2–3 years of age. RSV is the most common cause of bronchiolitis and pneumonia in children younger than 1 year old.

PATHOLOGY: RSV produces necrosis and sloughing of bronchial, bronchiolar and alveolar epithelium, associated with a predominantly lymphocytic inflammatory infiltrate. Multinucleated syncytial cells are sometimes seen in infected tissues.

CLINICAL FEATURES: Infants and young children with RSV bronchiolitis or pneumonitis present with wheezing, cough and respiratory distress, sometimes accompanied by fever. The illness is usually self-limited, resolving in 1–2 weeks. In older children and adults, RSV produces much milder disease. Among otherwise healthy young children, mortality from RSV infection is very low, but it rises dramatically, 20%–40%, among hospitalized children with congenital heart disease, chronic lung disease, prematurity or immunosuppression.

Severe Acute Respiratory Syndrome Is an Emergent Viral Disease Causing Outbreaks of Pneumonia

In early 2002, an epidemic of severe pneumonia was traced to Guangdong Province of China. As outbreaks occurred in Hong Kong, Vietnam and Singapore, the disease swept around the globe via international air travel. This emerging clinical disease, SARS, eventually spread to the United States, Canada and Europe. The causative agent is a novel coronavirus, termed the SARS-associated coronavirus (SARS-CoV). This agent is derived from a nonhuman host, now felt most likely to be bats, with civets and other animals as likely intermediate hosts. SARS is a potentially fatal viral respiratory illness, with an incubation period of 2–7 days and symptoms lasting up to 10 days. While this initial pandemic was spreading globally in 2003, there were over 8000 known cases and 775 deaths, a case fatality rate of 9.6%. Although the last infected human case occurred in mid-2003, SARS-CoV has not been eradicated and has the potential to reemerge.

PATHOLOGY: Lungs of patients who died from SARS show diffuse alveolar damage (see Chapter 18). Multinucleated syncytial cells without viral inclusions have also been observed.

CLINICAL FEATURES: Clinically, SARS begins with fever and headache, followed shortly by cough and dyspnea. Coryza is often absent and diarrhea is quite common. Some patients develop adult respiratory distress syndrome (ARDS; see Chapter 18) and are at high risk of complications and death. Most patients recover, but mortality may reach 15% in the elderly and in patients with other respiratory disorders. No specific treatment is available, although corticosteroids may offer some benefit.

VIRAL EXANTHEMS

Measles (Rubeola) Is a Highly Contagious Virus That May Cause Fatal Infection

Measles virus is an enveloped, single-stranded RNA paramyxovirus that causes an acute illness, characterized by upper respiratory tract symptoms, fever and rash.

EPIDEMIOLOGY: Measles virus is transmitted to humans by respiratory aerosols and secretions. Among nonimmunized populations, it is primarily a disease of children. Currently available live, attenuated vaccines are highly effective in preventing measles and in eliminating virus spread. Nationwide immunization has made measles uncommon in the United States.

Measles is a particularly severe disease in the very young, the sick or the malnourished. In impoverished countries, it has a high mortality rate (10%–25%). In immunocompromised patients, the fatality rate is approximately 30%. WHO estimates that there were 160,000 deaths worldwide in 2011 due to measles. When measles was first introduced to previously unexposed populations (e.g., Native Americans, Pacific Islanders), resulting widespread infections had devastatingly high mortality rates.

PATHOPHYSIOLOGY: The initial site of infection is the mucous membranes of the nasopharynx and bronchi. Two surface glycoproteins, "H" and "F," mediate viral attachment and fusion with

respiratory epithelium. The virus then spreads to regional lymph nodes and the bloodstream, leading to widespread dissemination and prominent involvement of the skin and lymphoid tissues. The rash results from the action of T lymphocytes on virally infected vascular endothelium.

PATHOLOGY: Measles virus produces necrosis of infected respiratory epithelium, with a predominantly lymphocytic inflammatory infiltrate, and a vasculitis of small blood vessels in the skin. Lymphoid hyperplasia is often prominent in cervical and mesenteric lymph nodes, spleen and appendix. In lymphoid tissues, the virus sometimes causes fusion of infected cells, producing multinucleated giant cells containing up to 100 nuclei, with both intracytoplasmic and intranuclear inclusions. These cells, **Warthin-Finkeldey giant cells** (Fig. 9-2), are pathognomonic for measles.

CLINICAL FEATURES: Measles first manifests with fever, rhinorrhea, cough and conjunctivitis and progresses to the characteristic mucosal and skin lesions. The mucosal lesions, or "Koplik spots," are minute gray-white dots on a red base that appear on the posterior buccal mucosa. Skin lesions begin on the face as an erythematous maculopapular rash, which usually spreads to involve the trunk and extremities. The rash fades in 3–5 days, and symptoms gradually resolve. The clinical course of measles may be much more severe in those who are very young, malnourished or immunocompromised. The disease often leads to secondary bacterial infections, especially otitis media and pneumonia. Central nervous system invasion is probably a common event, as suggested by changes in electroencephalographic (EEG) readings. Acute encephalitis is rare but does occur. Uncommonly, years after a measles infection, patients can develop subacute sclerosing panencephalitis (SSPE), a slow, chronic neurodegenerative disorder (see Chapter 32). The exact pathophysiology of SSPE is unclear, but prophylactic vaccination against measles has greatly reduced its incidence.

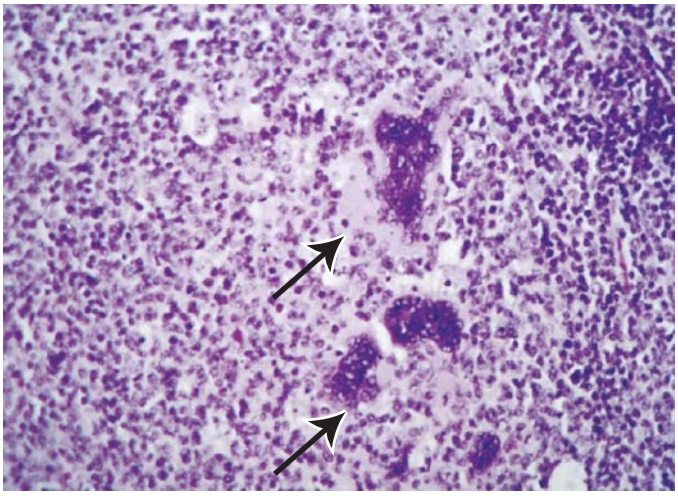

FIGURE 9-2. Warthin-Finkeldey giant cells in measles. A hyperplastic lymph node from a patient with measles shows several multinucleated giant cells (*arrows*).

Rubella Infection in Utero Causes Congenital Anomalies

Rubella virus is an enveloped, single-stranded RNA virus that causes a mild, self-limited systemic disease, usually associated with a rash (also known as "German measles"). Rubella virus is the only member of the genus *Rubivirus* in the family Togaviridae. Many infections are so mild that they go unnoticed. However, in pregnant women, rubella is a destructive fetal pathogen.

EPIDEMIOLOGY: Rubella virus spreads from person to person, primarily by the respiratory route. Infection occurs worldwide. The virus is not highly contagious, and in unvaccinated populations, 10%–15% of young women remain susceptible to infection into their reproductive years. The currently available live attenuated viral vaccine prevents rubella and has largely eliminated the disease from developed countries. Thus, in the Americas, no endemic case has been observed since February 2009.

PATHOPHYSIOLOGY: Rubella infects respiratory epithelium and then disseminates through the bloodstream and lymphatics. The rubella rash is believed to result from an immune response to the disseminated virus. Fetal infection occurs through the placenta during the viremic phase of maternal illness. A congenitally infected fetus remains persistently infected and sheds large amounts of virus in body fluids, even after birth. Maternal infection after 20 weeks' gestation usually does not cause fetal disease.

PATHOLOGY: In most patients, rubella is a mild, acute febrile illness, with rhinorrhea, conjunctivitis, postauricular lymphadenopathy and a rash that spreads from face to trunk and extremities. The rash resolves within 3 days; complications are rare. As many as 30% of infections are completely asymptomatic.

In the fetus, the heart, eye and brain are the organs most often affected. Cardiac lesions include pulmonary valvular stenosis, pulmonary artery hypoplasia, ventricular septal defects and patent ductus arteriosus (50%). Cataracts, glaucoma, microphthalmia and retinal defects may occur in half of patients. Sensorineural deafness is a common (60%) complication of fetal rubella. Severe brain involvement can produce microcephaly and mental retardation.

MUMPS

Mumps virus is a paramyxovirus, an enveloped, single-stranded RNA virus. It causes an acute, self-limited systemic illness, characterized by parotid gland swelling and meningoencephalitis.

EPIDEMIOLOGY: Mumps is a worldwide disease, primarily of children. It spreads from person to person via the respiratory route. The virus is highly contagious, and 90% of exposed, susceptible persons become infected, although only 65% develop

symptoms. A live attenuated mumps vaccine prevents mumps, and the disease has been largely eliminated from most developed countries.

PATHOPHYSIOLOGY: Mumps begins as viral infection of respiratory tract epithelium. The virus then disseminates through the blood and lymphatic systems to other sites, most commonly the salivary glands (especially parotids), central nervous system (CNS), pancreas and testes. Over half of infections involve the CNS, with symptomatic disease in 10%. Epididymoorchitis occurs in 20% of males infected after puberty.

PATHOLOGY: Mumps virus causes necrosis of infected cells, eliciting a predominantly lymphocytic inflammatory infiltrate. Affected salivary glands are swollen, their ducts lined by necrotic epithelium and their interstitium infiltrated with lymphocytes. In mumps epididymoorchitis, the testes swell to three times normal size. The swelling of testicular parenchyma, confined within the tunica albuginea, produces focal infarcts. Mumps orchitis is usually unilateral and, thus, rarely causes sterility.

CLINICAL FEATURES: Mumps begins with fever and malaise, followed by painful swelling of the salivary glands, usually one or both parotids. Symptomatic meningeal involvement most often manifests as headache, stiff neck and vomiting. Prior to widespread vaccination, mumps was a leading cause of viral meningitis and encephalitis in the United States. Although severe disease of the pancreas is rare in mumps, most patients have elevated serum amylase. Pancreatic infection has been implicated in some cases of type 1 diabetes.

INTESTINAL VIRUS INFECTIONS

Rotavirus Infection Is the Most Common Cause of Severe Diarrhea Worldwide

Rotavirus produces profuse watery diarrhea that can lead to dehydration and death if untreated. There are 5 species (A–E) of this double-stranded RNA member of the family Reoviridae. Type A, the most common, usually infects young children.

EPIDEMIOLOGY: Rotavirus infection spreads from person to person by the oral–fecal route. Infection is most common among children, who shed huge amounts of virus in the stool. Siblings, playmates and parents, as well as food, water and environmental surfaces, readily become contaminated. The peak age of infection is 6 months to 2 years, and virtually all children have been infected by the age of 4 years. In the United States, each year rotavirus causes about 100 deaths in young children, and throughout the world, 500,000 deaths in children under 5 years of age.

PATHOPHYSIOLOGY: Rotavirus infects enterocytes of the upper small intestine, disrupting absorption of sugars, fats and various ions. The resulting osmotic load causes a net loss of fluid into the bowel lumen, producing diarrhea and dehydration. Infected cells are shed from intestinal villi, and the regenerating epithelium initially lacks full absorptive capabilities.

PATHOLOGY: Pathologic changes in rotavirus infection are largely confined to the duodenum and jejunum. The intestinal villi are shortened and there is a mild infiltrate of neutrophils and lymphocytes.

CLINICAL FEATURES: Rotavirus infection manifests as vomiting, fever, abdominal pain and profuse, watery diarrhea. Vomiting usually lasts for 2–3 days, but diarrhea continues for 5–8 days. Without adequate fluid replacement, diarrhea can produce fatal dehydration in young children.

Norwalk Virus and Other Gastrointestinal Viruses Often Cause Outbreaks of Diarrhea

In addition to rotavirus, many other viruses cause diarrhea. The best understood is the Norwalk family of nonenveloped RNA viruses, a group of caliciviruses whose names derive from the locations of particular outbreaks (e.g., Norwalk virus, Snow Mountain virus, Sapporo virus). Norwalk viruses are responsible for one third of all outbreaks of diarrheal disease. They produce gastroenteritis in children and adults, with self-limited vomiting and diarrhea, similar to that caused by rotavirus. Norwalk viruses infect cells of the upper small bowel and produce changes similar to those that occur with rotavirus.

VIRAL HEMORRHAGIC FEVERS

Viral hemorrhagic fevers are a group of at least 20 distinct viral infections that cause varying degrees of hemorrhage, shock and sometimes death. There are many similar viral hemorrhagic fevers in different parts of the world, usually named for the area where they were first described. Four virus families are involved—the Bunyaviridae, Flaviviridae, Arenaviridae and Filoviridae. On the basis of differences in routes of transmission, vectors and other epidemiologic characteristics, viral hemorrhagic fevers have been divided into four epidemiologic groups (Table 9-3): mosquito-borne; tick-borne; zoonotic; and the filoviruses, Marburg and Ebola virus, in which the route of transmission is unknown.

Yellow Fever May Lead to Fulminant Hepatic Failure

Yellow fever is an acute hemorrhagic fever, sometimes associated with extensive hepatic necrosis and jaundice. It is caused by an insect-borne flavivirus, an enveloped, single-stranded RNA virus. Other pathogenic flaviviruses cause Omsk hemorrhagic fever and Kyasanur Forest disease.

EPIDEMIOLOGY: Yellow fever was first recognized in the New World in the 17th century, but its origins probably were in Africa. Today, the virus is restricted to parts of Africa and South America, including

TABLE 9-3
VIRAL HEMORRHAGIC FEVERS

	Kyasanur forest disease
Rodents	Lassa fever
	Bolivian hemorrhagic fever
	Argentine hemorrhagic fever
	Korean hemorrhagic fever
Fruit bats	Ebola virus disease

both jungle and urban settings. Its usual reservoir is tree-dwelling monkeys, which are unaffected by the virus. The agent is passed among them in the forest canopy by mosquitoes. Humans acquire jungle yellow fever by being bitten by infected ***Aedes mosquitoes***. Felling trees increases the risk of infection, because mosquitoes are brought down with the tree. On returning to the village or city, the human victim becomes a reservoir for epidemic yellow fever in the urban setting, where *Aedes aegypti* is the vector.

PATHOPHYSIOLOGY: On inoculation by the mosquito, the virus multiplies within tissue and vascular endothelium, then disseminates through the bloodstream. It has a tropism for liver cells, where it sometimes produces extensive acute hepatocellular destruction. Extensive damage to the endothelium of small blood vessels may lead to the loss of vascular integrity, hemorrhages and shock.

PATHOLOGY: Yellow fever virus causes coagulative necrosis of hepatocytes, beginning in the middle of hepatic lobules and spreading toward the central veins and portal tracts. The infection sometimes produces confluent necrosis in the middle of the hepatic lobules (i.e., midzonal necrosis). In the most severe cases, entire lobules may be necrotic. Some necrotic hepatocytes lose their nuclei and become intensely eosinophilic. They often dislodge from adjacent hepatocytes and are known as Councilman bodies (recognized today as apoptotic bodies).

CLINICAL FEATURES: Yellow fever is characterized by abrupt onset of fever, chills, headache, myalgias, nausea and vomiting. After 3–5 days, some patients develop signs of hepatic failure, with jaundice (hence the term "yellow" fever), deficiencies of clotting factors and diffuse hemorrhages. Vomiting of clotted blood ("black vomit") is a classic feature of severe disease. Patients with massive hepatic failure lapse into a coma and die, usually within 10 days of onset of illness. Overall mortality of yellow fever is 5%, but among those with jaundice, it rises to 30%.

Ebola Hemorrhagic Fever Is a Fatal African Disease

Ebola virus is an RNA virus belonging to the Filoviridae family. It causes a hemorrhagic disease with a **high mortality rate** in humans in several regions of Africa. The only other filovirus pathogenic to humans is Marburg virus, which produces Marburg hemorrhagic fever.

EPIDEMIOLOGY: Ebola virus first emerged in Africa with two major disease outbreaks that occurred almost simultaneously in Zaire and Sudan in 1976. Outbreaks have occurred in Africa up to the present time.

In the wild, the virus infects humans, gorillas, chimpanzees and monkeys. Recent field evidence from Gabon and the Congo area of western Africa has implicated several species of fruit bats as the natural reservoir of Ebola virus. Health care workers and family members have become infected as a result of viral exposure while treating patients with Ebola hemorrhagic fever or during funerary preparation of the bodies of deceased victims. The virus can be transmitted via bodily secretions, blood and used needles.

ETIOLOGIC FACTORS AND PATHOLOGY: ***Ebola virus results in the most widespread destructive tissue lesions of all viral hemorrhagic fever agents.*** The virus replicates massively in endothelial cells, mononuclear phagocytes and hepatocytes. Necrosis is most severe in the liver, kidneys, gonads, spleen and lymph nodes. The liver characteristically shows hepatocellular necrosis, Kupffer cell hyperplasia, Councilman bodies and microsteatosis. The lungs are usually hemorrhagic. Petechial hemorrhages are seen in the skin, mucous membranes and internal organs. Injury to the microvasculature and increased endothelial permeability are important causes of shock.

CLINICAL FEATURES: Ebola fever incubates 2–21 days, after which initial symptoms include headache, weakness and fever, followed by diarrhea, nausea and vomiting. Some patients develop overt hemorrhage, including bleeding from injection sites, petechiae, gastrointestinal bleeding and gingival hemorrhage.

West Nile Virus Is Spread by Mosquito Vectors and Birds

EPIDEMIOLOGY: The virus, a member of the family Flaviviridae, is increasing its geographic distribution as a result of spread by infected migratory birds and arthropods transported between continents in pooled water in cargo ships. West Nile virus (WNV) was isolated in 1937 from the blood of a febrile woman in Uganda. It spread rapidly through the Mediterranean and temperate parts of Europe. In 1999, WNV was first identified in the Western Hemisphere when it caused an outbreak of meningoencephalitis (West Nile fever) in New York City and the surrounding metropolitan area. In 2009, 660 cases of WNV infection and 30 fatalities in 34 states in the United

States occurred. By December 2012, WNV had been reported in people, birds or mosquitos from 48 states, with over 5000 human infections, of which half were neuroinvasive and 240 were fatal. WNV has also emerged as a potential threat to the safety of blood products (over 110 positive blood donors in 2009).

PATHOLOGY: WNV can be recovered from blood for up to 10 days in immunocompetent febrile patients, and as late as 22–28 days after infection in immunocompromised people. Laboratory findings include moderate pleocytosis and elevated protein of the cerebrospinal fluid. Brains show mononuclear meningoencephalitis or encephalitis. The brainstem, particularly the medulla, can be extensively involved, and in some cases the cranial nerve roots show endoneural mononuclear inflammation. There are varying degrees of neuronal necrosis in gray matter, neuronal degeneration and neuronophagia.

CLINICAL FEATURES: Most human WNV infections are subclinical and overt disease occurs in only 1 of 100 cases. The incubation period ranges from 3 to 15 days. Symptoms, if they occur, usually consist of fever, often with rash, lymphadenopathy and polyarthropathy. Patients with severe illness can develop acute aseptic meningitis or encephalitis, convulsions and coma. Anterior myelitis, hepatosplenomegaly, hepatitis, pancreatitis and myocarditis may occur. The probability of severe illness increases with increasing age. CNS infection is associated with 4%–13% mortality and is highest among the elderly.

Viral Infections: DNA Viruses

ADENOVIRUS

Adenoviruses are nonenveloped DNA viruses that are isolated from the respiratory and intestinal tracts of humans and animals. Certain serotypes are common causes of acute respiratory disease and adenovirus pneumonia in military recruits. Some adenoviruses are important causes of chronic pulmonary disease in infants and young children. Adenoviruses spread via direct contact, fecal–oral transmission and occasionally water-borne transmission.

PATHOLOGY: Pathologic changes include necrotizing bronchitis and bronchiolitis, in which sloughed epithelial cells and inflammatory infiltrate fill damaged bronchioles. Interstitial pneumonitis is characterized by areas of consolidation, with extensive necrosis, hemorrhage and a mononuclear inflammatory infiltrate. Two distinctive types of intranuclear inclusions—Cowdry type A inclusions and smudge cells (Fig. 9-3)—involve bronchiolar epithelial cells and alveolar lining cells. Infected cells with intranuclear inclusion bodies may be found. In the early stages of adenovirus infection, cytopathic effects appear as granular, slightly enlarged nuclei containing eosinophilic bodies intermixed with clumped basophilic chromatin. The eosinophilic bodies coalesce, forming larges

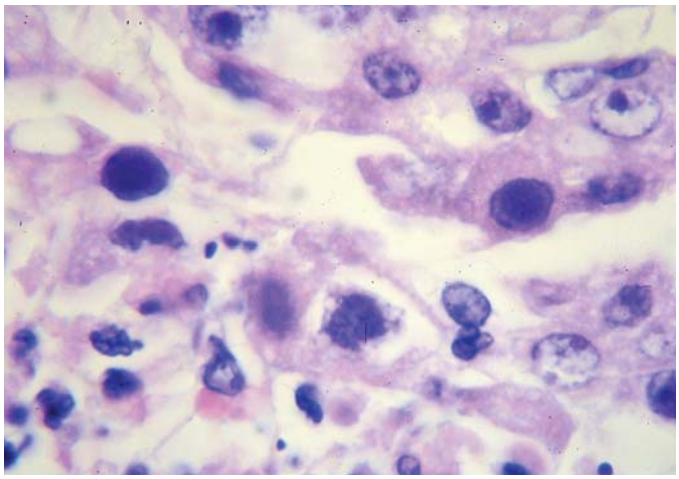

FIGURE 9-3. Adenovirus infection of the liver from a child. The two forms of viral inclusions are present: smudge cells and Cowdry A inclusions.

masses that end as a central, granular, ill-defined mass surrounded by a halo—the so-called Cowdry A inclusions. The second type of inclusion, which is more common and probably corresponds to a late-stage infected cell, is the "smudge cell." The nucleus is rounded or ovoid, large and completely occupied by a granular amphophilic to deeply basophilic mass. There is no halo, and the nuclear membrane and nucleus are indistinct.

Adenoviruses types 40 and 41 infect colonic and small intestinal epithelial cells and may cause diarrhea. People with AIDS are particularly susceptible to urinary tract infections caused by adenovirus type 35. In immunocompromised patients and transplant recipients, adenovirus can cause fulminant or disseminated disease, such as colitis, pneumonitis, pancreatitis, nephritis, meningoencephalitis and hepatitis.

HUMAN PARVOVIRUS (ERYTHROVIRUS) B19

Human parvovirus B19, now called erythrovirus, is a single-stranded DNA virus that causes **erythema infectiosum,** a benign self-limited febrile illness in children. It also produces systemic infections, characterized by rash, arthralgias and transient interruption in erythrocyte production in nonimmune adults.

ETIOLOGIC FACTORS: The virus spreads from person to person by the respiratory route. Infection is common and occurs in outbreaks, mostly among children. It is not known which cells, other than erythroid precursors, support virus replication, but the agent probably replicates in the respiratory tract before it spreads to erythropoietic cells.

PATHOLOGY: Human parvovirus B19 gains entry to erythroid precursor cells via the P-erythrocyte antigen and produces characteristic cytopathic effects in those cells. Nuclei of affected cells are enlarged, and chromatin is displaced peripherally by central, glassy, eosinophilic inclusion bodies (giant pronormoblasts).

CLINICAL FEATURES: Most people suffer a mild exanthematous illness, **erythema infectiosum ("fifth disease"),** accompanied by an asymptomatic interruption in erythropoiesis. In patients with chronic hemolytic anemias, however, the pause in erythrocyte production causes profound, potentially fatal anemia, known as **transient aplastic crisis** (see Chapter 26). When a fetus is infected by human parvovirus B19, cessation of erythropoiesis can lead to severe anemia, hydrops fetalis and death in utero, which occurs in about 10% of maternal infections.

SMALLPOX (VARIOLA)

Smallpox is a highly contagious exanthematous viral infection produced by variola virus, a member of the family Poxviridae.

EPIDEMIOLOGY: Smallpox is an ancient disease; a rash resembling smallpox was found in the mummified remains of Egyptian pharaoh Ramses V. In the 6th century, a Swiss bishop named the etiologic agent of smallpox "variola" from the Latin *varius,* meaning "pimple" or "spot." The infection was common in Europe and arrived in the New World with Spanish colonists, where it often decimated native populations. In 1796, Edward Jenner performed the first successful vaccination when he inoculated a child with exudate from the hand of a milkmaid infected with cowpox. Once the cowpox pustule had regressed, Jenner challenged that child with smallpox and demonstrated that he was protected from the disease. In 1967, the WHO began its uniquely successful campaign to eradicate smallpox. The last occurrence of endemic smallpox was in Somalia in 1977, and the last reported human cases were laboratory-acquired infections in 1978. On May 8, 1980, the WHO declared that smallpox had been eradicated. Two known repositories of variola virus remain: one at the Centers for Disease Control and Prevention (CDC) in the United States and one at the Institute for Virus Preparation in Russia. There has been considerable vigilance to its reemergence, either naturally or as a bioweapon.

ETIOLOGIC FACTORS: Smallpox was transmitted between victims and susceptible people via droplets or aerosol of infected saliva. Viral titers in the saliva were highest in the first week of infection. The virus is highly stable and remains infective for long periods outside its human host. Two types of smallpox have been recognized. *Variola major* was prevalent in Asia and parts of Africa and represented the prototypical form of the infection. *Variola minor* was found in Africa, South America and Europe and was distinguished by its milder systemic toxicity and smaller pox lesions.

PATHOLOGY: Skin vesicles of variola show cellular necrosis and scarce areas of ballooning degeneration. Eosinophilic, intracytoplasmic inclusion bodies (Guarnieri bodies) are seen but are not specific for smallpox since they occur in most poxviral infections. Vesicles also occur in the palate, pharynx, trachea and esophagus. In severe cases of smallpox, there is gastric and intestinal involvement, hepatitis and interstitial nephritis.

FIGURE 9-4. Child with smallpox, Bangladesh, 1973.

CLINICAL FEATURES: The incubation period of smallpox is 12 days (range, 7–17 days) after exposure. After entering the respiratory tract, variola travels to regional lymph nodes, where it replicates. Viremia follows. Clinical manifestations begin abruptly, with malaise, fever, vomiting and headache. The characteristic rash, most prominent on the face but also involving the hands and forearms, follows in 2–3 days. After subsequent eruptions on the lower extremities, the rash spreads centrally during the next week to the trunk. Lesions progress quickly from macules to papules, then to pustular vesicles (Fig. 9-4), and generally remain synchronous in their stage of development. By 8–14 days after onset, the pustules form scabs, which leave depressed scars on healing after 3–4 weeks. The case fatality rate is 30% in unvaccinated individuals.

MONKEYPOX

Monkeypox, a rare viral disease occurring mostly in Central and Western Africa, and more recently in Sudan, is the only remaining potentially fatal infection of humans to be caused by a member of the Poxviridae.

EPIDEMIOLOGY: The virus was first isolated from monkeys, giving it its name, but it is actually more prevalent in rodents in endemic areas. It is mainly a zoonotic disease in parts of Central and Western Africa. Recent data suggest that since the eradication of smallpox in Africa, residents of the Democratic Republic of the Congo are now 20 times more likely to acquire monkeypox infection than they were in 1986. An outbreak of monkeypox occurred in seven states in the United States in 2003 among 93 people who either owned or had exposure to pet prairie dogs. Infected animals had been exposed to an infected Gambian pouched rat in an exotic pet store. Dormice and squirrels have also been implicated as natural reservoirs of the virus. Human infection can follow a bite from an infected host or contact with its body fluids. Human-to-human transmission is uncommon.

CLINICAL FEATURES: The incubation period in humans is approximately 12 days. Its clinical presentation is similar to that of smallpox, but milder. Illness begins with fever, headache, lymphadenopathy, malaise, muscle ache and backache. Within 1–3 days after onset of fever, a papular rash occurs in the face or other body parts, which ultimately crusts and fall off. Illness typically lasts for 2 weeks. In Africa, the case fatality is as high as 10%.

HERPESVIRUSES

The virus family Herpesviridae includes a large number of enveloped DNA viruses, many of which infect humans. Almost all herpesviruses express some common antigenic determinants, and many produce type A nuclear inclusions (acidophilic bodies surrounded by a halo). The most important pathogenic herpesviruses (HHVs) are varicella-zoster virus (VZV, or HHV-3); herpes simplex virus 1 and 2 (HSV-1 and -2); EBV (HHV-4); HHV6, the cause of roseola; CMV (HHV-5); HHV-7, a cause of exanthema subitum; and Kaposi sarcoma–associated herpesvirus (HHV-8), a human oncovirus causing Kaposi sarcoma, primary effusion lymphoma and some types of Castleman disease. ***These viruses are distinguished by their capacity to remain latent for long periods of time.***

Varicella-Zoster Infection Causes Chickenpox and Herpes Zoster

First exposure to VZV produces chickenpox, an acute systemic illness characterized by a generalized vesicular skin eruption (Fig. 9-5). The virus then becomes latent, and its reactivation many years later causes herpes zoster ("shingles"), a localized vesicular skin eruption.

ETIOLOGIC FACTORS AND EPIDEMIOLOGY: VZV is restricted to human hosts and spreads from person to person primarily by the respiratory route. It can also be spread by contact with secretions from skin lesions. The virus is present worldwide and is highly contagious. Most children in the United States were formerly infected by early school age, but an effective vaccine has reduced this incidence.

VZV initially infects the respiratory tract or conjunctival epithelium. There it reproduces and spreads through the blood and lymphatic systems. Many organs are infected during this viremic stage, but skin involvement usually dominates the clinical picture. The virus spreads from the capillary endothelium to the epidermis, where its replication destroys the basal cells. As a result, the upper layers of the epidermis separate from the basal layer to form vesicles.

During primary infection, VZV establishes latent infection in perineuronal satellite cells of the dorsal nerve root ganglia. Transcription of viral genes continues during latency, and viral DNA can be demonstrated years after the initial infection.

Shingles occurs when virus replication occurs in ganglion cells and the agent travels down the sensory nerve from a single dermatome. It then infects the corresponding epidermis, producing a localized, painful vesicular eruption. The risk of shingles in an infected person increases with age, and most cases occur among the elderly. Impaired cell-mediated immunity also increases the risk of VZV reactivation.

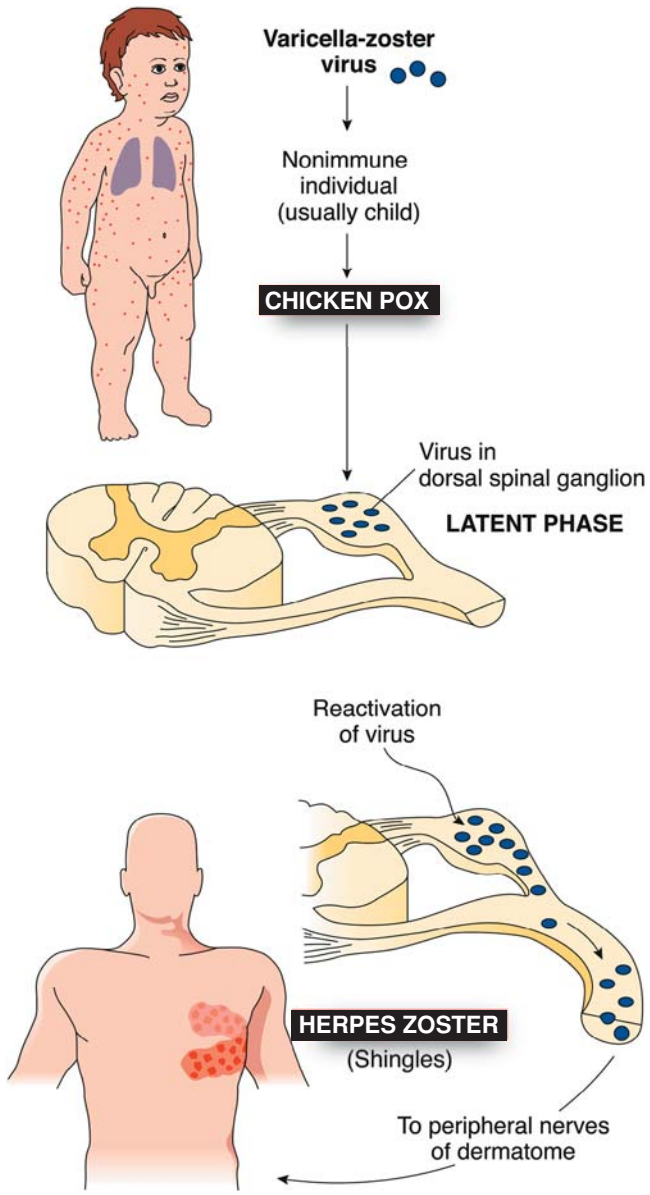

FIGURE 9-5. Varicella (chickenpox) and herpes zoster (shingles). Varicella-zoster virus (VZV) in droplets is inhaled by a nonimmune person (usually a child) and initially causes a "silent" infection of the nasopharynx. This progresses to viremia, seeding of fixed macrophages and dissemination of VZV to skin (chickenpox) and viscera. VZV resides in a dorsal spinal ganglion, where it remains dormant for many years. Latent VZV is reactivated and spreads from ganglia along the sensory nerves to the peripheral nerves of sensory dermatomes, causing shingles.

PATHOLOGY: The skin lesions of chickenpox and shingles are identical to each other and also to lesions caused by HSV. Vesicles fill with neutrophils, soon erode and become shallow ulcers. In infected cells, VZV produces a characteristic cytopathic effect, with nuclear homogenization and intranuclear inclusions (Cowdry type A). Inclusions are large and eosinophilic and are separated from the nuclear membrane by a clear zone (halo). Multinucleated cells are common (Fig. 9-6). Over several days, vesicles become pustules, which then rupture and heal.

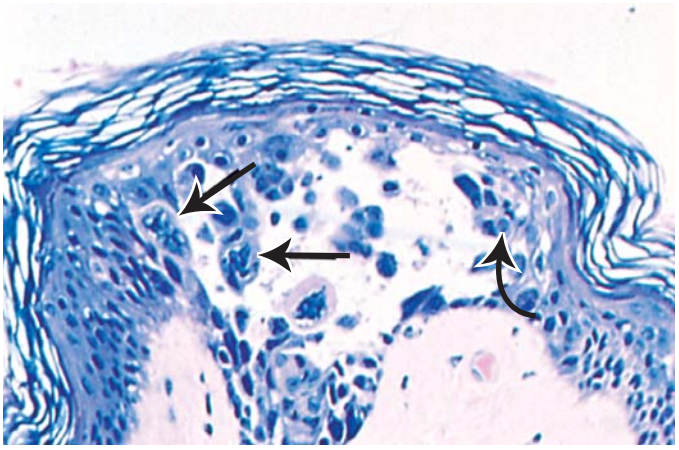

FIGURE 9-6. Varicella. Photomicrograph of the skin from a patient with chickenpox shows an intraepidermal vesicle. Multinucleated giant cells (*straight arrows*) and nuclear inclusions (*curved arrow*) are present.

CLINICAL FEATURES: Chickenpox causes fever, malaise and a distinctive pruritic rash that starts on the head and spreads to the trunk and extremities. Skin lesions begin as maculopapules that rapidly evolve into vesicles, then pustules that soon ulcerate and crust. Vesicles may also appear on mucous membranes, especially the mouth. Fever and systemic symptoms resolve in 3–5 days; skin lesions heal in several weeks.

Shingles presents with a unilateral, painful, vesicular eruption, similar in appearance to chickenpox, usually remaining localized to a single dermatome. Pain can persist for months after skin lesions resolve.

Herpes Simplex Viruses Produce Recurrent Painful Vesicular Eruptions of the Skin and Mucous Membranes

HSVs are common human viral pathogens (Table 9-4). Two antigenically and epidemiologically distinct HSVs cause human disease (Fig. 9-7):

- **HSV-1** is transmitted in oral secretions and typically causes disease "above the waist," including oral, facial and ocular lesions.
- **HSV-2** is transmitted in genital secretions and typically produces genital ulcers and neonatal herpes infection.

TABLE 9-4
HERPES SIMPLEX VIRUS (HSV) DISEASES

Viral Type	Common Presentations	Infrequent Presentations
HSV-1	Oral–labial herpes	Conjunctivitis, keratitis Encephalitis Herpetic whitlow Esophagitis[a] Pneumonia[a] Disseminated infection[a]
HSV-2	Genital herpes	Perinatal infection Disseminated infection[a]

[a]These conditions usually occur in immunocompromised hosts.

EPIDEMIOLOGY: HSV spreads from person to person, mainly via direct contact with infected secretions or open lesions. HSV-1 spreads in oral secretions, and infection frequently occurs in childhood, most people (50%–90%) being infected by adulthood. HSV-2 spreads by contact with genital lesions and is primarily a venereally transmitted pathogen. Neonatal herpes is acquired when a baby passes through an infected birth canal.

PATHOPHYSIOLOGY: Primary HSV disease occurs at a site of initial viral inoculation, such as the oropharynx, genital mucosa or skin. The virus infects epithelial cells, producing progeny viruses and destroying basal cells in the squamous epithelium, with resulting formation of vesicles. Cell necrosis also elicits an inflammatory response, initially dominated by neutrophils and then followed by lymphocytes. Primary infection resolves when humoral and cell-mediated immunity to the virus develop.

Latent infection is established in a manner analogous to that of VZV. The virus invades sensory nerve endings in the oral or genital mucosa, ascends within axons and establishes a latent infection in sensory neurons within corresponding ganglia. From time to time, the virus awakens from latency and travels back down the nerve to the epithelial site served by the ganglion, where it again infects epithelial cells. Sometimes this secondary infection produces ulcerating vesicular lesions. At other times, the secondary infection does not cause visible tissue destruction, but contagious progeny viruses are shed from the site of infection. Various factors, usually typical for a given person, can induce reactivation of latent HSV infection. These include intense sunlight, emotional stress, febrile illness and, in women, menstruation. Both HSV-1 and HSV-2 can cause severe protracted and disseminated disease in immunocompromised persons.

Herpes encephalitis is a rare (1 in 100,000 HSV infections), but devastating, manifestation of HSV-1 infection. In some instances, it occurs when virus that is latent in the trigeminal ganglion is reactivated and travels retrograde to the brain. However, herpes encephalitis also occurs in people who have no history of "cold sores," and the pathogenesis of the encephalitis in these cases is poorly understood (see Chapter 28). Equally rare is **herpes hepatitis,** which may occur in immunocompromised patients but is also seen in previously healthy pregnant women.

Neonatal herpes is a serious complication of maternal genital herpes. The virus is transmitted to the fetus from the infected birth canal, often the uterine cervix, and readily disseminates in the unprotected newborn child.

Aseptic meningitis without genital involvement may be a manifestation of HSV-2 infection.

PATHOLOGY: The skin and mucous membranes are the usual sites of HSV infection, but the disease sometimes involves the brain, eye, liver, lungs and other organs. In any location, both HSV-1 and HSV-2 cause

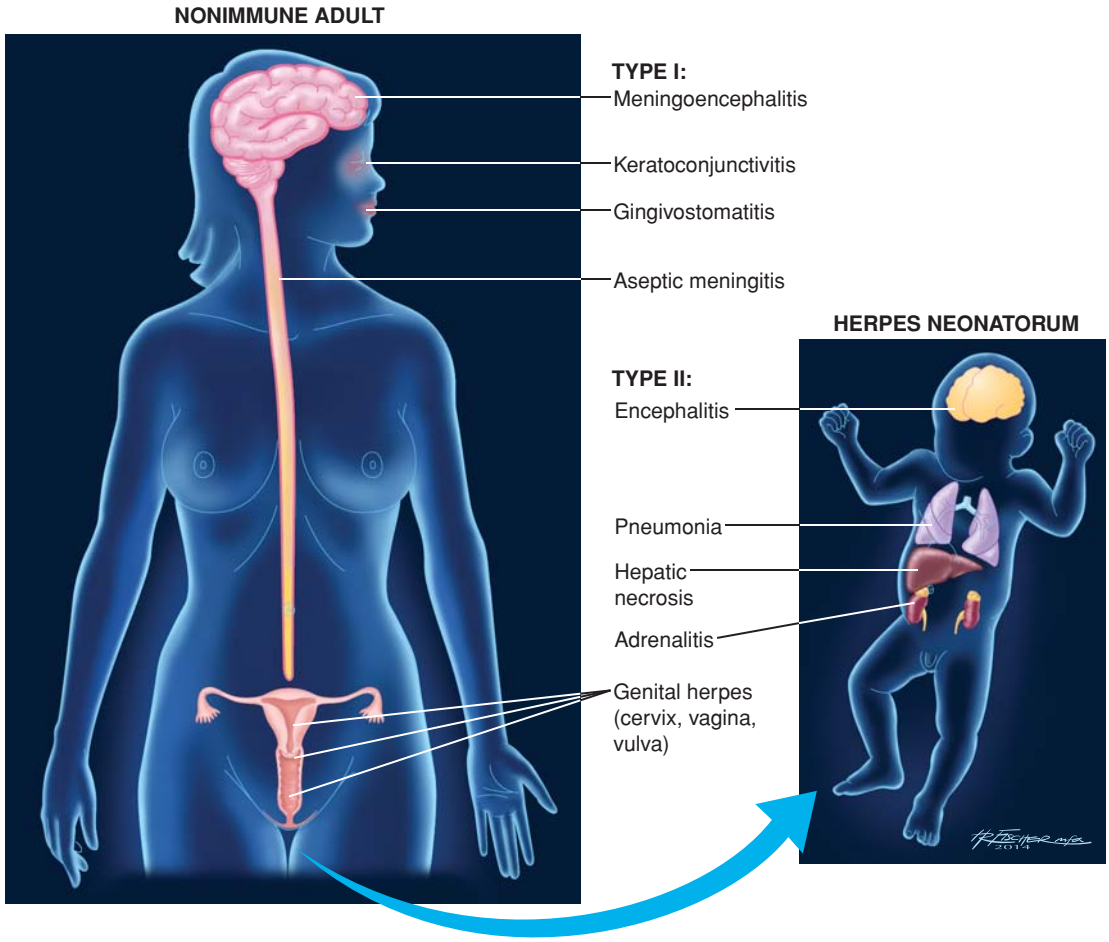

FIGURE 9-7. Herpesvirus infections. Herpes simplex virus type 1 (HSV-1) infects a nonimmune adult, causing gingivostomatitis ("fever blister" or "cold sore"), keratoconjunctivitis, meningoencephalitis and aseptic spinal meningitis. HSV-2 infects the genitalia of a nonimmune adult, involving the cervix, vagina and vulva. HSV-2 infects the fetus as it passes through the birth canal of an infected mother. The infant's lack of a mature immune system results in disseminated infection with HSV-1. The infection is often fatal, involving lung, liver, adrenal glands and central nervous system.

necrosis of infected cells, accompanied by a vigorous inflammatory response. Clusters of painful ulcerating vesicular lesions on the skin or mucous membranes are the most frequent manifestation of HSV infection (Fig. 9-8A). These lesions persist for 1–2 weeks and then resolve. The cellular alterations include (1) nuclear homogenization, (2) Cowdry type A intranuclear inclusions and (3) multinucleated giant cells (Fig. 9-8B).

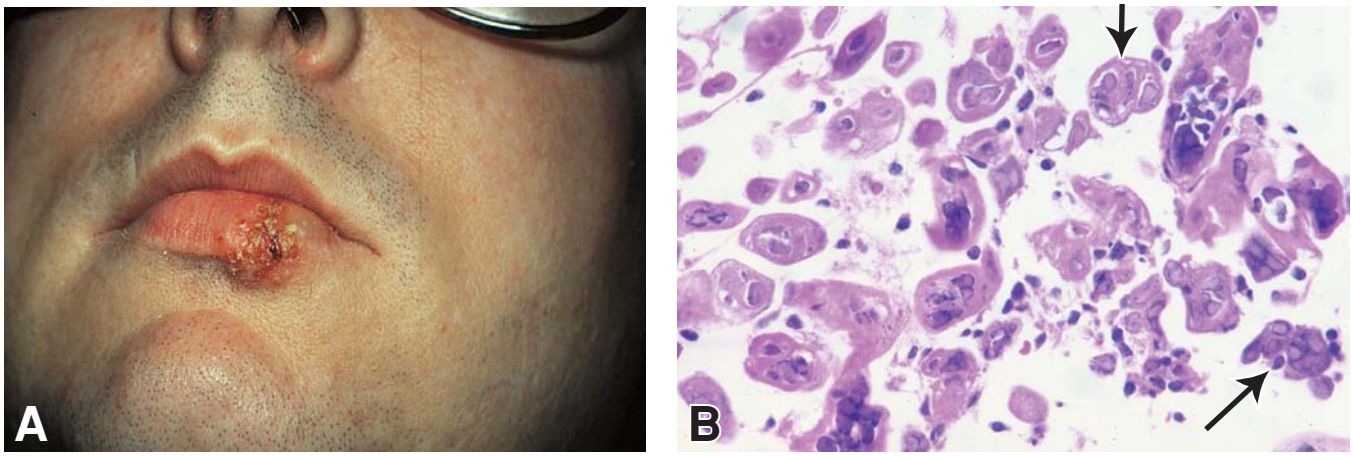

FIGURE 9-8. Herpes simplex virus type 1 (HSV-1). A. Herpetic vesicles are seen on the surface of the lower lip. **B.** Epithelial cells infected with HSV-1 demonstrate Cowdry type A intranuclear inclusions and multinucleated giant cells.

CLINICAL FEATURES: Clinical features of HSV infections vary according to host susceptibility (e.g., neonate, normal host, compromised host), viral type and site of infection. A prodromal "tingling" sensation at the site often precedes the appearance of skin lesions. Recurrent lesions appear weeks, months or years later, at the initial site or at a location subserved by the same nerve ganglion. Recurrent herpetic lesions in the mouth or on the lip, commonly called "cold sores" or "fever blisters," frequently appear after sun exposure, trauma or a febrile illness.

Patients with AIDS and other immunocompromised people are prone to develop herpes esophagitis. Early lesions consist of rounded 1–3-mm vesicles predominantly in the mid- to distal esophagus. As HSV-infected squamous cells slough from these lesions, sharply demarcated ulcers with elevated margins form and coalesce. This process may result in denudation of the esophageal mucosa. Superimposed *Candida* infection is common at this stage. In immunocompromised patients, HSV may also infect the anal mucosa, where it causes painful blisters and ulcers.

Neonatal herpes begins 5–7 days after delivery, with irritability, lethargy and a mucocutaneous vesicular eruption. The infection rapidly spreads to involve multiple organs, including the brain. The infected newborn develops jaundice, bleeding problems, respiratory distress, seizures and coma. Treatment of severe HSV infections with acyclovir is often effective, but neonatal herpes still carries a high mortality.

EPSTEIN-BARR VIRUS

Infectious mononucleosis is a viral disease with fever, pharyngitis, lymphadenopathy and increased circulating lymphocytes. By adulthood, most people have been infected with EBV. Most EBV infections are asymptomatic, but EBV may cause infectious mononucleosis. It is also associated with several cancers, including **African Burkitt lymphoma, B-cell lymphoma** in immunosuppressed patients and **nasopharyngeal carcinoma**. These neoplastic complications are discussed in Chapters 5, 26 and 29.

EPIDEMIOLOGY: In areas of the world where children live in crowded conditions, EBV infection usually occurs before 3 years of age, and infectious mononucleosis is rare. In developed countries, many people remain uninfected into adolescence or early adulthood. Two thirds of those newly infected after childhood develop clinically evident infectious mononucleosis.

EBV spreads from person to person primarily through contact with infected oral secretions (Fig. 9-9). Once it enters the body, EBV remains for life, analogous to latent infections with other herpesviruses. A few people (10%–20%) shed the virus intermittently. Transmission requires close contact with infected individuals. Thus, EBV spreads readily among young children in crowded conditions, where there is considerable "sharing" of oral secretions. Kissing is also an effective mode of transmission, hence the term "kissing disease."

PATHOPHYSIOLOGY: The virus first binds to and infects nasopharyngeal cells and then B lymphocytes, which carry the virus throughout the body, producing a generalized infection of lymphoid tissues.

EBV is a polyclonal activator of B cells. In turn, activated B cells stimulate proliferation of specific killer T lymphocytes and suppressor T cells. The former destroy virally infected B cells, whereas suppressor cells inhibit production of immunoglobulins by B cells.

PATHOLOGY: The pathology of infectious mononucleosis mainly involves the lymph nodes and spleen. In most patients, lymphadenopathy is symmetric and most striking in the neck. The nodes are movable, discrete and tender. General nodal architecture is preserved. Germinal centers are enlarged with indistinct margins, because of proliferation of immunoblasts. Nodes contain occasional large hyperchromatic cells with polylobular nuclei that resemble Reed-Sternberg cells of Hodgkin disease. In fact, lymph node histology may be difficult to distinguish from Hodgkin disease or other lymphomas (see Chapter 26).

The spleen is large and soft owing to hyperplasia of the red pulp, and is susceptible to rupture. Immunoblasts are abundant and infiltrate vessel walls, the trabeculae and the capsule. The liver is almost always involved, with sinusoids and portal tracts containing atypical lymphocytes.

Infectious mononucleosis is characterized by lymphocytosis with **atypical lymphocytes**. These are activated T cells with lobulated, eccentric nuclei and vacuolated cytoplasm that kill EBV-infected B lymphocytes. Patients with infectious mononucleosis develop a specific **heterophile antibody**—an immunoglobulin produced in one species that reacts with antigens of another species. These antibodies in infectious mononucleosis are detected by their affinity for sheep erythrocytes, which is used as a standard diagnostic test for infectious mononucleosis. Specific serologic tests for antibodies against EBV are also available.

CLINICAL FEATURES: Infectious mononucleosis manifests as fever, malaise, lymphadenopathy, pharyngitis and splenomegaly. Patients usually have elevated leukocyte counts, with a predominance of lymphocytes and monocytes. Treatment is supportive; symptoms usually resolve in 3–4 weeks.

CYTOMEGALOVIRUS

CMV is a congenital and opportunistic pathogen that usually produces asymptomatic infection. However, the fetus and immunocompromised patients are particularly vulnerable to its destructive effects. CMV infects 0.5%–2.0% of all fetuses and injures 10%–20% of those infected, making it the most common congenital pathogen.

EPIDEMIOLOGY: CMV spreads from person to person by contact with infected secretions and bodily fluids and is transmitted to the fetus across the placenta. Children spread it in saliva or urine, while transmission among adolescents and adults is primarily through sexual contact.

ETIOLOGIC FACTORS: CMV infects various human cells, including epithelial cells, lymphocytes and monocytes, and establishes latency in white blood cells. Normal immune responses rapidly control

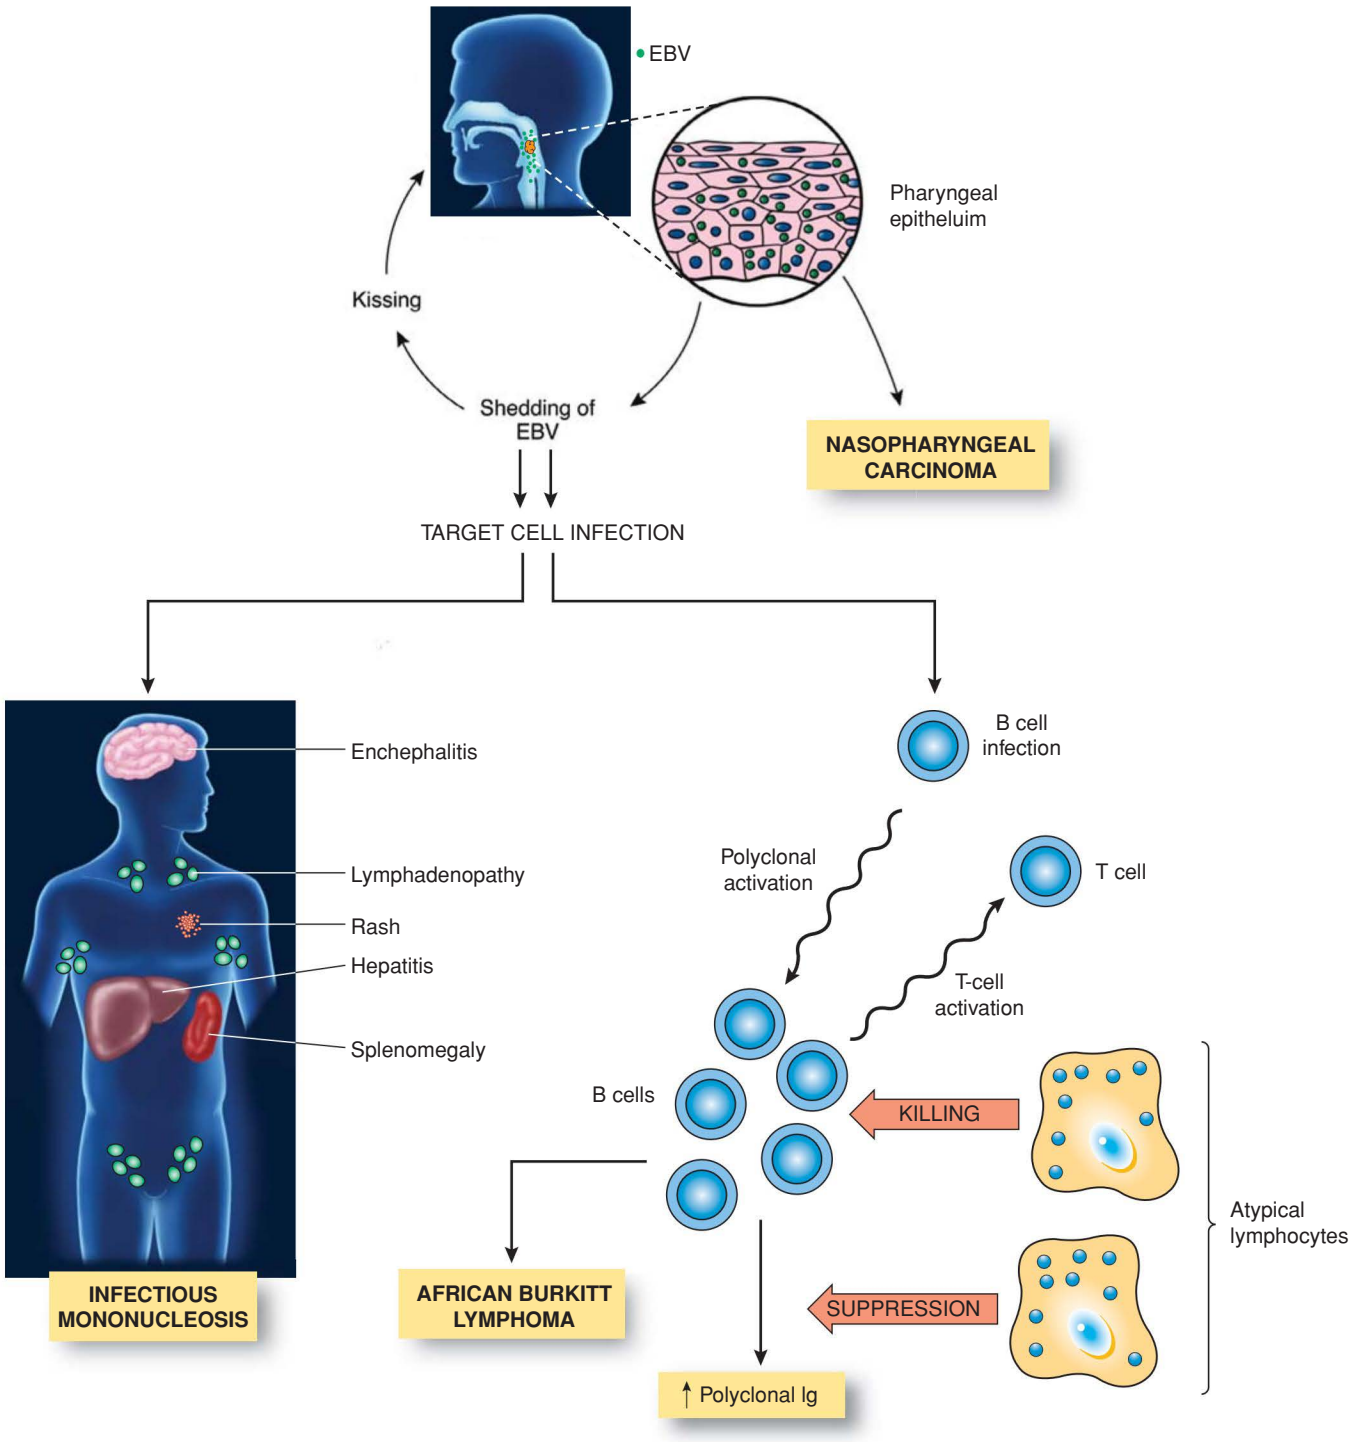

FIGURE 9-9. Role of Epstein-Barr virus (EBV) in infectious mononucleosis, nasopharyngeal carcinoma and Burkitt lymphoma. EBV invades and replicates within the salivary glands or pharyngeal epithelium and is shed into the saliva and respiratory secretions. In some people, the virus transforms pharyngeal epithelial cells, leading to nasopharyngeal carcinoma. In persons who are not immune from childhood exposure, EBV causes infectious mononucleosis. EBV infects B lymphocytes, which undergo polyclonal activation. These B cells stimulate the production of atypical lymphocytes, which kill virally infected B cells and suppress the production of immunoglobulins. Some infected B cells are transformed into immature malignant lymphocytes of Burkitt lymphoma.

infection, and ill effects are rare. However, virus is shed periodically in body secretions. Like other herpesviruses, CMV may remain latent for life.

When an infected pregnant woman passes CMV to her fetus, the fetus is not protected by maternally derived antibodies. As a result, the virus invades fetal cells with little initial immunologic response, causing widespread necrosis and inflammation. CMV produces similar lesions in patients with suppressed cell-mediated immunity.

CMV infection is often symptomatic in immunosuppressed individuals, such as organ transplant recipients. In that setting, the CMV infection usually represents

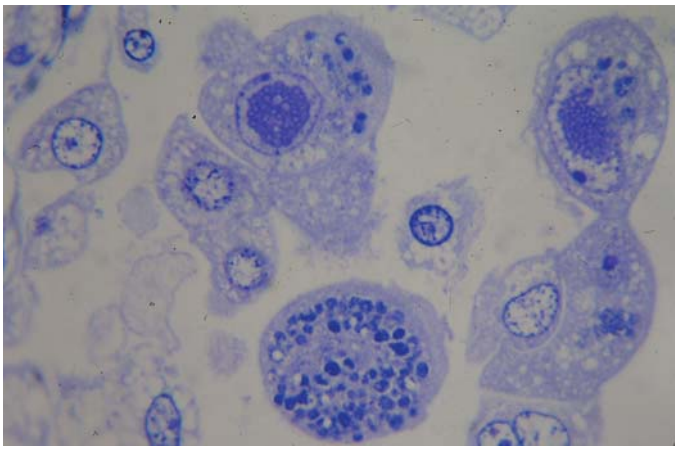

FIGURE 9-10. Cytomegalovirus (CMV) pneumonitis. Two type II pneumocytes display enlarged nuclei containing solitary CMV inclusions surrounded by a clear zone. The cell at the bottom shows numerous intracytoplasmic CMV inclusions.

reactivation of endogenous latent infection, whether the source is the graft or the recipient. Subsequent dissemination may lead to severe systemic disease.

PATHOLOGY: Fetal CMV disease most commonly involves the brain, inner ears, eyes, liver and bone marrow. Severely affected fetuses may have microcephaly, hydrocephalus, cerebral calcifications, hepatosplenomegaly and jaundice. Lesions of fetal CMV disease show cellular necrosis and a characteristic cytopathic effect, consisting of marked cellular and nuclear enlargement, with nuclear and cytoplasmic inclusions. The giant nucleus, which is usually solitary, contains a large central inclusion surrounded by a clear zone. The smaller, granular intracytoplasmic inclusions of CMV occur after formation of the intranuclear inclusion (Fig. 9-10), so that not all CMV-infected cells demonstrate them.

CLINICAL FEATURES: Congenital CMV disease has diverse clinical presentations. At its worst, it many lead to fetal death in utero with conspicuous CNS lesions, liver disease and bleeding. Most congenital CMV infection may not be detected until later in life and manifest as subtle neurologic or hearing defects without gross abnormalities.

CMV disease in immunosuppressed patients has a wide range of clinical manifestations. It can lead to decreased visual acuity (chorioretinitis), diarrhea or gastrointestinal hemorrhage (colonic ulcerations), change in mental status (encephalitis), shortness of breath (pneumonitis) or any number of other symptoms.

HUMAN PAPILLOMAVIRUS

HPVs cause proliferative lesions of squamous epithelium, including common warts, flat warts, plantar warts, anogenital warts (condyloma acuminatum) and laryngeal papillomatosis. Some HPV serotypes cause squamous cell dysplasias and squamous cell carcinomas of the genital tract (see Chapters 5 and 24).

HPVs are nonenveloped, double-stranded DNA viruses. Over 100 HPV types are known, different ones causing different lesions. Thus, HPV types 1, 2 and 4 produce common warts and plantar warts. Types 6, 10, 11 and 40 through 45 cause anogenital warts. Types 16, 18 and 31 are associated with squamous carcinomas of the female genital tract.

HPV infection is widespread. It is transmitted by direct person-to-person contact. Most children develop common warts. The viruses that cause genital lesions are transmitted sexually.

PATHOPHYSIOLOGY: HPV infection begins with viral inoculation into a stratified squamous epithelium, where the virus enters the nuclei of basal cells. Infection stimulates proliferation of the squamous epithelium, producing the various HPV-associated lesions. The rapidly growing squamous epithelium replicates innumerable progeny viruses, which are shed in the degenerating superficial cells. Many HPV lesions resolve spontaneously. Depressed cell-mediated immunity may lead to persistence and spread of HPV lesions. Malignant change in HPV infections is discussed in Chapter 5.

PATHOLOGY: HPV infections produce squamous proliferations, which vary in appearance and biological behavior. Most show thickening of affected epithelium. Some HPV-infected cells show characteristic **koilocytosis,** with large squamous cells with shrunken nuclei enveloped in large cytoplasmic vacuoles (koilocytes).

CLINICAL FEATURES: Common warts (verruca vulgaris) are firm, circumscribed, raised, rough-surfaced lesions, which usually appear on surfaces subject to trauma, especially the hands (see Chapter 28). **Plantar warts** are similar squamous proliferative lesions on the soles of the feet but are compressed inward by standing and walking.

Anogenital warts (condyloma acuminatum) are soft, raised, fleshy lesions found on the penis, vulva, vaginal wall, cervix or perianal region. When caused by certain HPV types, flat warts can evolve into malignant squamous cell proliferations. The relationship between HPV, cervical intraepithelial neoplasia (CIN) and invasive squamous carcinoma of the cervix is discussed in Chapter 18. Many squamous carcinomas of the upper respiratory tract and lung have recently been shown to harbor HPV.

Prions: A New Disease Paradigm

In the last several decades, it has become clear that infection can be transmitted and propagated solely by proteins, without the participation of nucleic acids. To date, these particles, prions, are only known to cause CNS disease. Prions are essentially misfolded proteins that aggregate in the CNS and cause progressive neurodegeneration. The prion protein (PrP) exists in a normal isoform and in a pathogenic form. The latter is transmissible. Of particular importance is the uncommon

persistence of these infectious agents. Normal methods of sterilization do not inactivate them, so they may be transmitted via surgical instruments or electrodes. All prion diseases feature spongiform encephalopathy. The mechanisms of prion-associated diseases are discussed more fully in Chapter 32.

- **Kuru:** Kuru is a progressive neurodegenerative disease only found in the South Fore tribe in the remote highlands of Papua New Guinea. Kuru, the Fore word for "trembling," was transmitted via cannibalism. Once funerary cannibalism among the Fore was eliminated, kuru disappeared within a generation.
- **Sporadic, familial and iatrogenic Creutzfeldt-Jakob disease** (sCJD, fCJD and iCJD): CJD is a rapidly progressive neurodegenerative disorder characterized by myoclonus, behavior changes and dementia (see Chapter 32). With a frequency of 1 in 1,000,000, sCJD is probably the most common human prion disease. Rarely, CJD has resulted from transmission through transplanting such tissues as cornea and dural matter. Before the advent of recombinant protein therapeutics, CJD was also transmitted from human growth hormone isolated by cadaver pituitaries.
- **New variant Creutzfeldt-Jakob disease** (vCJD): One of the more infamous emerging infectious diseases of the last few decades, both vCJD and bovine spongiform encephalopathy (BSE), also known as "mad cow "disease, underscore the interrelatedness of animal and human infectious agents. The use of certain animal products in feeds for domestic ungulates led to a prion disease epidemic in cattle herds of the United Kingdom. Nearly 150 people are known to have been infected with this relentless terminal disease. All patients to date have had an uncommon genetic homozygosity: methionine–methionine at codon 129 of the gene (PRNP) for the prion protein. Presentations have differed from previously recognized forms of CJD in a number of important ways, with age of onset being most notable. Whereas the mean onset of CJD has been 65 years, vCJD has mainly occurred in young adults, with a mean age of 26. Psychiatric signs and symptoms have also been predominant in vCJD. Pathologic changes in vCJD are strikingly similar to those seen in BSE and differ somewhat from changes seen in the sporadic form.
- **Fatal familial insomnia:** This is a rare inherited prion disorder that has as its hallmark a progressive course of insomnia that worsens over time until the patient sleeps barely or not at all. There is also autonomic instability, which usually manifests as increased sympathetic tone. Altered sensorium may also be present, and signs of motor system degeneration follow. Spongiform changes like those seen in other transmissible spongiform encephalopathies are also seen later in the disease.
- **Gerstmann-Sträussler-Scheinker syndrome:** This rare transmissible spongiform encephalopathy is usually familial, although rare sporadic cases have been described. Patients may present with a variety of symptoms, but signs and symptoms of cerebellar degeneration usually predominate. Later, dementia becomes common.

Bacterial Infections

Bacteria, at 0.1–10 µm, are the smallest living cells. They have three basic structural components: nuclear body, cytosol and envelope. The **nuclear body** consists of a single, coiled, circular molecule of double-stranded DNA with associated RNA and proteins. It is not separated from the cytoplasm by a special membrane, a feature that distinguishes bacteria, as prokaryotes, from eukaryotes. The **cytosol** is densely packed with ribosomes, proteins and carbohydrates and lacks the structured organelles, such as mitochondria and Golgi apparatus, of eukaryotic cells. The **bacterial envelope** is a permeability barrier and is also actively involved in transport, protein synthesis, energy generation, DNA synthesis and cell division.

Bacteria are classified by the structural features of their envelope. The simplest envelope is only a phospholipid–protein bilayer membrane. Mycoplasmas have such an envelope. Most bacteria, however, have a rigid cell wall that surrounds the cell membrane. Two types of bacterial cell walls are identified by their Gram stain properties:

- **Gram-positive bacteria** retain iodine–crystal violet complexes when decolorized and appear dark blue. Their cell walls contain teichoic acids and a thick peptidoglycan layer.
- **Gram-negative bacteria** lose the iodine–crystal violet stain when decolorized and appear red with a counterstain. Outer membranes of gram-negative bacteria contain a lipopolysaccharide component, known as endotoxin, which is a potent mediator of the shock that complicates infections with these organisms.

Both gram-positive and gram-negative cell walls may be surrounded by an additional layer of polysaccharide or protein gel, a **capsule**. Capsules aid bacterial attachment and colonization and may protect bacteria from phagocytosis. Because capsules are important in many infections, bacteria may be classified as **encapsulated** or **unencapsulated**.

The cell wall confers rigidity to bacteria and allows them to be distinguished on the basis of shape and pattern of growth in cultures. Round or oval bacteria are **cocci** .Those that grow in clusters are called **staphylococci,** while those that grow in chains are **streptococci**. Elongate bacteria are **rods,** or **bacilli,** and curved ones are **vibrios.** Some spiral-shaped bacteria are named **spirochetes**.

Most bacteria can be cultured on chemical media, and so may be described according to their growth requirements on these media. Bacteria that need high levels of oxygen are called **aerobic,** those that grow best without oxygen are **anaerobic** and those that thrive with limited oxygen are **microaerophilic**. Bacteria that grow well with or without oxygen are **facultative anaerobes**.

BACTERIAL EXOTOXINS: Many bacteria secrete toxins (exotoxins) that damage human cells, either at the site of bacterial growth or at distant sites. These toxins are often named for the site or mechanism of their activity. Thus, those that act on the nervous system are **neurotoxins;** those that affect intestinal cells are **enterotoxins**. Some toxins that kill target cells, such as diphtheria toxin or some of the *Clostridium perfringens* toxins, are known as **cytotoxins.** Others may disturb normal functions of their target cells and damage or kill them, like the diarrheagenic toxin of *Vibrio cholerae* or the neurotoxin of *Clostridium botulinum. C. perfringens* produces over 20 highly diverse toxins.

BACTERIAL ENDOTOXINS: As mentioned above, gram-negative bacteria contain a structural element called **lipopolysaccharide,** or **endotoxin,** in their outer membranes. Lipopolysaccharide activates complement, coagulation, fibrinolysis and bradykinin systems (see Chapter 2). It also

causes release of primary inflammatory mediators, including tumor necrosis factor (TNF) and interleukin-1 (IL-1), and various colony-stimulating factors. Endotoxin may cause shock, complement depletion and disseminated intravascular coagulation.

Many bacteria damage tissues by eliciting inflammatory or immune responses. The capsule of *Streptococcus pneumoniae* protects it from phagocytosis while activating a host's inflammatory response. Within the lung, the encapsulated organism causes exudation of fluid and cells that fill alveoli. This inflammation impairs breathing but does not, at least initially, limit the organism's proliferation. *Treponema pallidum,* the spirochete that causes syphilis, persists in the body for years and elicits inflammatory and immune responses that continuously damage host tissues.

Many common bacterial infections (e.g., *Staphylococcus aureus* skin infections) are characterized by purulent exudates, but tissue responses to bacteria are highly variable. In some cases, such as cholera, botulism and tetanus, there is no inflammatory response at critical sites of cellular injury. Other bacterial infections, including syphilis and Lyme disease, lead to a predominantly lymphocytic and plasma cellular response. Still others (e.g., brucellosis) are characterized by granuloma formation.

Many bacterial diseases are caused by organisms that normally inhabit the human body. The gastrointestinal tract, upper respiratory tract, skin and vagina are all home to diverse bacteria. These microorganisms are normally commensal and cause no harm. However, if they gain access to usually sterile sites, or if host defenses are impaired, they can produce extensive destruction. *S. aureus, S. pneumoniae* and *Escherichia coli* are normal flora that are also major human pathogens.

PYOGENIC GRAM-POSITIVE COCCI

Staphylococcus aureus Produces Suppurative Infections

S. aureus is a gram-positive coccus that typically grows in clusters and is among the most common bacterial pathogens. It normally resides on the skin and is readily inoculated into deeper tissues, where it causes suppurative infections. ***It is the most common cause of suppurative infections of the skin, joints and bones and is a leading cause of infective endocarditis***. *S. aureus* is commonly distinguished from other, less virulent staphylococci by the coagulase test. *S. aureus* is coagulase positive; the other staphylococci are coagulase negative.

S. aureus spreads by direct contact with colonized surfaces or persons. Most people are intermittently colonized with *S. aureus* and carry it on the skin, nares or clothing. The organism also survives on inanimate surfaces for long periods.

PATHOPHYSIOLOGY: Many *S. aureus* infections begin as localized infections of skin and skin appendages, producing cellulitis and abscesses. The organism, equipped with destructive enzymes and toxins, sometimes invades beyond the initial site, spreading by blood or lymphatics to almost any location in the body. Bones, joints and heart valves are the most common sites of metastatic *S. aureus* infections. *S. aureus* also causes several distinct diseases by elaborating toxins that are carried to distant sites.

PATHOLOGY: When *S. aureus* is introduced into a previously sterile site, infection usually produces suppuration and abscesses. These range from microscopic foci to lesions several centimeters in diameter, which are filled with pus and bacteria.

CLINICAL FEATURES: The clinical manifestations of *S. aureus* disease vary according to the sites and types of infection.

- **Furuncles (boils) and styes:** Deep-seated *S. aureus* infections occur in and around hair follicles, often in a nasal carrier. They localize on hairy surfaces, such as the neck, thighs and buttocks of men and the axillae, pubic area and eyelids of both sexes. Boils begin as nodules at the bases of hair follicles, becoming pimples that remain painful and red for a few days. Yellow apices form and central cores become necrotic and fluctuant. Rupture or incision relieves the pain. **Styes** are boils that involve the sebaceous glands around the eyelid. **Paronychia** are staphylococcal infections of nail beds, and **felons** are the same infections on the palmar side of the fingertips.
- **Carbuncles:** These lesions, mostly on the neck, result from coalescing infections with *S. aureus* around hair follicles and produce draining sinuses (Fig. 9-11).
- **Scalded skin syndrome:** This disease affects infants and children under 3 years, who present with a sunburn-like rash that begins on the face and spreads over the body. Bullae begin to form and even gentle rubbing causes skin to desquamate. The disease begins to resolve in 1–2 weeks, as the skin regenerates. Desquamation is due to systemic effects of a specific exotoxin, and the site of *S. aureus* proliferation is often occult.

FIGURE 9-11. Staphylococcal carbuncle. The posterior neck is indurated and shows multiple follicular abscesses discharging purulent material.

- **Osteomyelitis:** Acute staphylococcal osteomyelitis, usually in the leg bones, most commonly afflicts boys between 3 and 10 years old. There is usually a history of infection or trauma. If not properly treated, osteomyelitis may become chronic. Adults older than 50 years are more frequently afflicted with vertebral osteomyelitis, which may follow staphylococcal infections of the skin or urinary tract, prostatic surgery or pinning of a fracture.
- **Infections of burns or surgical wounds:** These sites often become infected with *S. aureus* from the patient's own nasal carriage or from medical personnel. Newborns and elderly, malnourished, diabetic and obese persons all have increased susceptibility.
- **Respiratory tract infections:** Staphylococcal respiratory tract infections occur mostly in infants under 2 years, and especially under 2 months. The infection is characterized by ulcers of the upper airway, scattered foci of pneumonia, pleural effusion, empyema and pneumothorax. In adults, staphylococcal pneumonia may follow viral influenza, which destroys the ciliated surface epithelium and leaves the bronchial surface vulnerable to secondary infection.
- **Bacterial arthritis:** *S. aureus* is responsible for half of all septic arthritis, mostly in patients 50–70 years old. Rheumatoid arthritis and corticosteroid therapy are common predisposing conditions.
- **Septicemia:** Septicemia with *S. aureus* afflicts patients with lowered resistance who are in the hospital for other diseases. Some have underlying staphylococcal infections (e.g., septic arthritis, osteomyelitis), some have had surgery (e.g., transurethral prostate resection) and some have infections from an indwelling intravenous catheter. Miliary abscesses and endocarditis are serious complications.
- **Bacterial endocarditis:** This common complication of *S. aureus* septicemia may develop spontaneously on normal valves, on valves damaged by rheumatic fever or on prosthetic valves. Intravenous drug abuse predisposes to staphylococcal endocarditis.
- **Toxic shock syndrome:** This potentially fatal disorder most commonly afflicts menstruating women, who present with high fever, nausea, vomiting, diarrhea and myalgias. Subsequently, they develop shock and within several days a sunburn-like rash. Toxic shock syndrome is associated with use of tampons, particularly hyperabsorbent ones, which provide a site for *S. aureus* replication and toxin elaboration. Toxic shock syndrome occurs rarely in children and men, and is then usually associated with an occult *S. aureus* infection.
- **Staphylococcal food poisoning:** Staphylococcal food poisoning typically begins less than 6 hours after a meal. Nausea and vomiting begin abruptly and usually resolve within 12 hours. This disease is caused by preformed toxin present in the food at the time it is eaten.
- **Antibiotic-resistant *S. aureus:*** One of the most important clinical issues concerning *S. aureus* is the relentless increase in its antibiotic resistance since penicillin was introduced in the early 1940s. *S. aureus* was one of the first important pathogens to become completely resistant to penicillin and, with time, to each subsequent generation of penicillin derivatives. Today, methicillin-resistant *S. aureus* (MRSA) infections are usually acquired in the hospital, in an environment that selects for antibiotic-resistant bacteria. MRSA represents one of the most dreaded of nosocomial infections. Between 1995 and 2004, the percentage of *S. aureus* infections due to MRSA in patients in intensive care units doubled to almost two thirds. As of 2007, 0.8% of the U.S. population were colonized with MRSA. MRSA infections in the United States are responsible for 19,000 deaths annually. Community-acquired MRSA appears to be a different strain from hospital-acquired MRSA infections with enhanced virulence and different susceptibility to antibiotics.

Coagulase-Negative Staphylococci Infect Prosthetic Devices

Coagulase-negative staphylococci are the major cause of infections involving medical devices, including intravenous catheters, prosthetic heart valves, heart pacemakers, orthopedic prostheses, cerebrospinal fluid shunts and peritoneal catheters.

Disease caused by coagulase-negative staphylococci usually derives from the normal bacterial flora. Of the more than 20 known species of coagulase-negative staphylococci, 10 are normal residents of human skin and mucosal surfaces. Staphylococcus epidermidis *is the most frequent cause of infections associated with medical devices.* Another species, *Staphylococcus saprophyticus,* causes 10%–20% of acute urinary tract infections in young women.

PATHOPHYSIOLOGY: Coagulase-negative staphylococci readily contaminate foreign bodies, on which they proliferate slowly, inducing inflammatory responses that damage adjacent tissue. Bacteria present on an intravascular surface, such as the tip of an intravascular catheter, can spread through the bloodstream to cause metastatic infections. Coagulase-negative staphylococci lack the enzymes and toxins that permit *S. aureus* to cause extensive local tissue destruction. Some strains of coagulase-negative staphylococci produce a polysaccharide gel biofilm, which enhances their adherence to foreign objects and protects them from host antimicrobial defenses and from many antibiotics.

PATHOLOGY: Medical devices infected with coagulase-negative staphylococci are usually thinly coated with tan, fibrinous material. Coagulase-negative staphylococcal infections usually do not produce extensive local tissue necrosis or large quantities of pus. Microscopic examination of infected devices shows clusters of gram-positive bacteria embedded in fibrin and cellular debris, with an associated acute inflammatory infiltrate.

CLINICAL FEATURES: Coagulase-negative staphylococcal infections usually have subtle clinical presentations, and the only symptom of infection may be persistent low-grade fever. Infection of orthopedic prostheses frequently causes progressive loosening and dysfunction of the devices. These infections are usually indolent, but in compromised hosts, they may be fatal. Treatment usually requires replacement of any infected foreign object and appropriate antibiotic therapy. Nosocomial strains of coagulase-negative *Staphylococcus* are often multidrug resistant. Some 80% of such hospital-acquired isolates have

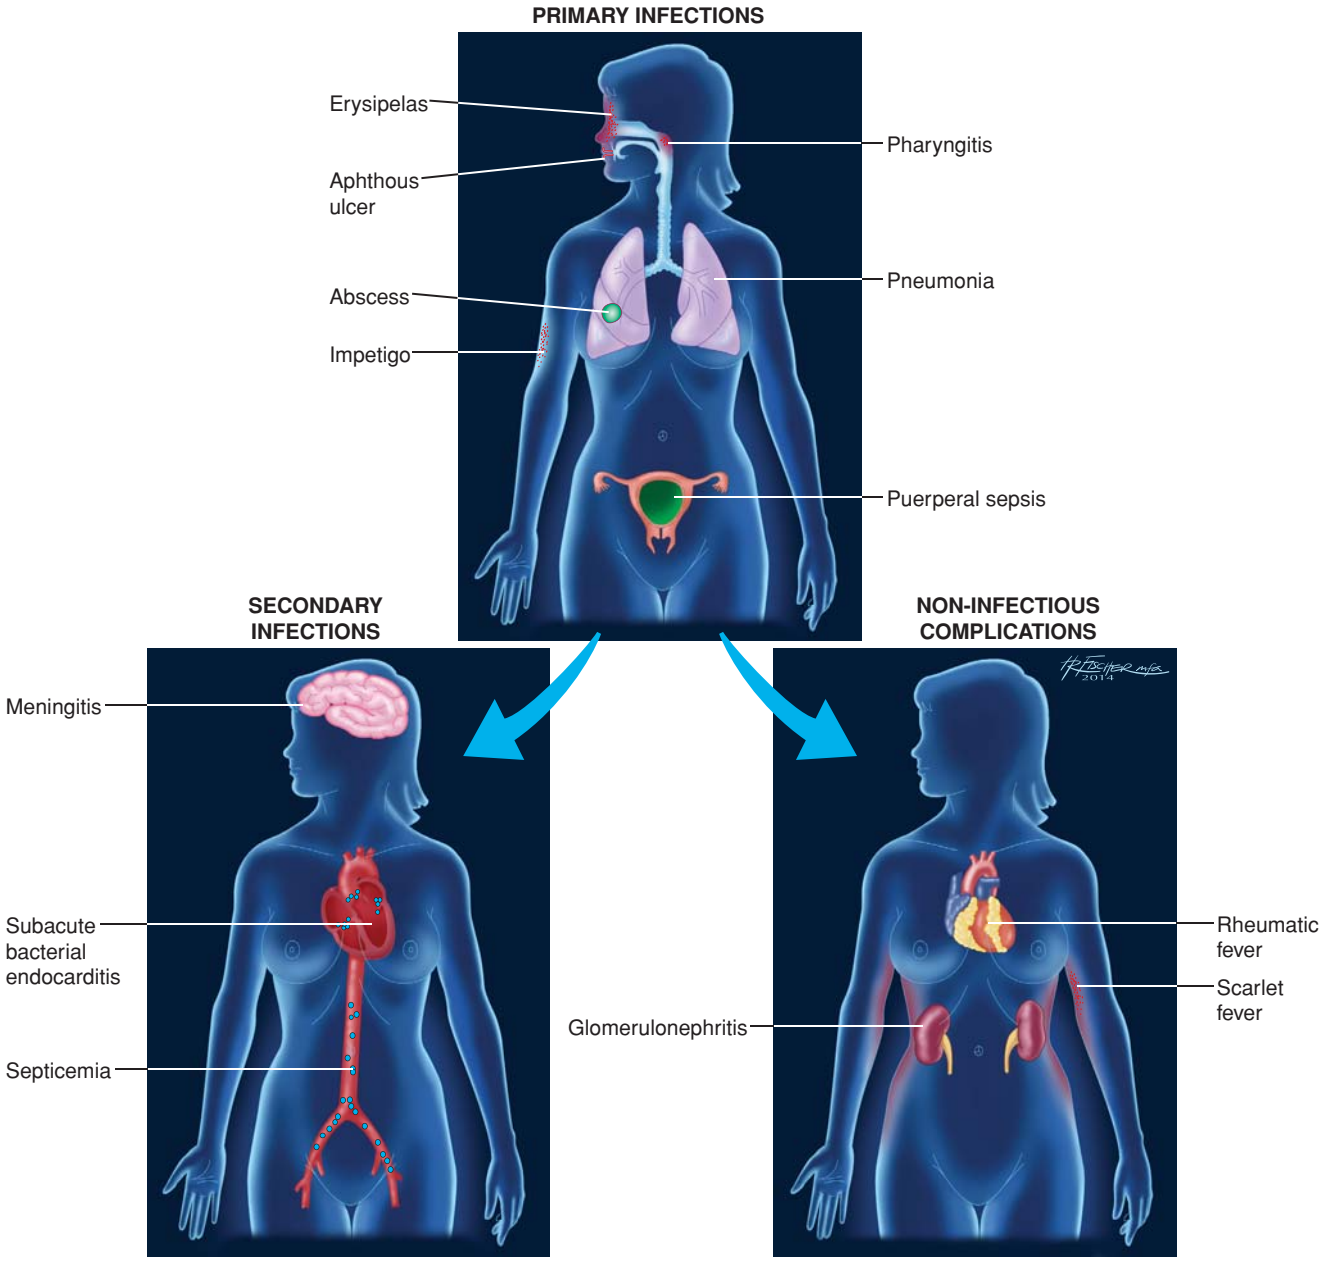

FIGURE 9-12. Streptococcal diseases.

the *mecA* gene, which encodes resistance to all classes of β-lactam antibiotics.

Streptococcus pyogenes Causes Suppurative, Toxin-Related and Immunologic Reactions

Streptococcus pyogenes, ***also known as group A streptococcus, is one of the most common human pathogens, causing diseases of diverse organ systems, from acute self-limited pharyngitis to major illnesses such as rheumatic fever*** (Fig. 9-12). This gram-positive coccus is frequently part of the endogenous flora of the skin and oropharynx.

Diseases caused by *S. pyogenes* may be suppurative or nonsuppurative. The former occur at sites of bacterial invasion and consequent tissue necrosis and usually involve acute inflammatory responses. Suppurative *S. pyogenes* infections include pharyngitis, impetigo, cellulitis, myositis, pneumonia and puerperal sepsis. By contrast, the locations of nonsuppurative diseases caused by *S. pyogenes* are remote from the site of bacterial invasion. The two major nonsuppurative complications of *S. pyogenes* are rheumatic fever and acute poststreptococcal glomerulonephritis. These involve (1) organs far from the sites of streptococcal invasion, (2) a time delay after the acute infection and (3) immune reactions. Rheumatic fever is discussed in Chapter 17 and poststreptococcal glomerulonephritis in Chapter 22.

S. pyogenes elaborates several exotoxins, including erythrogenic toxins and cytolytic toxins **(streptolysins S and O)**. Erythrogenic toxins cause the rash of scarlet fever. Streptolysin S lyses bacterial protoplasts (L forms) and probably destroys neutrophils after they ingest *S. pyogenes*. Streptolysin O induces a persistently high antibody titer, an effect that provides a useful marker for the diagnosis of *S. pyogenes* infections and their nonsuppurative complications.

Streptococcal Pharyngitis ("Strep Throat")

S. pyogenes, the common bacterial cause of pharyngitis, spreads from person to person by direct contact with oral or respiratory secretions. "Strep throat" occurs worldwide, predominantly affecting children and adolescents.

MOLECULAR PATHOGENESIS: *S. pyogenes* attaches to epithelial cells by binding to fibronectin on their surface. The bacterium produces hemolysins, DNAase, hyaluronidase and streptokinase, which allow it to damage and invade human tissues. *S. pyogenes* also has cell wall components that protect it from the inflammatory response. One of these, **M protein,** protrudes from cell walls of virulent strains and prevents complement deposition, thereby protecting bacteria from phagocytosis. Another surface protein destroys C5a, blocking its opsonizing effect and inhibiting phagocytosis. The invading organism elicits acute inflammation, often producing an exudate of neutrophils in the tonsillar fossae.

CLINICAL FEATURES: "**Strep throat**" is a sore throat with fever, malaise, headache and elevated leukocyte count. It usually lasts 3–5 days. ***In a few cases, streptococcal pharyngitis leads to rheumatic fever or acute poststreptococcal glomerulonephritis.*** Penicillin treatment shortens the course of strep throat and, more importantly, prevents nonsuppurative sequelae.

Scarlet Fever

Scarlet fever **(scarlatina)** describes a punctate red rash on the skin and mucous membranes in some suppurative *S. pyogenes* infections, most commonly pharyngitis. It usually begins on the chest and spreads to the extremities. The tongue may develop a yellow-white coating, which sheds to reveal a "beefy-red" surface. Scarlet fever is caused by an erythrogenic toxin.

Erysipelas

Erysipelas is an erythematous swelling of the skin caused chiefly by *S. pyogenes* (Fig. 9-13). This disorder is common in warm climates but is not often seen before the age of 20 years. It usually begins on the face and spreads rapidly. A diffuse, edematous, acute inflammatory reaction in the epidermis and dermis extends into subcutaneous tissues. The inflammatory infiltrate is principally composed of neutrophils and is most intense around vessels and adnexa of the skin. Cutaneous microabscesses and small foci of necrosis are common.

FIGURE 9-13. Erysipelas. Streptococcal infection of the skin has resulted in an erythematous and swollen finger.

FIGURE 9-14. Streptococcal impetigo. The lower extremities exhibit numerous erythematous papules, with central ulceration and the formation of crusts.

Impetigo

Impetigo **(pyoderma)** is a localized, intraepidermal infection caused by *S. pyogenes* or *S. aureus*. Strains of *S. pyogenes* that cause impetigo are antigenically and epidemiologically distinct from those that cause pharyngitis.

Impetigo spreads from person to person by direct contact and most commonly affects children aged 2–5 years. Infection begins with skin colonization with the causative organism. Minor trauma or an insect bite then inoculates the bacteria into the skin, where they form an intraepidermal pustule, which ruptures and leaks a purulent exudate.

Lesions begin on exposed body surfaces as localized erythematous papules (Fig. 9-14). These become pustules, which erode within a few days to form a thick honey-colored crust. Impetigo sometimes leads to poststreptococcal glomerulonephritis, but it does not give rise to rheumatic fever.

Streptococcal Cellulitis

S. pyogenes causes an acute spreading infection of the loose connective tissue of the deeper layers of the dermis. This suppurative process results from traumatic inoculation of microorganisms into the skin and frequently occurs on the extremities in the context of impaired lymphatic drainage. Cellulitis usually begins at sites of unnoticed injury and appears as spreading areas of redness, warmth and swelling.

Puerperal Sepsis

Puerperal sepsis is postpartum infection of the uterine cavity by *S. pyogenes*. The disease was once common but is now rare in developed countries. It is spread by the contaminated hands of attendants at delivery.

Streptococcus pneumoniae Infection Is a Major Cause of Lobar Pneumonia

S. pneumoniae, often called **pneumococcus,** causes pyogenic infections, primarily of the lungs **(pneumonia)**, middle ear **(otitis media)**, sinuses (**sinusitis**) and meninges **(meningitis)**. ***It is one of the most common human bacterial pathogens. Most children in the world have had at least one episode of pneumococcal disease (usually otitis media) by the age of 5 years.***

S. pneumoniae is an aerobic, gram-positive diplococcus. Most strains that cause clinical disease have a capsule, although nonserotypeable isolates are a known cause of epidemic conjunctivitis. There are over 80 antigenically distinct serotypes of pneumococcus; antibody to one does not protect from infection with another. These are commensal organisms in the oropharynx, and virtually everyone has been colonized at some time.

PATHOPHYSIOLOGY: Pneumococcal disease begins when the organism gains access to sterile sites, usually those in proximity to its normal residence in the oropharynx. Pneumococcal sinusitis and otitis media are usually preceded by a viral illness, such as the common cold, which injures the protective ciliated epithelium and fills affected air spaces with fluid. Pneumococci then thrive in the nutrient-rich tissue fluid. Infection of the sinuses or middle ear can spread to the adjacent meninges.

Pneumococcal pneumonia arises in a similar fashion. The lower respiratory tract is protected by the mucociliary blanket and cough response, which normally expel organisms that reach the lower airways. Insults that interfere with respiratory defenses, including influenza, other viral respiratory illnesses, smoking and alcoholism, allow *S. pneumoniae* to reach the alveoli. Once there, the organisms proliferate and elicit an acute inflammatory response. As the bacteria multiply and fill alveoli, they spread to other alveoli. Their polysaccharide capsule prevents activation of the alternate complement pathway, thereby blocking production of the opsonin C3b. Consequently, the organism can proliferate and spread unimpeded by phagocytes until antibody is produced. In the lungs, *S. pneumoniae* spreads rapidly to involve an entire lobe or several lobes (lobar pneumonia).

PATHOLOGY: Alveoli fill with proteinaceous fluid, neutrophils and bacteria. Clinical features of pneumococcal infections are discussed in Chapter 18. Pneumonia caused by *S. pneumoniae* often resolves completely, unlike that caused by *S. aureus,* which can cause permanent lung damage. If there is an underlying problem such as chronic aspiration, diabetes or alcohol abuse, or if bacterial opsonization is compromised, as in multiple myeloma, hypogammaglobulinemia or sickle cell disease, pneumococcal disease may spread. Patients with prior splenectomies are at high risk of rapid, fulminant septic shock and death. Immunization for pneumococcal pneumonia, particularly among the elderly, is available.

Group B Streptococci Are the Leading Cause of Neonatal Pneumonia, Meningitis and Sepsis

Group B streptococci are gram-positive bacteria that grow in short chains. Several thousand neonatal infections with group B streptococci occur in the United States each year; 30% of infected infants die. Group B streptococci are part of the normal vaginal flora in 10%–30% of women. Most babies born to colonized women acquire the organisms as they pass through the birth canal. Group B streptococci infrequently cause pyogenic infections in adults.

PATHOPHYSIOLOGY AND PATHOLOGY: Particular risk factors associated with development of neonatal group B streptococcal infections include premature delivery and low levels of maternally derived IgG antibodies against the organism. Newborns have little functional reserve for granulocyte production, so once the bacterial infection is established, it rapidly overwhelms the body's defenses. Group B streptococcal infection may be limited to the lungs or CNS or may be widely disseminated. The involved tissues show a pyogenic response, often with overwhelming numbers of gram-positive cocci.

BACTERIAL INFECTIONS OF CHILDHOOD

Diphtheria Is a Necrotizing Upper Respiratory Tract Infection

Infection with *Corynebacterium diphtheriae*—an aerobic, pleomorphic, gram-positive rod—may lead to cardiac and neurologic disturbances due to toxin production. The disease is preventable by vaccination with inactivated *C. diphtheriae* toxin (toxoid).

EPIDEMIOLOGY: Humans are the only known reservoir for *C. diphtheriae,* and most people are asymptomatic carriers. The organism spreads from person to person in respiratory droplets or oral secretions. Diphtheria was once a leading cause of death in children 2–15 years of age. Immunization programs have largely eliminated the disease in the Western world, but diphtheria persists as a major health problem in less developed countries. A recent outbreak in Nigeria mainly affected children, with a case-fatality ratio of 20%.

MOLECULAR PATHOGENESIS: *C. diphtheriae* enters the pharynx and proliferates, often on the tonsils. Diphtheria toxin is absorbed systemically and acts on many tissues, with the heart, nerves and kidneys being most susceptible to damage. Diphtheria toxin is a protein composed of two peptide chains—the A and B subunits—held together by a disulfide bond. The B subunit binds glycolipid receptors on target cells, and the A subunit acts within the cytoplasm on elongation factor 2 to interrupt protein synthesis. The toxin is one of the most potent known: one molecule suffices to kill a cell. Not all strains of *C. diphtheriae* produce exotoxin. The exotoxin is encoded by a lysogenic β-bacteriophage.

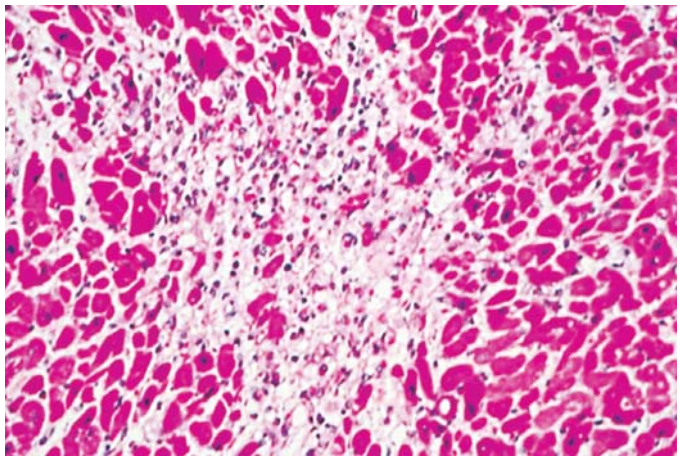

FIGURE 9-15. Diphtheric myocarditis. Focal degeneration of cardiac myocytes is evident.

PATHOLOGY: The characteristic lesions of diphtheria (from the Greek, *diphtheria,* "pair of leather scrolls") are the thick, gray, leathery membranes composed of sloughed epithelium, necrotic debris, neutrophils, fibrin and bacteria that line affected respiratory passages. The epithelial surface beneath the membranes is denuded, and the submucosa is acutely inflamed and hemorrhagic. The inflammation often causes swelling in surrounding soft tissues, which can be severe enough to cause respiratory compromise. When the heart is affected, the myocardium displays fat droplets in the myocytes and focal necrosis (Fig. 9-15). In the case of neural involvement, affected peripheral nerves show demyelination.

CLINICAL FEATURES: Diphtheria begins with fever, sore throat and malaise. The dirty gray membrane usually develops first on the tonsils and then spreads throughout the posterior oropharynx (Fig. 9-16). The membrane is firmly adherent, and an attempt to strip it from the underlying mucosa produces bleeding. Cardiac and neurologic symptoms develop in a minority of those infected, usually people with the most severe local disease.

Cutaneous diphtheria results from inoculation of the organism into a break in the skin and manifests as a pustule or ulcer; it rarely leads to cardiac or neurologic complications. Diphtheria is treated by prompt administration of antitoxin and antibiotics.

Pertussis Features Debilitating Paroxysmal Coughing

The paroxysm is followed by a long, high-pitched inspiration, the "whoop," which gives the disease its name, "whooping cough." The causative organism is *Bordetella pertussis,* a small, gram-negative coccobacillus.

EPIDEMIOLOGY: *B. pertussis* is highly contagious and spreads from person to person, primarily by respiratory aerosols. Humans are the only reservoir of infection. In susceptible populations, pertussis is primarily a disease of children under 5 years, but incidence is increasing among adults. Vaccination is protective, but there are 50 million cases of pertussis each year worldwide, and almost 1 million deaths, particularly in infants. In 2012, the United States experienced the worst outbreak of pertussis in 50 years—over 40,000 new cases—highlighting a major public health problem in a vaccine-preventable disease.

MOLECULAR PATHOGENESIS: *B. pertussis* initiates infection by attaching to the cilia of respiratory epithelial cells. The organism then elaborates a cytotoxin that kills ciliated cells. Progressive destruction of ciliated respiratory epithelium and the ensuing inflammatory response cause the local respiratory symptoms. Several other toxins include "pertussis toxin," an agent that causes the pronounced lymphocytosis often associated with whooping cough. Another toxin inhibits adenylyl cyclase, an effect that blocks bacterial phagocytosis.

PATHOLOGY: *B. pertussis* causes an extensive tracheobronchitis, with necrosis of ciliated respiratory epithelium and an acute inflammatory response. With the loss of the protective mucociliary blanket, there is increased risk of pneumonia from aspirated oral bacteria. Coughing paroxysms and vomiting make aspiration likely. Secondary bacterial pneumonia is the most common cause of death.

CLINICAL FEATURES: **Whooping cough** is a prolonged upper respiratory tract illness, lasting 4–5 weeks and passing through three stages:

- The **catarrhal stage** resembles a common viral upper respiratory tract illness, with low-grade fever, runny nose, conjunctivitis and cough.
- The **paroxysmal stage** occurs 1 week into the illness. Cough worsens and becomes paroxysmal, with 5–15 consecutive coughs, often followed by an inspiratory whoop.

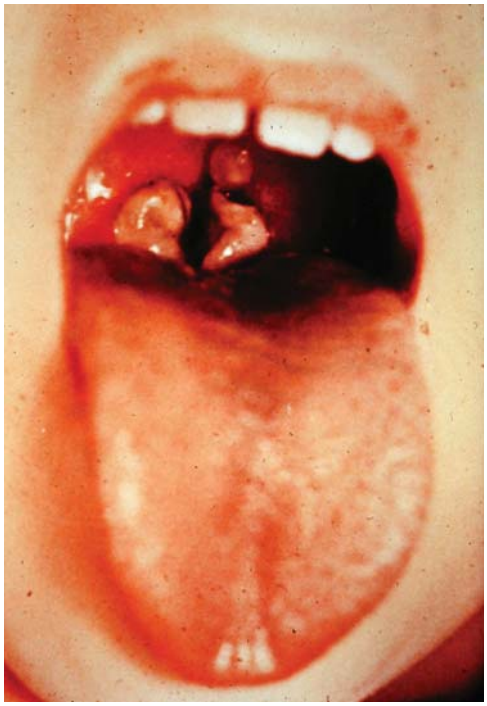

FIGURE 9-16. Child with characteristic diphtheric membrane in the oropharynx.

The patient develops a marked lymphocytosis; total leukocyte counts often exceed 40,000 cells/μL. The paroxysms persist for 2–3 weeks.
- The **convalescent phase** usually lasts for several weeks.

Haemophilus influenzae Causes Pyogenic Infections in Young Children

Haemophilus influenzae infections involve the middle ear, sinuses, facial skin, epiglottis, meninges, lungs and joints. The organism is a major pediatric pathogen and a leading cause of bacterial meningitis worldwide. It is an aerobic, pleomorphic gram-negative coccobacillus that may or may not be encapsulated. Nonencapsulated strains (type a) usually produce localized infections; encapsulated strains, type b, are more virulent and cause over 95% of the invasive bacteremic infections.

EPIDEMIOLOGY: *H. influenzae* only infects humans and spreads from person to person, mainly in respiratory droplets and secretions. It resides in the human nasopharynx of 20%–50% of healthy adults. Most colonizing strains are nonencapsulated, but 3%–5% are *H. influenzae* type b.

Most severe *H. influenzae* type b infections occur in children under the age of 6 years. The incidence of serious disease peaks at 6–18 months of age, corresponding to the period between the loss of maternally acquired immunity and the acquisition of native immunity. The *H. influenzae* type b vaccine has been credited with greatly reducing the complications of invasive *H. influenzae* type b disease, particularly meningitis, in children. However, as vaccination also reduces *H. influenzae* type b carriage and the repeated immunologic boosting effect that carriage provides, continued vigilance is important.

PATHOPHYSIOLOGY: Unencapsulated *H. influenzae* strains produce disease by spreading locally from their normal sites of residence to adjoining sterile locations, such as the sinuses or middle ear. This is facilitated by injury to normal defense mechanisms, as with a viral upper respiratory tract illness. At these previously sterile sites, unencapsulated organisms proliferate and elicit acute inflammatory responses, which injure local tissue but eventually contain the infection. Unencapsulated strains do not usually produce bacteremia.

By contrast, encapsulated H. influenzae type b is capable of tissue invasion. The capsular polysaccharide of type b organisms allows them to evade phagocytosis, and bacteremic infections are common. Epiglottitis, facial cellulitis, septic arthritis and meningitis result from invasive bacteremic infections. *H. influenzae* type b also elaborates an IgA protease, which facilitates local survival of the organism in the respiratory tract.

PATHOLOGY: *H. influenzae* elicits strong acute inflammatory responses. Specific pathologic features vary according to the sites affected. *H. influenzae* meningitis resembles other acute bacterial meningitides, with a predominantly acute inflammatory leptomeningeal infiltrate, sometimes involving the subarachnoid space.

H. influenzae pneumonia usually complicates chronic lung disease. In half of patients, it follows a viral infection of the respiratory tract. Alveoli are filled with neutrophils and macrophages, containing bacilli and fibrin. The bronchiolar epithelium is necrotic and infiltrated by macrophages.

Epiglottitis is swelling and acute inflammation of the epiglottis, aryepiglottic fold and pyriform sinuses. It may sometimes completely obstruct the upper airway. In **facial cellulitis,** the site of infection and inflammation is the dermis, usually of the cheek or periorbital region.

CLINICAL FEATURES: Most bacteremic *H. influenzae* infections afflict young children. **H. influenzae *is the most common cause of meningitis in children under 2 years,* although vaccination has reduced its frequency.** Onset is insidious and may follow an otherwise unremarkable upper respiratory tract infection or otitis media.

- **Bronchopneumonia and lobar pneumonia** are characterized by fever, cough, purulent sputum and dyspnea.
- **Epiglottitis** affects primarily children aged 2–7 years but also occurs in adults. Death may occur from obstruction of the upper respiratory tract.
- **Septic arthritis** is due to bacteremic seeding of large weight-bearing joints. Symptoms include fever, heat, erythema, swelling and pain on movement.
- **Facial cellulitis** or periorbital cellulitis is another severe bacteremic infection affecting primarily young children. Patients present with fever, profound malaise and a raised, hot, red-blue discolored area of the face, usually involving the cheek or an area about the eye. There is often concomitant meningitis or septic arthritis.

Neisseria meningitides Causes Pyogenic Meningitis and Overwhelming Shock

Neisseria meningitidis, or **meningococcus,** produces disseminated blood-borne infections, often accompanied by shock and profound disturbances in coagulation (Fig. 9-17). The organism is aerobic and appears as paired, bean-shaped, gram-negative cocci.

EPIDEMIOLOGY: Meningococci spread from person to person, primarily via respiratory droplets. About 5%–15% of the population carries them as commensals in the nasopharynx. Carriers develop antibodies to their colonizing strain and are not susceptible to disease caused by that strain.

Meningococcal diseases appear as sporadic cases, clusters of cases and epidemics. Most infections in industrialized countries are sporadic and afflict children under the age of 5 years. Epidemic disease occurs mostly in crowded quarters, such as among military recruits in barracks. There are over 6000 cases of meningococcal meningitis each year in the United States, and over 600 deaths. Fatal meningococcal disease is more common in less developed countries.

PATHOPHYSIOLOGY: Upon colonizing the upper respiratory tract, *N. meningitidis* attaches to nonciliated respiratory epithelium by means of its pili. Most exposed people then develop protective

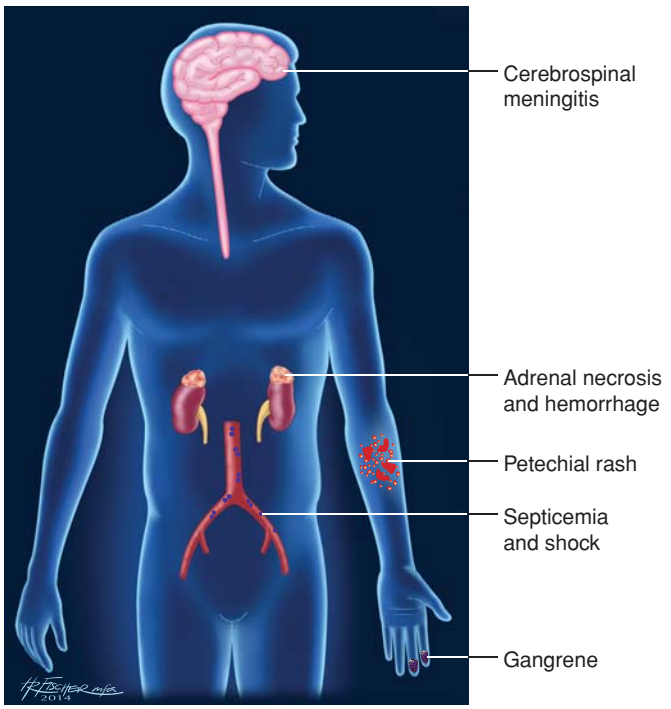

FIGURE 9-17. Meningococcemia. Meningococcal infections have a variety of clinical manifestations including meningitis, septicemia, shock and associated complications.

bactericidal antibodies over the following weeks, and some become carriers. If the organism spreads to the bloodstream before protective immunity develops, it can proliferate rapidly and cause fulminant meningococcal disease.

Many of the systemic effects of meningococcal disease are due to the endotoxin of the bacterial outer membrane lipopolysaccharide. Endotoxin promotes a conspicuous increase in TNF production and simultaneous activation of complement and coagulation cascades. Disseminated intravascular coagulation, fibrinolysis and shock follow.

PATHOLOGY: Meningococcal disease can be confined to the CNS or may be disseminated throughout the body in the form of septicemia. In the former case, the leptomeninges and subarachnoid space are infiltrated with neutrophils and the underlying brain parenchyma is swollen and congested. Meningococcal septicemia is characterized by diffuse damage to the endothelium of small blood vessels, with widespread petechiae and purpura in the skin and viscera.

Rarely (4% of cases), vasculitis and thrombosis produce hemorrhagic necrosis of both adrenals, **Waterhouse-Friderichsen syndrome**.

CLINICAL FEATURES: Meningitis begins with rapid onset of fever, stiff neck and headache. In meningococcal sepsis, fever, shock and mucocutaneous hemorrhages appear abruptly. Patients may progress to shock within minutes, and treatment requires blood pressure support and antibiotics. Meningococcal disease was once almost invariably fatal, but antibiotic treatment has reduced mortality to less than 15%. Some patients who survive the early phase of meningococcemia develop late immunologic complications, such as polyarthritis, cutaneous vasculitis and pericarditis. Severe vasculitis may be associated with extensive cutaneous ulceration and even gangrene of the distal extremities.

SEXUALLY TRANSMITTED BACTERIAL DISEASES

Gonorrhea Remains a Common Infection That Causes Sterility

Neisseria gonorrhoeae, also called **gonococcus,** causes gonorrhea, an acute suppurative genital tract infection, which manifests as urethritis in men and endocervicitis in women. It is one of the oldest and still one of the most common sexually transmitted diseases. *N. gonorrhoeae* is an aerobic, bean-shaped, gram-negative diplococcus.

Gonococcal pharyngitis and proctitis are not uncommon and are also sexually transmitted. In women, infection often ascends the genital tract, producing endometritis, salpingitis and pelvic inflammatory disease. Ascending spread in men is less common, but if it occurs, epididymitis results. Gonococcal infection may rarely be bacteremic, in which case septic arthritis and skin lesions develop. Neonatal infections, derived from the birth canal of a mother with gonorrhea, usually manifest as conjunctivitis, although disseminated infections occur occasionally. Neonatal gonococcal conjunctivitis is still a major cause of blindness in much of Africa and Asia but has been largely eliminated in developed countries by routine instillation of antibiotics into the conjunctiva at birth.

EPIDEMIOLOGY: This common infection is spread directly from person to person. Except for perinatal transmission, spread is almost always by sexual intercourse. Infected people who are asymptomatic are a significant reservoir of infection.

PATHOPHYSIOLOGY: Gonorrhea begins in the mucous membranes of the urogenital tract (Fig. 9-18). Bacteria attach to surface cells, after which they invade superficially and provoke acute inflammation. Gonococcus lacks a true polysaccharide capsule, but hair-like extensions, termed "pili," project from the cell wall. The pili contain a protease that digests IgA on the mucous membrane, thereby facilitating bacterial attachment to the columnar and transitional epithelium of the urogenital tract.

PATHOLOGY: Gonorrhea is a suppurative infection, eliciting a vigorous acute inflammatory response, with copious pus, and often forming submucosal abscesses. Smears of pus reveal numerous neutrophils, often containing phagocytosed bacteria. If untreated, the inflammation becomes chronic, with macrophages and lymphocytes predominant.

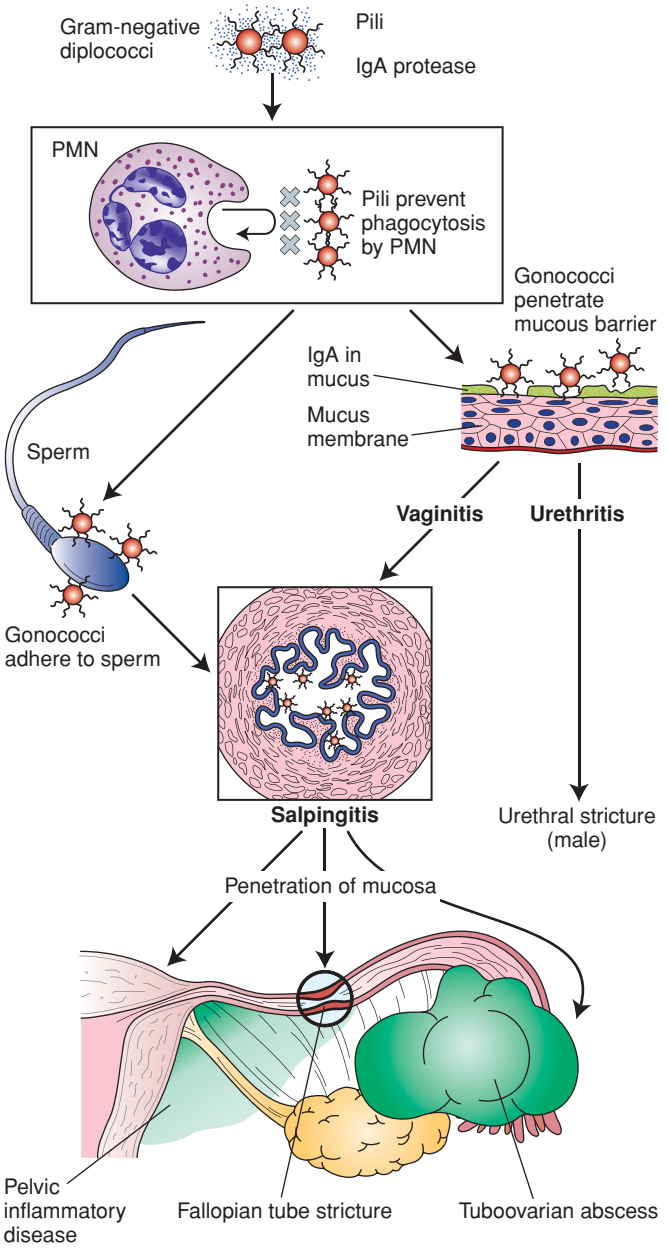

FIGURE 9-18. Pathogenesis of gonococcal infections. *Neisseria gonorrhoeae* is a gram-negative diplococcus whose surface pili form a barrier against phagocytosis by neutrophils. The pili contain an immunoglobulin A (IgA) protease that digests IgA on the luminal surface of the mucous membranes of the urethra, endocervix and fallopian tube, thereby facilitating attachment of gonococci. Gonococci cause endocervicitis, vaginitis and salpingitis. In men, gonococci attached to the mucous membrane of the urethra cause urethritis and, sometimes, urethral stricture. Gonococci may also attach to sperm heads and be carried into the fallopian tube. Penetration of the mucous membrane by gonococci leads to stricture of the fallopian tube, pelvic inflammatory disease (PID) or tuboovarian abscess.

CLINICAL FEATURES: Men exposed to *N. gonorrhoeae* present with purulent urethral discharge and dysuria. If treatment is not instituted promptly, urethral stricture is a common complication. The organisms may also extend to the prostate, epididymis and accessory glands, where they cause epididymitis and orchitis, and may result in infertility.

FIGURE 9-19. Gonorrhea of the fallopian tube. Cross-section of a "pus tube" shows thickening of the wall and a lumen swollen with pus.

In one half of infected women, gonorrhea remains asymptomatic. The other infected women initially exhibit endocervicitis, with vaginal discharge or bleeding. Urethritis presents as dysuria rather than as a urethral discharge. Infection often extends to the fallopian tubes, where it produces acute and chronic salpingitis and, eventually, pelvic inflammatory disease. Fallopian tubes swell with pus (Fig. 9-19), causing acute abdominal pain. Infertility occurs when inflammatory adhesions block the tubes.

From the fallopian tubes, gonorrhea spreads to the peritoneum, healing as fine "violin string" adhesions between the liver and the parietal peritoneum (Fitz-Hugh-Curtis syndrome). Chronic endometritis is a persistent complication of gonococcal infection and is usually the consequence of chronic gonococcal salpingitis.

Chancroid Causes Genital Ulcers in Less Developed Regions

Chancroid is an acute sexually transmitted infection caused by *Haemophilus ducreyi*. The organism is a small, gram-negative bacillus, which appears in tissue as clusters of parallel bacilli and as chains, resembling schools of fish. Infections lead to painful genital ulceration and lymphadenopathy. ***Chancroid is the leading cause of genital ulcers in many less developed countries, especially in Africa and parts of Asia.*** It has been suggested that these genital ulcers facilitate spread of HIV. In the United States, the incidence of chancroid has risen in the past decade; there are about 5000 cases annually.

PATHOLOGY: *H. ducreyi* enters through breaks in the skin, where it multiplies and produces a raised lesion, which then ulcerates. Ulcers vary from 0.1 to 2 cm in diameter. Organisms are carried within macrophages to regional lymph nodes, which may suppurate. Seven to 10 days after the primary lesion appears, half of patients develop unilateral, painful, suppurative, inguinal

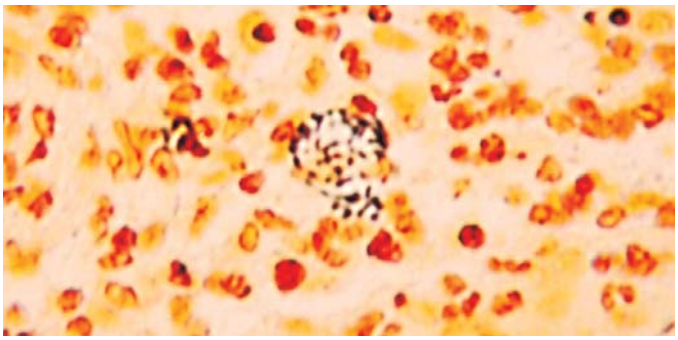

FIGURE 9-20. Granuloma inguinale. A photomicrograph of a skin lesion shows *Calymmatobacterium granulomatis* (Donovan bodies) clustered in a large macrophage. Intense silver staining by Warthin-Starry technique makes the organisms large, black and easily seen.

lymphadenitis **(bubo)**. Overlying skin becomes inflamed, breaks down and drains pus from the underlying node. The diagnosis is made by identifying the bacillus in tissue sections or Gram-stained smears from the ulcers. Treatment with erythromycin is usually effective.

Granuloma Inguinale Is a Tropical Ulcerating Disease

Granuloma inguinale is a sexually transmitted, chronic, superficial ulceration of the genitalia and inguinal and perianal regions. It is caused by *Calymmatobacterium granulomatis*, a small, encapsulated, nonmotile, gram-negative bacillus.

EPIDEMIOLOGY: Humans are the only hosts of *C. granulomatis.* Granuloma inguinale is rare in temperate climates but is common in tropical and subtropical areas. Papua New Guinea, central Australia and India have the highest incidence. Most patients are 15–40 years old.

PATHOLOGY: The characteristic lesion is a raised, soft, beefy-red, superficial ulcer. The exuberant granulation tissue resembles a fleshy mass herniating through the skin. Macrophages and plasma cells, and occasional neutrophils and lymphocytes, infiltrate the dermis and subcutis. Interspersed macrophages contain many bacteria, termed **Donovan bodies** (Fig. 9-20).

CLINICAL FEATURES: Untreated granuloma inguinale follows an indolent, relapsing course, often healing with an atrophic scar. Secondary fusospirochetal infection may cause ulceration, mutilation or amputation of the genitalia. Massive scarring of the dermis and subcutis may obstruct lymphatics and cause genital **elephantiasis**. Antibiotic therapy is effective in early cases.

ENTEROPATHOGENIC BACTERIAL INFECTIONS

Escherichia coli Commonly Causes Diarrhea and Urinary Tract Infections

E. coli ***is among the most frequent and important human bacterial pathogens, causing over 90% of all urinary tract infections and many cases of diarrheal illness worldwide.*** It is also a major opportunistic pathogen, frequently producing pneumonia and sepsis in immunocompromised hosts and meningitis and sepsis in newborns.

E. coli comprises a group of antigenically and biologically diverse, aerobic (facultatively anaerobic), gram-negative bacteria. Most strains are intestinal commensals, well adapted to growth in the human colon without harming the host. However, *E. coli* can be aggressive when it gains access to usually sterile body sites, such as the urinary tract, meninges or peritoneum. Strains of *E. coli* that produce diarrhea possess specialized virulence properties, usually plasmid-borne, that cause intestinal disease.

E. coli Diarrhea

There are four distinct strains of *E. coli* that cause diarrhea:

ENTEROTOXIGENIC* E. coli:** ***Enterotoxigenic* E. coli gives rise to diarrhea in poor tropical areas and probably causes most "traveler's diarrhea" among visitors to such regions. It is acquired from contaminated water and food. Many people in Latin America, Africa and Asia are asymptomatic carriers of the infection.

MOLECULAR PATHOGENESIS: Nonimmune people (local children or travelers from abroad) develop diarrhea when they encounter the organism. Enterotoxigenic strains produce diarrhea by adhering to the intestinal mucosa and elaborating one or more of at least three enterotoxins that cause secretory dysfunction of the small bowel. One of the enterotoxins is structurally and functionally similar to cholera toxin, and another acts on guanylyl cyclase. Enterotoxigenic *E. coli* produces no distinctive macroscopic or light-microscopic alterations in the intestine.

Enterotoxigenic *E. coli* causes an acute, self-limited diarrheal illness, with watery stools lacking neutrophils and erythrocytes. In severe cases, fluid and electrolyte loss can lead to extreme dehydration and even death.

ENTEROPATHOGENIC E. coli: Historically, enteropathogenic *E. coli* was the first group of this genus to be identified as a cause of diarrhea. The organism is responsible for diarrheal illness in poor tropical areas, especially in infants and young children. Although it has virtually disappeared from developed countries, it still produces sporadic outbreaks of diarrhea, particularly among hospitalized infants younger than 2 years. Enteropathogenic *E. coli* is acquired by ingesting contaminated food or water. The organism is not invasive and brings on disease by adhering to and deforming the microvilli of the intestinal epithelial cells (Fig. 9-21A). Enteropathogenic *E. coli* produces diarrhea, vomiting, fever and malaise.

***ENTEROHEMORRHAGIC* E. coli:** Enterohemorrhagic *E. coli* (serotype 0157:H7) causes a bloody diarrhea, which may be followed by the **hemolytic–uremic syndrome** (see Chapter 16). The source of infection is usually ingestion of contaminated meat or milk. Bacteria adhere to colonic mucosa and elaborate an enterotoxin, virtually identical to Shigatoxin (see below), that destroys the epithelial cells. Patients infected with *E. coli* 0157:H7 present with cramping abdominal pain, low-grade fever and sometimes bloody diarrhea. Microscopic examination of stool shows both leukocytes and erythrocytes.

***ENTEROINVASIVE* E. coli:** Enteroinvasive *E. coli* causes food-borne dysentery, which is clinically and pathologically

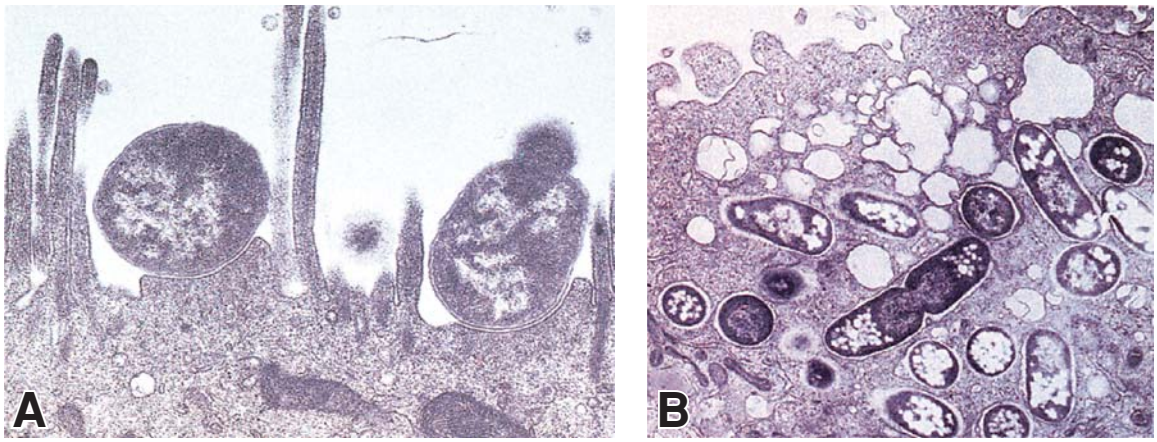

FIGURE 9-21. Enteric *Escherichia coli* infections. A. Enteropathogenic *E. coli* infection. An electron micrograph shows adherence of the bacteria to the intestinal mucosal cells and localized destruction of microvilli. **B.** Enteroinvasive *E. coli* infection. An electron micrograph shows organisms within a cell.

indistinguishable from that caused by *Shigella.* The agent shares extensive DNA homology and antigenic and biochemical characteristics with *Shigella.* It invades and destroys mucosal cells of the distal ileum and colon (Fig. 9-21B). As in shigellosis, the mucosa of the distal ileum and colon is acutely inflamed and focally eroded and is sometimes covered by an inflammatory pseudomembrane. Patients have abdominal pain, fever, tenesmus and bloody diarrhea, usually for about a week. Antibiotic treatment is similar to that for shigellosis.

E. coli Urinary Tract Infection

EPIDEMIOLOGY: Urinary tract infections with *E. coli* are most common in sexually active women and in people of both sexes who have structural or functional abnormalities of the urinary tract. ***Such infections afflict more than 10% of the human population, often repeatedly.*** *E. coli* in the urinary tract usually derives from resident flora of the perineum and periurethral areas, reflecting fecal contamination of these regions.

PATHOPHYSIOLOGY: *E. coli* gains access to the sterile proximal urinary tract by ascending from the distal urethra. Because the shorter female urethra provides a less effective mechanical barrier to infection, women are much more prone to urinary tract infections. Sexual intercourse can suffice to propel organisms into the female urethra. Uropathogenic *E. coli* organisms have specialized adherence factors (Gal-Gal) on the pili, which enable them to bind to galactopyranosyl-galactopyranoside residues on the uroepithelium. Structural abnormalities of the urinary tract (e.g., congenital deformities, prostatic hyperplasia, strictures) and instrumentation (catheterization) overwhelm normal host defenses and facilitate the establishment of urinary tract infections. These conditions account for most urinary tract infections in men.

PATHOLOGY AND CLINICAL FEATURES: *E. coli* urinary tract infections initially produce an acute inflammatory infiltrate at the site of infection, usually the bladder mucosa. Infections involving the bladder or urethra manifest as urinary urgency, burning on urination **(dysuria)** and leukocytes in the urine. If infection ascends to involve the kidney **(pyelonephritis)**, patients develop acute flank pain, fever and elevated leukocyte counts. An infiltrate of neutrophils spills from the mucosa into the urine, and the blood vessels of the submucosa are dilated and congested. Chronic infections exhibit an inflammatory infiltrate of neutrophils and mononuclear cells. Chronic renal infection may lead to chronic pyelonephritis and renal failure (see Chapter 22).

E. coli Pneumonia

Pneumonia caused by enteric gram-negative bacteria is considered opportunistic, occurring mostly in debilitated persons. *E. coli* is the most common cause, but other normal bowel flora, such as *Klebsiella, Serratia* and *Enterobacter* species, produce similar disease. *The discussion below applies to all opportunistic gram-negative pneumonias.*

PATHOPHYSIOLOGY: Enteric gram-negative bacteria are transiently introduced into the oral cavity of healthy people but cannot compete successfully with the predominant gram-positive flora, which adhere to the fibronectin that coats mucosal cell surfaces. Chronically ill or severely stressed persons elaborate a salivary protease that degrades fibronectin, allowing gram-negative enteric bacteria to overcome the normal gram-positive flora and colonize the oropharynx.

Inevitably, droplets of the resident oral flora are aspirated into the respiratory tract. Debilitated patients often have weak local defenses and cannot destroy these organisms. Decreased gag and cough reflexes, abnormal neutrophil chemotaxis, injured respiratory epithelium and foreign bodies, such as endotracheal tubes, all facilitate entry and survival of the aspirated organisms.

PATHOLOGY: *E. coli* pneumonia results from proliferation of aspirated organisms in terminal airways, usually at multiple sites in the lung.

Multifocal areas of consolidation result and terminal airways and alveoli are filled with proteinaceous fluid, fibrin, neutrophils and macrophages.

CLINICAL FEATURES: Because pneumonia caused by *E. coli* and other enteric gram-negative organisms afflicts patients who are often already severely ill, symptoms of pneumonia may be less obvious than in healthy persons. Increased malaise, fever and labored breathing are often the first signs of pneumonia. If *E. coli* pneumonia remains untreated, the organisms may invade the blood to produce fatal septicemia. Treatment requires parenteral antibiotics.

E. coli Sepsis (Gram-Negative Sepsis)

E. coli is the most common cause of enteric gram-negative sepsis, but other gram-negative rods, including *Pseudomonas, Klebsiella* and *Enterobacter* species, produce identical disease. The discussion below relates to gram-negative sepsis in general.

PATHOPHYSIOLOGY: *E. coli* sepsis is usually an opportunistic infection, occurring in people with predisposing conditions, such as neutropenia, pyelonephritis or cirrhosis, and in hospitalized patients. Together with other enteric gram-negative rods that normally reside in the human colon, *E. coli* occasionally seeds the bloodstream. In healthy individuals, macrophages and circulating neutrophils phagocytose these bacteria. Patients with neutropenia or cirrhosis develop *E. coli* sepsis because of impaired ability to eliminate even low-level bacteremias. People with ruptured abdominal organs or acute pyelonephritis suffer gram-negative sepsis because the large numbers of organisms that gain access to the circulation overwhelm the normal defenses.

The presence of *E. coli* in the bloodstream causes septic shock through the effects of TNF (among other factors), whose release from macrophages is stimulated by bacterial endotoxin. Septic shock is discussed in Chapters 7 and 26.

Neonatal *E. coli* Meningitis and Sepsis

E. coli and group B streptococci are the main causes of meningitis and sepsis in the first month after birth. Both colonize the vagina, and newborns acquire them on passage through the birth canal. *E. coli* then colonizes the infant's gastrointestinal tract. It is postulated that the organisms spread to the bloodstream from the gastrointestinal tract and then seed the meninges. The pathology of *E. coli* meningitis is identical to that of other bacterial meningitides. Although antibiotic treatment for neonatal *E. coli* meningitis and sepsis is often effective, the mortality rate is still up to 50%. Almost half of survivors suffer neurologic sequelae.

Salmonella Enterocolitis and Typhoid Fever Are Both Intestinal Infections

The bacterial genus *Salmonella* contains over 1500 antigenically distinct but biochemically and genetically related gram-negative rods. The agents cause two important human diseases, namely, *Salmonella* enterocolitis and typhoid fever.

Salmonella Enterocolitis

Salmonella enterocolitis is an acute, self-limited (1–3 days) gastrointestinal illness that presents as nausea, vomiting, diarrhea and fever. Infection is typically acquired by eating food containing nontyphoidal *Salmonella* strains and is commonly called ***Salmonella food poisoning***.

EPIDEMIOLOGY: Nontyphoidal *Salmonella* infect diverse animal species, including amphibians, reptiles, birds and mammals. They also readily contaminate foodstuffs derived from infected animals (e.g., meat, poultry, eggs, dairy products). If these foods are not cooked, pasteurized or irradiated, the bacteria persist and proliferate, particularly at warm temperatures. Once someone is infected, the organism can spread from person to person by the fecal–oral route. Although such dissemination is infrequent among adults, it is common among small children in daycare settings or within families. *Salmonella* enterocolitis remains a major cause of childhood mortality in less developed countries.

PATHOPHYSIOLOGY: *Salmonella* proliferate in the small intestine and invade enterocytes in the distal small bowel and colon. The nontyphoidal *Salmonella* species elaborate several toxins that injure intestinal cells. The mucosa of the ileum and colon is acutely inflamed and sometimes superficially ulcerated.

CLINICAL FEATURES: *Salmonella* enterocolitis typically manifests as diarrhea, within 12–48 hours after consuming contaminated food. This contrasts with staphylococcal food poisoning, which is caused by a preformed toxin and begins 1–6 hours after eating. The diarrhea of *Salmonella* food poisoning is self-limited. It lasts 1–3 days and is often accompanied by nausea, vomiting, cramping abdominal pain and fever. Treatment is supportive and antibiotics rarely improve the clinical course.

Typhoid Fever

Typhoid fever is an acute systemic illness caused by infection with *Salmonella typhi.* **Paratyphoid fever** is a clinically similar but milder disease that results from infection with other species of *Salmonella,* including *Salmonella paratyphi.* The term **enteric fever** includes both typhoid and paratyphoid fever.

EPIDEMIOLOGY: Humans are the only natural reservoir for *S. typhi,* and typhoid fever is acquired from infected patients or chronic carriers. The latter tend to be older women with gallstones or biliary scarring; *S. typhi* colonizes their gallbladder or biliary tree. The disease is spread primarily by ingestion of contaminated water and food, especially dairy products and shellfish. Less commonly, the organisms are disseminated by direct finger-to-mouth contact with feces, urine

or other secretions. Infected food handlers with poor personal hygiene and urine from patients with typhoid pyelonephritis can be a significant source of spread. Typhoid fever accounts for over 25,000 annual deaths worldwide but is uncommon in the United States.

MOLECULAR PATHOGENESIS: *S. typhi* attaches to and invades the small bowel mucosa without causing clinical enterocolitis. Invasion tends to be most prominent in the ileum in areas overlying Peyer patches. The organisms are engulfed by macrophages, after which they block the respiratory burst of the phagocytes and multiply within these cells. Infected cells spread first to regional lymph nodes, then throughout the body via the lymphatics and bloodstream, affecting mononuclear macrophages in lymph nodes, bone marrow, liver and spleen. Infection of macrophages stimulates IL-1 and TNF production, thereby causing the prolonged fever, malaise and wasting characteristic of typhoid fever.

PATHOLOGY: The earliest pathologic change in typhoid fever is degeneration of the intestinal epithelium brush border. As bacteria invade, Peyer patches become hypertrophic. In some cases, intestinal lymphoid hyperplasia progresses to capillary thrombosis, causing necrosis of overlying mucosa and the characteristic ulcers oriented along the long axis of the bowel (Fig. 9-22). These ulcers frequently bleed and occasionally perforate, producing infectious peritonitis. Systemic dissemination of the organisms leads to focal granulomas in the liver, spleen and other organs, termed **typhoid nodules**. These are composed of aggregates of macrophages ("typhoid cells") containing ingested bacteria, erythrocytes and degenerated lymphocytes.

CLINICAL FEATURES: Untreated typhoid fever was classically divided into five stages (Fig. 9-23):

- **Incubation:** 10–14 days.
- **Active invasion/bacteremia:** The patient suffers for about a week with a variety of nonspecific symptoms, including daily stepwise elevation in temperature (up to 41°C [105.8°F]), malaise, headache, arthralgias and abdominal pain.
- **Fastigium:** Fever and malaise increase over several days until the infected person is prostrate. Patients may become toxic from the release of endotoxins from dead bacteria. Hepatomegaly is accompanied by derangement in liver function. The spleen is conspicuously enlarged.
- **Lysis:** In patients destined to survive, fever and toxic symptoms gradually diminish. Gastrointestinal bleeding and intestinal perforation at sites of ulceration may occur in any stage but are most common during lysis, which commonly lasts a week.
- **Convalescence:** Fever abates and patients gradually recover over several weeks to months. Some relapse or have metastatic foci of infection.

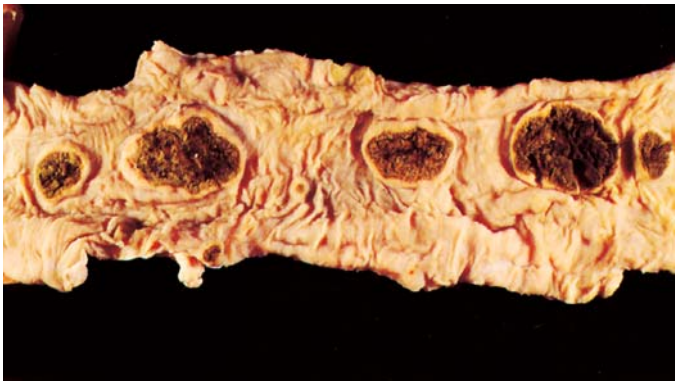

FIGURE 9-22. Ulcers of the terminal ileum in fatal typhoid fever. The ulcers have a longitudinal orientation because they are located over hyperplastic and necrotic Peyer patches.

The treatment of typhoid fever entails antibiotics and supportive care. Ten to 20% of untreated patients die, usually of secondary complications, such as pneumonia. However, treatment within 3 days of the onset of fever is generally curative.

Shigellosis Is a Necrotizing Infection of the Distal Small Bowel and Colon

It is caused by any of four species of *Shigella* (*Shigella boydii, Shigella dysenteriae, Shigella flexneri* and *Shigella sonnei*), which are aerobic, gram-negative rods. Of these species, *S. dysenteriae* is the most virulent. Shigellosis is a self-limited disease that typically presents with abdominal pain and bloody, mucoid stools.

EPIDEMIOLOGY: *Shigella* organisms are spread from person to person by the fecal–oral route. They have no animal reservoir and do not survive well outside the stool. Infection usually occurs through ingestion of fecally contaminated food or water but can be acquired by oral contact with any contaminated surface (e.g., clothing, towels or skin surfaces). As a result, endemic shigellosis is more common in areas with poor hygiene and sanitation. It is also spread in closed communities, such as hospitals, barracks and households. In developed countries, *S. flexneri* and *S. sonnei* are more common, and infection tends to be sporadic.

In the United States, about 300,000 cases occur annually, but the incidence of the disease is much higher in countries lacking sanitary systems for human waste disposal. Like other diarrheal illnesses, shigellosis is a significant cause of childhood mortality in developing countries.

MOLECULAR PATHOGENESIS: Shigellae are among the most virulent enteropathogens. Disease is produced by ingesting as few as 10–100 organisms, and there are few asymptomatic carriers. The agent proliferates rapidly in the small bowel and attaches to enterocytes, where it replicates within the cytoplasm. Endocytosis is essential for virulence, and the virulence factor is encoded by a plasmid. Replicating shigellae kill infected cells and then spread to adjacent cells.

Shigellae also produce a potent exotoxin, known as **Shiga toxin,** that is like the verotoxin of *E. coli* O157:H7. This toxin interferes with 60S ribosomal subunits and inhibits protein synthesis. It also causes watery diarrhea, probably by interfering with fluid absorption in the colon. Although shigellae extensively damage the epithelium of the ileum and colon, they rarely invade beyond the intestinal lamina propria, and bacteremia is uncommon.

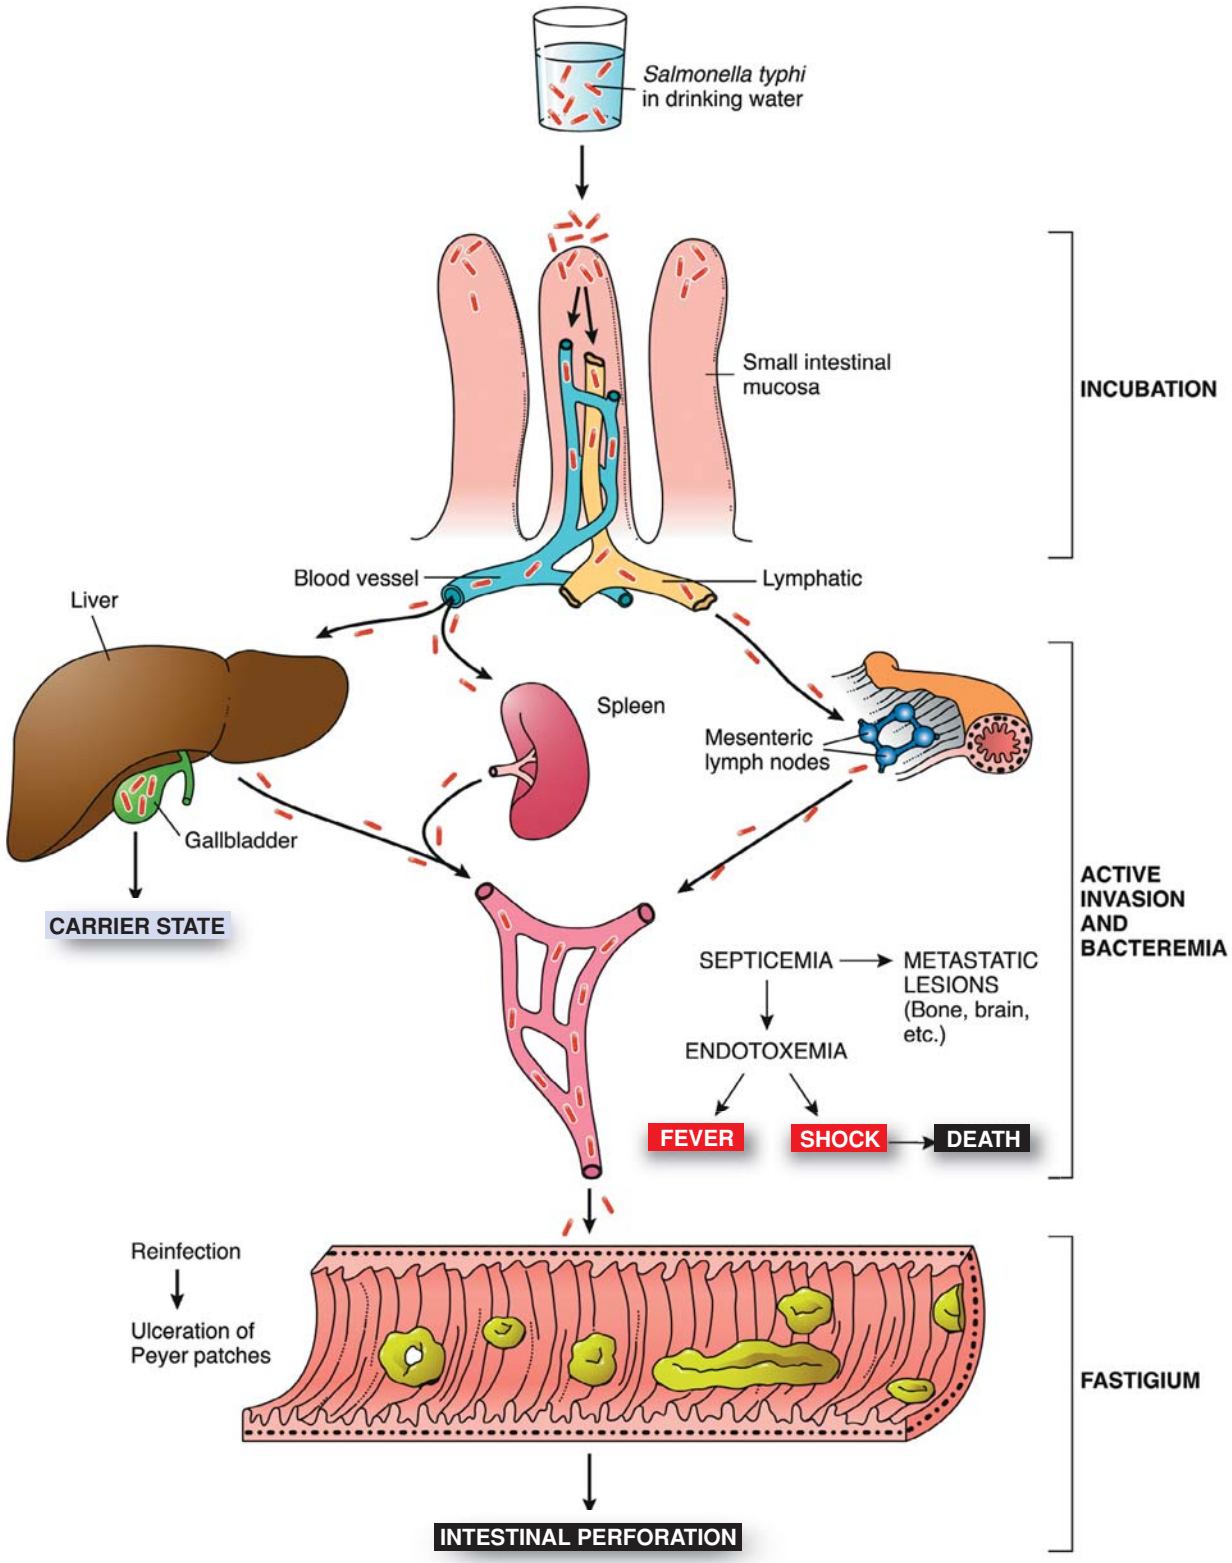

FIGURE 9-23. Stages of typhoid fever. Incubation (10–14 days). Water or food contaminated with *Salmonella typhi* is ingested. Bacilli attach to the villi in the small intestine, invade the mucosa and pass to the intestinal lymphoid follicles and draining mesenteric lymph nodes. The organisms proliferate further within mononuclear phagocytic cells of the lymphoid follicles, lymph nodes, liver and spleen. Bacilli are sequestered intracellularly in the intestinal and mesenteric lymphatic system. **Active invasion/bacteremia** (1 week). Organisms are released and produce a transient bacteremia. The intestinal mucosa becomes enlarged and necrotic, forming characteristic mucosal lesions. The intestinal lymphoid tissues become hyperplastic and contain "typhoid nodules"—aggregates of macrophages ("typhoid cells") that phagocytose bacteria, erythrocytes and degenerated lymphocytes. Bacilli proliferate in several organs, reappear in the intestine, are excreted in stool and may invade through the intestinal wall. **Fastigium** (1 week). Dying bacilli release endotoxins that cause systemic toxemia. **Lysis** (1 week). Necrotic intestinal mucosa sloughs, producing ulcers, which hemorrhage or perforate into the peritoneal cavity.

PATHOLOGY: The distal colon is almost always affected, although the entire colon and distal ileum can be involved. The mucosa is edematous, acutely inflamed and focally eroded. Ulcers appear first on the edges of mucosal folds, perpendicular to the long axis of the colon. A patchy inflammatory **pseudomembrane,** composed of neutrophils, fibrin and necrotic epithelium, is commonly found on the most severely affected areas. Regeneration of infected colonic epithelium occurs rapidly, and healing is usually complete within 10–14 days.

CLINICAL FEATURES: Shigellosis often begins with watery diarrhea, which changes in character within 1–2 days to the classic dysenteric stools. These are small-volume stools that contain gross blood, sloughed pseudomembranes and mucus. Cramping abdominal pain, tenesmus and urgency at stool typically accompany the diarrhea. Symptoms persist for 3–8 days, if the disease is untreated. Treatment with antibiotics shortens the course of the illness.

Cholera Is an Epidemic Enteritis Usually Acquired from Contaminated Water

Cholera is a severe diarrheal illness caused by the enterotoxin of* Vibrio cholerae*, an aerobic, curved gram-negative rod. The organism proliferates in the lumen of the small intestine and causes profuse watery diarrhea, rapid dehydration and (if fluids are not restored) shock and death within 24 hours of the onset of symptoms.

EPIDEMIOLOGY: Cholera is common in most parts of the world, but it periodically "disappears" spontaneously. A major pandemic occurred between 1961 and 1974, extending throughout Asia, the Middle East, southern Russia, the Mediterranean basin and parts of Africa. Cholera remains endemic in the river deltas of India and Bangladesh. This infection is a worldwide public health problem, affecting an estimated 3–5 million people per year. It is responsible for 100,000–130,000 deaths annually, a marked decrease from the estimated 3 million deaths per year in the 1980s. Following the 2010 earthquake in Haiti, an outbreak of cholera occurred, the largest in recent history, which killed 8000 Haitians and hospitalized hundreds of thousands more, while spreading to neighboring nations Cuba and the Dominican Republic.

Cholera is acquired by ingesting *V. cholerae,* mainly in contaminated food or water. Epidemics spread readily in areas where human feces pollute the water supply. Shellfish and plankton may serve as a natural reservoir for the organism. Shellfish ingestion accounts for most of the sporadic cases in the United States.

MOLECULAR PATHOGENESIS AND PATHOLOGY: Bacteria that survive passage through the stomach thrive and multiply in the mucous layer of the small bowel. They do not invade the mucosa but cause diarrhea by elaborating a potent exotoxin, **cholera toxin,** which is composed of A and B subunits. The latter binds to GM_1 ganglioside in the enterocyte cell membrane. The A subunit then enters the cell, where it activates adenylyl cyclase. The consequent rise in cell cyclic adenosine 3′,5′-monophosphate (cAMP) content causes massive secretion of sodium and water by the enterocyte into the intestinal lumen (Fig. 9-24). Most fluid secretion occurs in the small bowel, where there is a net loss of water and electrolytes. *V. cholerae* causes little visible alteration in the affected intestine, which appears grossly normal or only slightly hyperemic. The intestinal epithelium remains intact but depleted of mucus.

CLINICAL FEATURES: Cholera begins with a few loose stools, usually evolving within hours into severe watery diarrhea. The stools are often flecked with mucus, imparting a "rice water" appearance. The amount of diarrhea is highly variable, but the rapidity and volume loss in severe cases can be staggering. With adequate fluid replacement, infected adults can lose up to 20 L in a day. Water and electrolyte loss can lead to shock and death within hours if the volume is not replaced. Untreated cholera has a 50% mortality rate. Replacing lost salts and water is a simple, effective treatment, often achievable by oral rehydration with preparations of salt, glucose and water. The illness subsides spontaneously in 3–6 days, which can be shortened by antibiotic therapy. Infection with *V. cholerae* confers long-term protection from recurrent illness, but available vaccines have limited effectiveness.

Vibrio parahaemolyticus

There are several "noncholera" vibrios, of which *Vibrio parahaemolyticus* is the most common. This organism is a gram-negative bacillus that causes acute gastroenteritis. It is found in marine life and coastal waters around the world in temperate climates, causing outbreaks in the summer. Its range may be expanding, as confirmed cases have occurred in Alaska, more than 1000 miles north of any previous outbreaks. Gastroenteritis is associated with consumption of inadequately cooked or poorly refrigerated seafood. The clinical syndrome resembles *Salmonella* enteritis. No deaths have been reported.

Campylobacter jejuni Is the Most Common Cause of Bacterial Diarrhea in the Developed World

Campylobacter jejuni is the major human pathogen in the genus *Campylobacter.* It causes an acute, self-limited, inflammatory diarrheal illness. The organism is distributed worldwide and is responsible for over 2 million cases annually in the United States. *C. jejuni* is a microaerophilic, curved gram-negative rod, morphologically similar to the vibrios.

EPIDEMIOLOGY: *C. jejuni* infection is acquired through contaminated food or water. The bacteria inhabit gastrointestinal tracts of many animal species, including cows, sheep, chickens and dogs, which are a significant animal reservoir for infection. Raw milk and inadequately cooked poultry and meat are frequent sources of disease. *C. jejuni* can also spread from person to person by the fecal–oral route. The organism is a major cause of childhood mortality in developing countries and causes many cases of "travelers' diarrhea."

PATHOPHYSIOLOGY: Ingested *C. jejuni* that survives gastric acidity multiplies in the alkaline environment of the upper small intestine. The agent elaborates several toxic proteins that correlate with the severity of the symptoms.

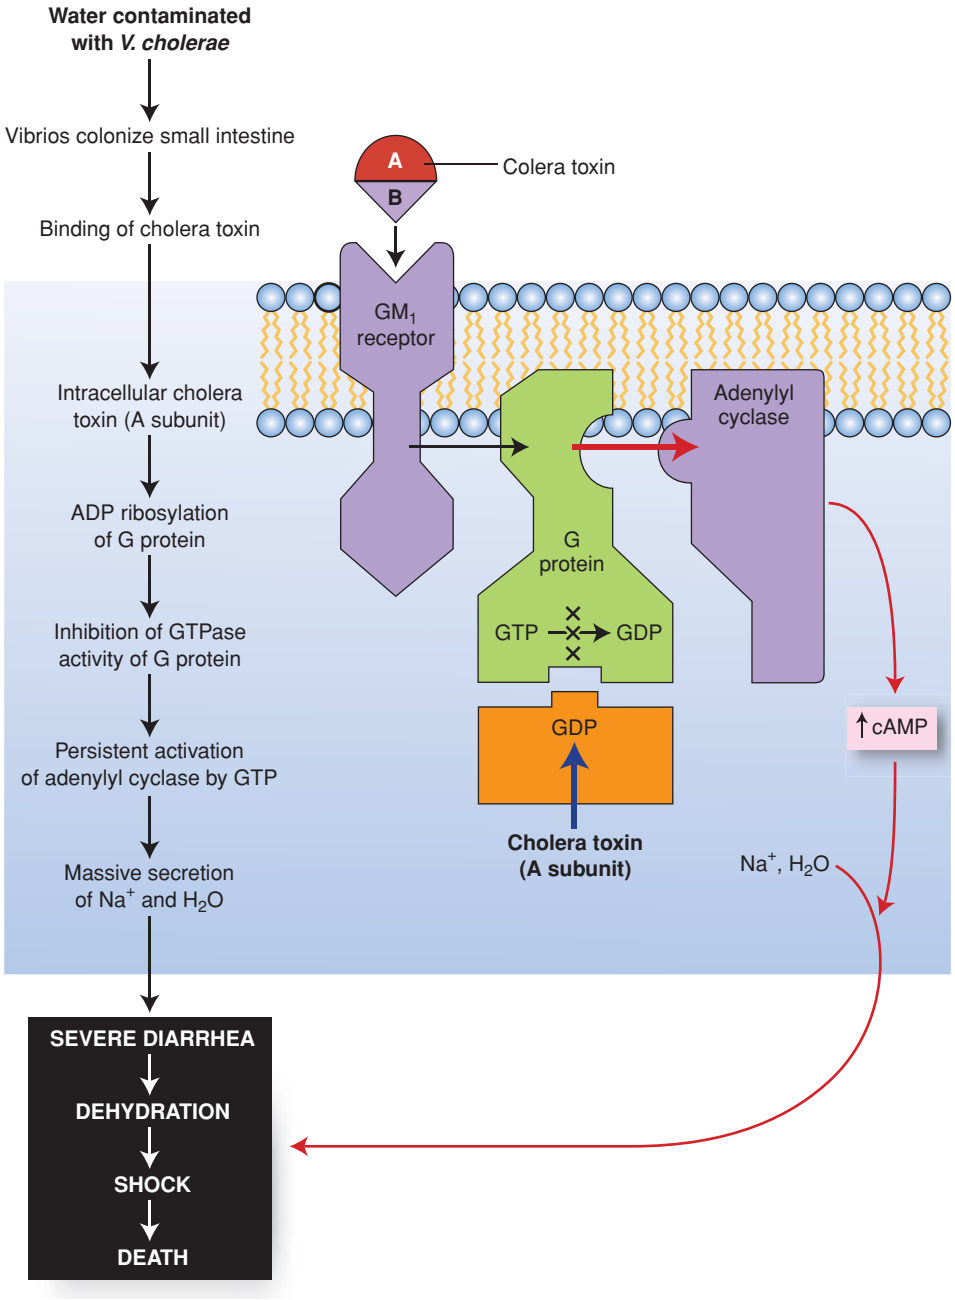

FIGURE 9-24. Cholera. Infection comes from water contaminated with *Vibrio cholerae* or food prepared with contaminated water. Vibrios traverse the stomach, enter the small intestine and propagate. Although they do not invade the intestinal mucosa, vibrios elaborate a potent toxin that induces a massive outpouring of water and electrolytes. Severe diarrhea ("rice water stool") leads to dehydration and hypovolemic shock.

PATHOLOGY: *C. jejuni* causes a superficial enterocolitis, primarily involving the terminal ileum and colon, with focal necrosis of intestinal epithelium and acute inflammation. In severe cases, infection progresses to small ulcers and patchy inflammatory exudates (pseudomembranes) composed of necrotic cells, neutrophils, fibrin and debris. Epithelial crypts in the colon often fill with neutrophils, forming so-called crypt abscesses. These changes resolve in 7–14 days.

CLINICAL FEATURES: Patients with *C. jejuni* usually produce more than 10 stools per day, varying from profuse watery stools to small-volume stools containing gross blood and mucus. Symptoms resolve in 5–7 days. Treatment with antibiotics is probably of marginal benefit. A few patients develop a more severe, protracted illness, resembling acute ulcerative colitis. Gastrointestinal infections with *C. jejuni* have been associated with Guillain-Barré syndrome.

Yersinia Infections Produce Painful Diarrhea

Yesinia enterocolitica and *Yersinia pseudotuberculosis* are gram-negative coccoid or rod-shaped bacteria.

EPIDEMIOLOGY: These organisms are facultative anaerobes found in feces of wild and domestic animals, including rodents, sheep, cattle, dogs, cats and horses. *Y. pseudotuberculosis* is also often seen in domestic birds, including turkeys, ducks, geese and canaries. Both organisms have been isolated from drinking water and milk. *Y. enterocolitica* is more likely to be acquired from contaminated meat, and *Y. pseudotuberculosis* from contact with infected animals.

PATHOLOGY AND CLINICAL FEATURES: *Y. enterocolitica* proliferates in the ileum and invades the mucosa, causing ulceration and necrosis of Peyer patches. It migrates by way of lymphatics to mesenteric lymph nodes. Fever, diarrhea (sometimes bloody) and abdominal pain begin 4–10 days after mucosal penetration. Abdominal pain in the right lower quadrant has led to an incorrect diagnosis of appendicitis. Arthralgia, arthritis and erythema nodosum are complications. Septicemia is uncommon but kills about one half of those in whom it occurs.

Y. pseudotuberculosis penetrates ileal mucosa, localizes in ileal–cecal lymph nodes and produces abscesses and granulomas in the lymph nodes, spleen and liver. Fever, diarrhea and abdominal pain may also suggest appendicitis.

PULMONARY INFECTIONS WITH GRAM-NEGATIVE BACTERIA

Klebsiella and *Enterobacter* Produce Nosocomial Infections That Cause Necrotizing Lobar Pneumonia

Klebsiella and *Enterobacter* species are short, encapsulated, gram-negative bacilli.

EPIDEMIOLOGY: These organisms cause 10% of all hospital-acquired (nosocomial) infections, involving the lungs, urinary tract, biliary tract and surgical wounds. Person-to-person transmission by hospital personnel is a special hazard. Predisposing factors are obstructive pulmonary disease in endotracheal tubes, indwelling catheters, debilitating conditions and immunosuppression. Secondary pneumonia caused by these bacteria may complicate influenza or other respiratory viral infections.

PATHOLOGY: *Klebsiella* and *Enterobacter* are inhaled and multiply in the alveolar spaces. The pulmonary parenchyma becomes consolidated, and a mucoid exudate of macrophages, fibrin and edema fluid fills the alveoli. As the exudate accumulates, alveolar walls become compressed and then necrotic. Numerous small abscesses may coalesce and lead to cavitation.

CLINICAL FEATURES: The onset of pneumonia is sudden, with fever, pleuritic pain, cough and a characteristic **thick mucoid sputum**. When infection is severe, these symptoms progress to dyspnea, cyanosis and death in 2–3 days. *Klebsiella* and *Enterobacter* infections may be complicated by fulminating, often fatal, septicemia, and aggressive antibiotic therapy is required. Recently, a group of highly drug-resistant members of the Enterobacteriaceae, including *Klebsiella* and *Enterobacter*, have emerged and are spreading throughout the world. These organisms, termed carbapenem-resistant Enterobacteriaceae (CRE), are resistant to the carbapenem class of antibiotics, considered the "drugs of last resort" for such infections. Carbapenem-resistant *Klebsiella pneumoniae* (CRKP) produces an enzyme, or a β-metallo-lactamase 1 (NDM-1), such that these strains are resistant to almost all available antibiotics.

Legionella Cause Mild to Life-threatening Pneumonia

Legionella pneumophila is a minute aerobic bacillus that has the cell wall structure of a gram-negative organism but reacts poorly with Gram stains. It was first identified 6 months after an outbreak of a severe respiratory disease of unknown cause at the 1976 American Legion convention in Philadelphia. Subsequently, retrospective studies demonstrated antibodies in sera from previously unexplained epidemics, dating to 1957.

EPIDEMIOLOGY: *Legionella* are present in small numbers in natural bodies of fresh water. They survive chlorination and proliferate in devices such as cooling towers, water heaters, humidifiers and evaporative condensers. Infection occurs when people inhale aerosols from contaminated sources. The disease is not contagious, and the organism is not part of normal human flora. An estimated 8000–18,000 cases of *Legionella* infection occur in the United States annually.

PATHOPHYSIOLOGY: *Legionella* cause two distinct diseases, namely, **pneumonia** and **Pontiac fever**. The pathogenesis of *Legionella* pneumonia (Legionnaires disease) is understood in some detail, whereas that of Pontiac fever remains largely a mystery. *Legionella* pneumonia begins when the organisms arrive in the terminal bronchioles or alveoli, where they are phagocytosed by alveolar macrophages. The bacteria replicate within phagosomes and protect themselves by blocking fusion of lysosomes with the phagosomes. The multiplying *Legionella* are released and infect freshly arriving macrophages. When immunity develops, macrophages are activated and cease to support such intracellular growth.

Native respiratory tract defenses, such as the mucociliary blanket of the airway, provide a first line of defense against *Legionella* infection in the lower respiratory tract. Conditions that interfere with respiratory defenses, such as smoking, alcoholism and chronic lung diseases, increase the risk of developing *Legionella* pneumonia.

PATHOLOGY: Legionnaires disease is an acute bronchopneumonia. It is usually patchy but may show a lobar pattern of infiltration. Affected alveoli and bronchioles are filled with an exudate composed of proteinaceous fluid, fibrin, macrophages and neutrophils (Fig. 9-25) and microabscesses. Alveolar walls become necrotic and are destroyed. Many macrophages show eccentric nuclei, pushed aside by cytoplasmic vacuoles containing *L. pneumophila*. As the pneumonia resolves, the lungs heal with little permanent damage.

CLINICAL FEATURES: After incubating 2–10 days, clinical onset is characterized by rapidly progressive pneumonia, fever, nonproductive cough and myalgia. Chest radiographs reveal unilateral, diffuse, patchy consolidation, progressing to widespread nodular consolidation. Toxic symptoms, hypoxia and obtundation may be prominent, and death may follow within a few days. In those who survive, convalescence is prolonged. Mortality

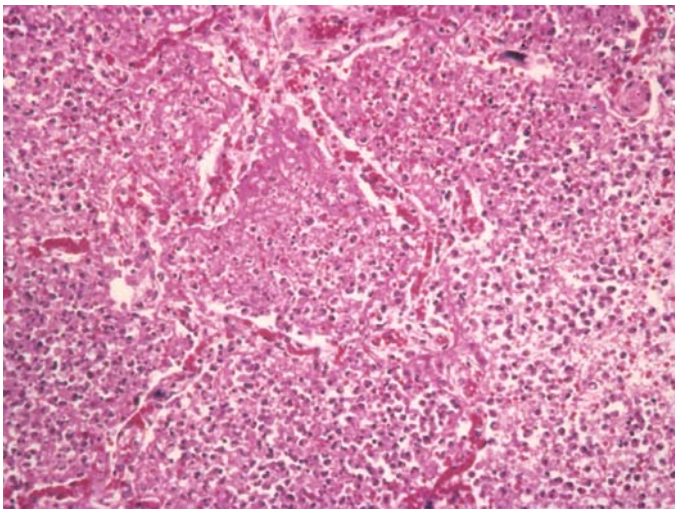

FIGURE 9-25. Legionnaires pneumonia. The alveoli are packed with an exudate composed of fibrin, macrophages and neutrophils.

among hospitalized patients averages 15% but is much greater if there is a serious underlying illness. Infection is amenable to treatment with macrolide antibiotics.

Pontiac fever is a self-limited, flu-like illness with fever, malaise, myalgias and headache. It differs from Legionnaires disease in that it lacks pulmonary consolidation and resolves spontaneously in 3–5 days.

Pseudomonas aeruginosa Is a Highly Antibiotic-Resistant Opportunistic Pathogen

The organism only infrequently infects humans. However, it causes disease, particularly in hospital environments, where it is associated with pneumonia, wound infections, urinary tract disease and sepsis in debilitated or immunosuppressed persons. Burns, urinary catheterization, cystic fibrosis, diabetes and neutropenia all predispose to infection with *Pseudomonas aeruginosa.*

The organism is a ubiquitous aerobic, gram-negative rod that requires moisture and only minimal nutrients. It thrives in soil and water, on animals and on moist environmental surfaces. Antibiotic use selects for *P. aeruginosa,* as it is resistant to most antibiotics.

PATHOPHYSIOLOGY: *P. aeruginosa* elaborates an array of proteins that allow it to attach to, invade and destroy host tissues while avoiding host inflammatory and immune defenses. Injury to epithelial cells uncovers surface molecules that serve as binding sites for the pili of *P. aeruginosa.* Many strains of *P. aeruginosa* produce a proteoglycan that surrounds and protects them from mucociliary action, complement and phagocytes. The organism releases extracellular enzymes—including an elastase, an alkaline protease and a cytotoxin—which facilitate tissue invasion and are partially responsible for the necrotizing lesions of *Pseudomonas* infections. The elastase probably determines the distinctive ability of *P. aeruginosa* to invade blood vessel walls. The organism also causes systemic pathologic effects through endotoxin and several systemically active exotoxins.

PATHOLOGY: *Pseudomonas* infection produces an acute inflammatory response. The bacterium often invades small arteries and veins, causing thrombosis and hemorrhagic necrosis, particularly in the lungs and skin. Blood vessel invasion predisposes to dissemination and sepsis and causes multiple nodular lesions in the lungs. Gram stains of necrotic tissue infected with *Pseudomonas* commonly show blood vessel walls densely infiltrated with organisms. Sometimes disseminated infection is marked by skin lesions called **ecthyma gangrenosum**. These nodular, necrotic lesions represent sites where the organism has disseminated to the skin, invaded blood vessels and produced localized hemorrhagic infarcts.

CLINICAL FEATURES: These are among the most aggressive human bacterial diseases, often progressing rapidly to sepsis. They require immediate medical intervention and are associated with a high mortality.

Melioidosis Is Characterized by Abscesses in Many Organs

Melioidosis (Rangoon beggars disease) is an uncommon disease caused by *Burkholderia* (formerly *Pseudomonas*) *pseudomallei,* a small gram-negative bacillus in the soil and surface water of Southeast Asia and other tropical areas. During the Vietnam conflict, several hundred American servicemen acquired melioidosis. The organism flourishes in wet environments, such as rice paddies and marshes. The skin is the usual portal of entry; organisms enter preexisting lesions, including penetrating wounds and burns. Humans may also be infected by inhaling contaminated dust or aerosolized droplets. The incubation period may last months to years, and the clinical course is variable.

PATHOLOGY AND CLINICAL FEATURES: **Acute melioidosis** is a pulmonary infection, ranging from a mild tracheobronchitis to an overwhelming cavitary pneumonia (Fig. 9-26). Patients with severe cases present with the sudden onset of high fever, constitutional symptoms and a cough that may produce blood-stained sputum. Splenomegaly, hepatomegaly and jaundice are sometimes present. Diarrhea may be as severe as in cholera. Fulminating septicemia,

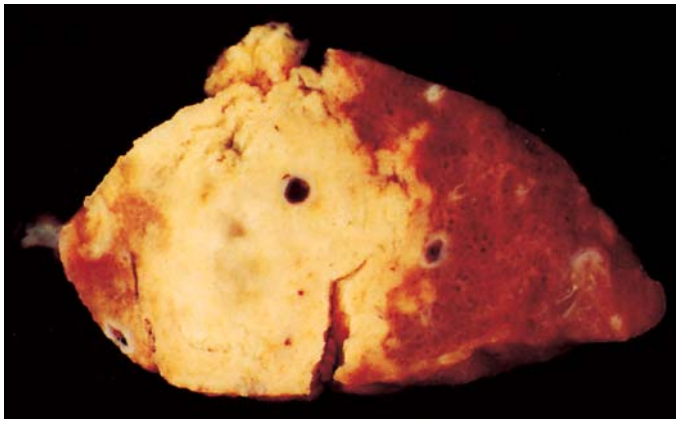

FIGURE 9-26. Acute melioidosis. The lung is consolidated and necrotic.

shock, coma and death may develop in spite of antibiotic therapy. Acute septicemic melioidosis causes discrete abscesses throughout the body, especially in the lungs, liver, spleen and lymph nodes.

Chronic melioidosis is a persistent localized infection of the lungs, skin, bones or other organs. Lesions are suppurative or granulomatous abscesses and in the lung may be mistaken for tuberculosis. In some cases, chronic melioidosis lies dormant for months or years, only to appear suddenly.

CLOSTRIDIAL DISEASES

Clostridia are gram-positive, spore-forming, obligate anaerobic bacilli. The vegetative bacilli are found in the gastrointestinal tract of herbivorous animals and humans. Anaerobic conditions promote vegetative division. Aerobic environments lead to sporulation. Spores pass in animal feces and contaminate soil and plants and survive well in unfavorable environments. Under anaerobic conditions, spores revert to vegetative cells, thus completing the cycle. During sporulation, vegetative cells degenerate, and their plasmids produce a variety of specific toxins that cause widely differing diseases, depending on the species (Fig. 9-27).

- **Food poisoning and necrotizing enteritis** are caused by enterotoxins of *Clostridium perfringens.*
- **Gas gangrene** is produced by myotoxins of *C. perfringens, Clostridium novyi, Clostridium septicum* and other species.
- **Tetanus** is due to *Clostridium tetani* neurotoxin.
- **Botulism** results from neurotoxins of *C. botulinum.*
- **Pseudomembranous enterocolitis** is caused by exotoxins made by *Clostridium difficile.*

Clostridial Food Poisoning Is Self-Limited

C. perfringens is one of the most common causes of bacterial food poisoning in the world, causing an acute, generally benign, diarrheal disease, usually lasting less than 24 hours. It is omnipresent in the environment, contaminating soil, water, air samples, clothing, dust and meat.

Its spores survive cooking and germinate to yield vegetative forms, which proliferate when food is allowed to stand without refrigeration. Cooking drives out enough air to make the food anaerobic, which is conducive to growth but not to sporulation. As a result, contaminated food contains vegetative clostridia but little preformed enterotoxin. The vegetative bacteria sporulate in the small bowel, where they elaborate several exotoxins, which are cytotoxic to enterocytes and cause loss of intracellular ions and fluid. Certain types of food, including meats, gravies and sauces, are ideal substrates for *C. perfringens.* Clostridial food poisoning presents as abdominal cramping and watery diarrhea. Symptoms begin 8–24 hours after ingestion of contaminated food and usually resolve within 24 hours.

Necrotizing Enteritis Is a Catastrophic Childhood Infection in New Guinea

C. perfringens type C also produces an enterotoxin that causes necrotizing enterocolitis. The illness is rare in the industrialized world but is endemic in parts of New Guinea, especially in children who have participated in pig feasts (hence the pidgin term, *pigbel*). Adults, because they have circulating antibodies, tend not to develop the disease. Pigbel is segmental and may be restricted to a few centimeters or may involve the entire small intestine. Green, necrotic pseudomembranes are seen in areas of necrosis and peritonitis. More-advanced lesions perforate the bowel wall. Infarction of intestinal mucosa, with edema, hemorrhage and a suppurative transmural infiltrate, is characteristic. The mortality in children is high.

Gas Gangrene May Complicate Penetrating Wounds

Gas gangrene (clostridial myonecrosis) is a necrotizing, gas-forming infection that begins in contaminated wounds and spreads rapidly to adjacent tissues. It can be fatal within hours of onset. *C. perfringens* is the most common cause of gas gangrene, but other clostridial species occasionally produce the disease.

MOLECULAR PATHOGENESIS: Gas gangrene follows anaerobic deposition of *C. perfringens* into tissue. Clostridial growth requires extensive devitalized tissue, as in severe penetrating trauma, wartime injuries and septic abortions. Clostridial myonecrosis is rare if wounds are débrided promptly.

Necrosis of previously healthy muscle is caused by myotoxins elaborated by a few species of clostridia. *C. perfringens* type A is the source of the myotoxin in 80%–90% of cases, but *C. novyi* and *C. septicum* may also produce myotoxin. Clostridial myotoxin is a phospholipase that destroys the membranes of muscle cells, leukocytes and erythrocytes.

PATHOLOGY: Affected tissues rapidly become mottled and then frankly necrotic. Muscle may even liquefy. Overlying skin becomes tense, as edema and gas expand underlying soft tissues. There is extensive tissue necrosis with dissolution of the cells. A striking feature is the paucity of neutrophils, which are destroyed by the myotoxin. Affected tissues often show typical, lozenge-shaped, gram-positive rods.

CLINICAL FEATURES: The incubation period of gas gangrene is 2–4 days after injury. Sudden, severe pain occurs at the wound site, which is tender and edematous. Skin darkens, because of hemorrhage and cutaneous necrosis. The lesion develops a thick, smelly serosanguineous discharge that may contain gas bubbles. Hemolytic anemia, hypotension and renal failure may develop; in the terminal stages, coma, jaundice and shock supervene.

Tetanus Is Spastic Skeletal Muscle Contractions Caused by *Clostridium tetani* Neurotoxin

It is also known as "lockjaw" because of early involvement of the muscles of mastication.

EPIDEMIOLOGY: *C. tetani* is present in the soil and lower intestine of many animals. Tetanus occurs when the organism contaminates wounds and proliferates in tissue, releasing its exotoxin. A vaccine composed of inactivated tetanus toxin has largely eliminated the disease from developed countries. Nonetheless, tetanus is still a common and lethal disease in developing countries.

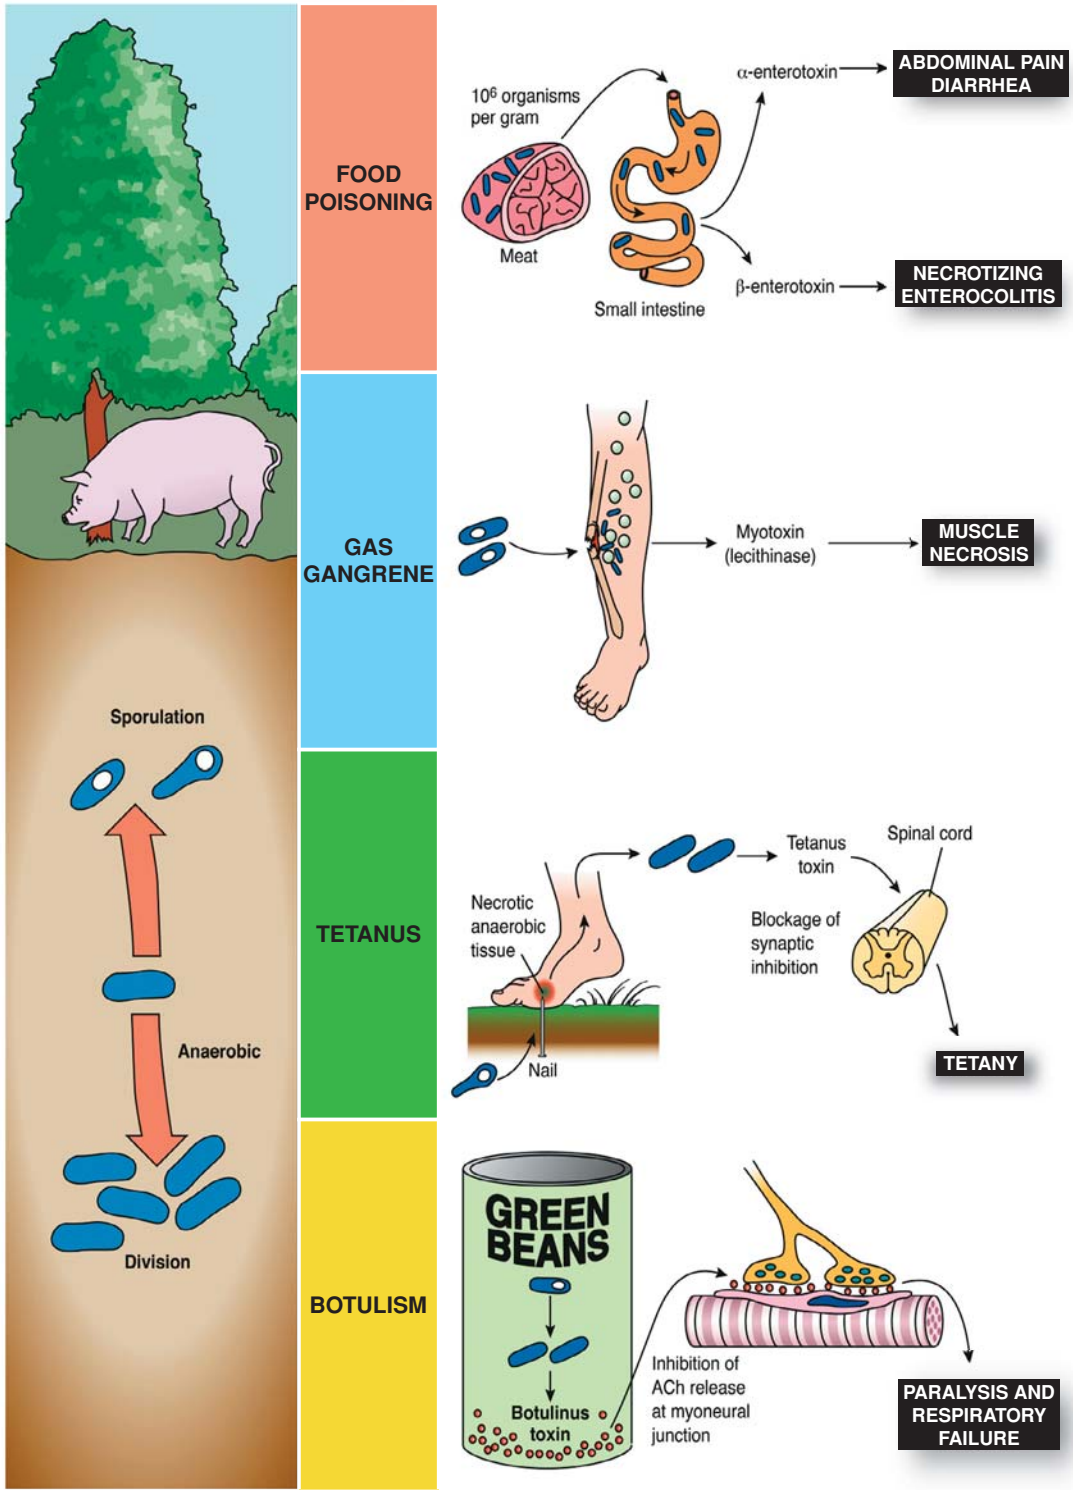

FIGURE 9-27. Clostridial diseases. Clostridia in the vegetative form (bacilli) inhabit the gastrointestinal tract of humans and animals. Spores pass in the feces, contaminate soil and plant materials and are ingested or enter sites of penetrating wounds. Under anaerobic conditions, they revert to vegetative forms. Plasmids in the vegetative forms elaborate toxins that cause several clostridial diseases. **Food poisoning and necrotizing enteritis.** Meat dishes left to cool at room temperature grow large numbers of clostridia (>10^6 organisms per gram). When contaminated meat is ingested, *Clostridium perfringens* types A and C produce α enterotoxin in the small intestine during sporulation, causing abdominal pain and diarrhea. Type C also produces β enterotoxin. **Gas gangrene.** Clostridia are widespread and may contaminate a traumatic wound or surgical operation. *C. perfringens* type A elaborates a myotoxin (α toxin), an α lecithinase that destroys cell membranes, alters capillary permeability and causes severe hemolysis following intravenous injection. The toxin causes necrosis of previously healthy skeletal muscle. **Tetanus.** Spores of *Clostridium tetani* are in soil and enter the site of an accidental wound. Necrotic tissue at the wound site causes spores to revert to the vegetative form (bacilli). Autolysis of vegetative forms releases tetanus toxin. The toxin is transported in peripheral nerves and (retrograde) through axons to the anterior horn cells of the spinal cord. The toxin blocks synaptic inhibition, and the accumulation of acetylcholine in damaged synapses leads to rigidity and spasms of the skeletal musculature (tetany). **Botulism.** Improperly canned food is contaminated by the vegetative form of *Clostridium botulinum,* which proliferates under aerobic conditions and elaborates a neurotoxin. After the food is ingested, the neurotoxin is absorbed from the small intestine and eventually reaches the myoneural junction, where it inhibits the release of acetylcholine (ACh). The result is a symmetric descending paralysis of cranial nerves, trunk and limbs, with eventual respiratory paralysis and death.

Many deaths occur in newborns in primitive societies owing to the custom of coating umbilical stumps with dirt or dung to prevent bleeding.

MOLECULAR PATHOGENESIS: Necrotic tissue and suppuration create a fertile anaerobic environment for the spores to revert to vegetative bacteria. Tetanus toxin is released from autolyzed vegetative cells. Infection remains localized, but the potent neurotoxin **(tetanospasmin)** is transported retrograde through the ventral roots of peripheral nerves to the anterior horn cells of the spinal cord. It crosses the synapse and binds to ganglioside receptors on presynaptic terminals of motor neurons in the ventral horns. After it is internalized, its endopeptidase activity selectively cleaves a protein that mediates exocytosis of synaptic vesicles. Thus, release of inhibitory neurotransmitters is blocked, permitting unopposed neural stimulation and sustained contraction of skeletal muscles **(tetany)**. The loss of inhibitory neurotransmitters also accelerates the heart rate and leads to hypertension and cardiovascular instability.

CLINICAL FEATURES: Tetanus incubates for 1–3 weeks, then begins subtly with fatigue, weakness and muscle cramping that progresses to rigidity. Spastic rigidity often begins in the muscles of the face, hence **"lockjaw,"** which extends to several facial muscles, causing a fixed grin **(risus sardonicus)**. Rigidity of the muscles of the back produces a backward arching **(opisthotonos)** (Fig. 9-28). Abrupt stimuli, including noise, light or touch, can precipitate painful generalized muscle spasms. Prolonged spasm of respiratory and laryngeal musculature may be fatal. Infants and people older than 50 years have the highest mortality.

Botulism Is a Paralyzing Disease Due to *Clostridium botulinum* Neurotoxin

The disease entails symmetric descending paralysis of cranial nerves, limbs and trunk.

EPIDEMIOLOGY: *C. botulinum* spores are widely distributed and are especially resistant to drying and boiling. In the United States, the toxin is most often present in foods that have been improperly home canned and stored without refrigeration. These circumstances provide suitable anaerobic conditions for growth of the vegetative cells that elaborate the neurotoxin.

FIGURE 9-28. Tetanus. Opisthotonus (backward arching) in an infant due to intense contraction of the paravertebral muscles.

Botulism can be contracted from home-cured ham and other meats left unrefrigerated for several days and from raw, smoked and fermented fish products. It is also caused by absorption of toxin from organisms proliferating in infants' intestines **(infantile botulism)** or rarely by absorption of toxin from bacteria growing in contaminated wounds **(wound botulism)**.

PATHOPHYSIOLOGY: Ingested botulinum neurotoxin resists gastric digestion and is readily absorbed into the blood from the proximal small intestine. Circulating toxin reaches the cholinergic nerve endings at the myoneural junction. There are 7 serotypes of neurotoxin (A–G), with diverse mechanisms of action. The most common serotype, A, binds gangliosides at presynaptic nerve terminals and inhibits acetylcholine release.

CLINICAL FEATURES: Botulism is characterized by a descending paralysis, first affecting cranial nerves and causing blurred vision, photophobia, dry mouth and dysarthria. Weakness progresses to involve the neck muscles, extremities, diaphragm and accessory muscles of breathing. Respiratory weakness can progress rapidly to complete respiratory arrest and death. Untreated botulism is usually lethal, but treatment with antitoxin reduces mortality to 25%. Botulinum toxin is often used as treatment for many forms of dystonia and has recently found popularity as a cosmetic vehicle to erase frown lines transiently (Botox).

Clostridium difficile Colitis Follows Antibiotic Treatment

C. difficile ***colitis is an acute necrotizing infection of the terminal small bowel and colon. It is responsible for 25%–50% of antibiotic-associated diarrhea and can be lethal.***

EPIDEMIOLOGY: *C. difficile* resides in the colon in some healthy individuals. A change in intestinal flora, often due to antibiotic administration (e.g., clindamycin), allows it to flourish, produce toxin and damage the colonic mucosa. Such colitis can also be precipitated by other insults to the colonic flora, such as bowel surgery, dietary changes and chemotherapeutic agents. In hospitals where many patients receive antibiotics, fecal shedding of *C. difficile* results in person-to-person spread.

MOLECULAR PATHOGENESIS: Commensal colonic bacteria normally limit growth of *C. difficile*, but when normal flora are disturbed (e.g., by antibiotic treatment), the organism can proliferate, elaborate toxins and destroy mucosal cells. *C. difficile* does not invade, but rather produces two exotoxins. Toxin A causes fluid secretion; toxin B is directly cytopathic.

PATHOLOGY: *C. difficile* destroys colonic mucosal cells and incites an acute inflammatory infiltrate. Lesions range from focal colitis limited to a few crypts and only detectable on biopsy, to massive

confluent mucosal ulceration. Inflammation initially involves only the mucosa, but it can extend into the submucosa and muscularis propria. An inflammatory exudate, "pseudomembrane" of cellular debris, neutrophils and fibrin, often forms over affected areas of the colon. *C. difficile* colitis is often called **pseudomembranous colitis,** even though that condition may have many etiologies.

CLINICAL FEATURES: *C. difficile* colitis may start with very mild symptoms or with diarrhea, fever and abdominal pain. Stools may be profuse and often contain neutrophils. The symptoms and signs are not specific and do not distinguish *C. difficile* colitis from other acute inflammatory diarrheal illnesses. Mild cases can often be treated simply by discontinuing the precipitating antibiotic. More-severe cases require an antibiotic effective against *C. difficile.*

BACTERIAL INFECTIONS WITH ANIMAL RESERVOIRS OR INSECT VECTORS

Brucellosis Is a Chronic Febrile Disease Acquired from Domestic Animals

Human brucellosis may manifest as an acute systemic disease or as a chronic infection with waxing and waning febrile episodes, weight loss and fatigue. *Brucella* are small, aerobic, gram-negative rods. In humans, they primarily infect monocytes/macrophages.

EPIDEMIOLOGY: Brucellosis is a zoonotic disease caused by one of four *Brucella* species. Each species of *Brucella* has its own animal reservoir:

- *Brucella melitensis:* sheep and goats
- *Brucella abortus:* cattle
- *Brucella suis:* swine
- *Brucella canis:* dogs

Brucellosis occurs worldwide; virtually every type of domesticated animal and many wild ones are infected. The organisms reside in the animals' genitourinary systems, and infection is often endemic in animal herds. Humans acquire the bacteria by (1) contact with infected blood or tissue, (2) ingesting contaminated meat or milk or (3) inhaling contaminated aerosols. Brucellosis is an occupational hazard among ranchers, herders, veterinarians and slaughterhouse workers.

Elimination of infected animals and vaccination of herds have reduced the incidence of brucellosis in many countries, so that only about 200 cases are reported annually in the United States. Yet, the disease remains prevalent throughout Central and South America, Africa, Asia and Southern Europe, where unpasteurized milk and cheese are major sources of infection. In the arctic and subarctic regions, humans acquire brucellosis by eating raw bone marrow of infected reindeer.

PATHOLOGY: Bacteria enter the circulation through skin abrasions, lungs, conjunctiva or oropharynx. They then spread in the bloodstream to the liver, spleen, lymph nodes and bone marrow, where they multiply in macrophages. Generalized hyperplasia of these cells may ensue, causing lymphadenopathy and hepatosplenomegaly in 15% of patients infected with *B. melitensis,* and in 40% of those infected with *B. abortus.* Patients infected with *B. abortus* develop conspicuous noncaseating granulomas in the liver, spleen, lymph nodes and bone marrow. By contrast, patients infected with *B. melitensis* do not develop classic granulomas, but may have only small aggregates of mononuclear inflammatory cells scattered throughout the liver. *B. suis* infection may cause suppurative liver abscesses. The organisms usually cannot be demonstrated histologically. Periodic release of organisms from infected phagocytic cells may be responsible for the febrile episodes of the illness.

CLINICAL FEATURES: Brucellosis is a systemic infection that can involve any organ or organ system, with an insidious onset in half of cases. It is characterized by a multitude of somatic complaints, such as fever, sweats, anorexia, fatigue, weight loss and depression. Fever occurs in all patients at some time during the illness, but it can wax and wane (hence the term **undulant fever**) over weeks to months if untreated. Mortality from brucellosis is less than 1%; death is usually caused by endocarditis.

The most common complications of brucellosis involve the bones and joints and include spondylitis of the lumbar spine and suppuration in large joints. Peripheral neuritis, meningitis, orchitis, endocarditis, myocarditis and pulmonary lesions are described. Prolonged treatment with tetracycline is usually effective; the relapse rate is dramatically reduced if rifampin or an aminoglycoside antibiotic is used.

Yersinia pestis Causes Bubonic Plague

Plague is a bacteremic, often fatal, infection that is usually accompanied by enlarged, painful regional lymph nodes **(buboes)**. Historically, plague caused massive epidemics that killed much of the then-civilized world and has been credited with major impact on the course of history.

Major plague epidemics have occurred when *Yersinia pestis* was introduced into large urban rat populations in crowded, squalid cities. Infection spread first among rats; then, as they died, infected fleas fed on the human population, causing widespread disease. Plague has been a common cohabitant of war. An Athenian plague in the 5th century BC developed during the Peloponnesian wars. Two huge epidemics occurred in the Roman empire, one in the 2nd century AD and one in the 6th century AD, both involving either wars or trade routes. The latter may have killed as many as 100 million people. The Black Death pandemic in mid-14th-century (1347–1350) Europe killed 30%–60% of Europe's population. In the United States, 30–40 cases of plague occur annually, mostly in the desert Southwest. Between 2000 and 3000 cases of plague are reported worldwide each year, but the likely number of infections is considerably higher.

Y. pestis is a short gram-negative rod that stains more heavily at the ends (i.e., bipolar staining), particularly with Giemsa stains.

EPIDEMIOLOGY: *Y. pestis* infection is an endemic zoonosis in many parts of the world, including the Americas, Africa and Asia. The organisms are found in wild rodents, such as rats, squirrels

and prairie dogs. Fleas transmit it from animal to animal, and most human infections result from bites of infected fleas. Some infected humans develop plague pneumonia and shed large numbers of organisms in aerosolized respiratory secretions, which allows person-to-person transmission.

PATHOPHYSIOLOGY: After inoculation into the skin, *Y. pestis* is phagocytosed by neutrophils and macrophages. Organisms ingested by neutrophils are killed, but those engulfed by macrophages survive and replicate intracellularly. The bacteria are carried to regional lymph nodes, where they continue to multiply, producing extensive hemorrhagic necrosis. From regional lymph nodes, they disseminate via the bloodstream and lymphatics. In the lungs, *Y. pestis* produces a necrotizing pneumonitis that releases organisms into the alveoli and airways. These are expelled by coughing, enabling pneumonic spread of the disease. Affected lymph nodes, known as "buboes," are frequently enlarged and fluctuant, owing to extensive hemorrhagic necrosis. Infected patients often develop necrotic, hemorrhagic skin lesions, hence the name "black death" for this disease.

CLINICAL FEATURES: The three clinical presentations of *Y. pestis* infection often overlap.

- **Bubonic plague** begins 2–8 days after the flea bite. Symptoms include headache, fever and myalgias and painful enlargement of regional lymph nodes, mostly in the groin, because flea bites usually occur in the lower extremities. Disease progresses to septic shock within hours to days after appearance of the bubo.
- **Septicemic plague** (10% of cases) occurs when bacteria enter directly into the blood and do not produce buboes. Patients die of overwhelming bacterial growth in the bloodstream. Fever, prostration and meningitis occur suddenly, and death ensues within 48 hours. All blood vessels contain bacilli, and fibrin casts surround the organisms in renal glomeruli and dermal vessels.
- **Pneumonic plague** results from inhalation of airborne particles from carcasses of animals or the cough of infected people. Within 2–5 days after infection, high fever, cough and dyspnea begin suddenly. The sputum teems with bacilli. Respiratory insufficiency and endotoxic shock kill patients within 1–2 days.

All types of plague carry a high mortality rate (50%–75%) if untreated. Tetracycline, combined with streptomycin, is the recommended therapy.

Tularemia Is a Febrile Disease Caused by *Francisella tularensis*

Francisella tularensis is a small, gram-negative coccobacillus.

EPIDEMIOLOGY: Tularemia is a zoonosis whose most important reservoirs are rabbits and rodents, although other wild and domestic animals may harbor the organisms. Human infection results from contact with infected animals or from the bites of infected insects, including ticks, deerflies and mosquitoes. Ticks and rabbits are responsible for most human cases. Bacteria enter the body when blood-sucking insects inoculate them through the skin or via unnoticed breaks in the skin if there is direct contact with an infected animal, ingestion of contaminated food and water or inoculation into the eye. Inhalational tularemia can also result from inhalation of infected aerosols. It is found in temperate zones. The incidence of tularemia has declined dramatically in the United States, to about 250 cases annually, probably owing to a decline in hunting and trapping.

PATHOPHYSIOLOGY: *F. tularensis* multiplies at the site of inoculation, producing a focal ulcer. The bacteria then spread to regional lymph nodes. Dissemination in the bloodstream leads to metastatic infections that involve the monocyte/macrophage system and sometimes the lungs, heart and kidneys. *F. tularensis* survives within macrophages until these cells are activated by a cell-mediated immune response to the infection.

PATHOLOGY: Lesions of tularemia occur at the inoculation site and in lymph nodes, spleen, liver, bone marrow, lungs (Fig. 9-29), heart and kidneys. Initial skin lesions are exudative, pyogenic ulcers. Later, disseminated lesions undergo central necrosis and are surrounded by a perimeter of granulomatous reaction resembling the lesions of tuberculosis. Hyperemia and abundant macrophages in the sinuses make lymph nodes large and firm; they later soften as necrosis and suppuration develop. Pulmonary lesions resemble those of primary tuberculosis.

CLINICAL FEATURES: The incubation period of tularemia is 1–14 days, depending on the dose and route of transmission, with a mean of 3–4 days. There are four distinct clinical presentations:

- **Ulceroglandular tularemia** is the most common (80%–90% of cases). It begins as a tender, erythematous papule at the site of inoculation, usually on a limb. This develops

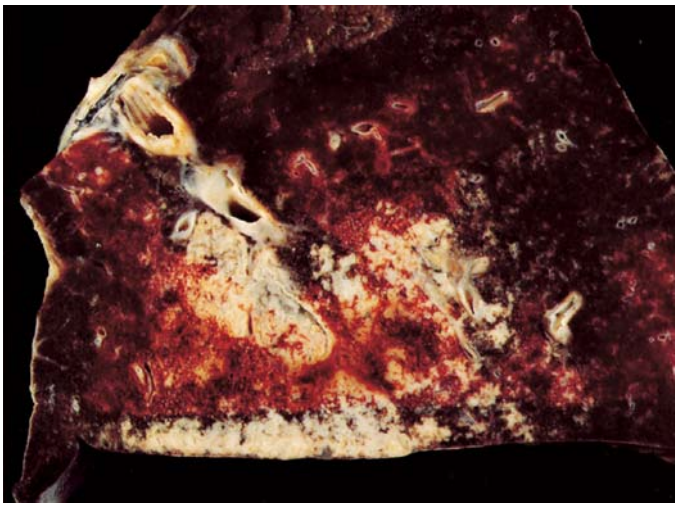

FIGURE 9-29. Tularemia. The lung shows firm, consolidated and necrotic areas.

into a pustule, which then ulcerates. Regional lymph nodes become large and tender and may suppurate and drain through sinus tracts. In some instances, generalized lymphadenopathy **(glandular tularemia)** is the first manifestation of infection.

Initial bacteremia is accompanied by fever, headache, myalgias and occasionally prostration. Within a week, generalized lymphadenopathy and splenomegaly develop. The most serious infections are complicated by secondary pneumonia and endotoxic shock, in which case the prognosis is grave. Some patients develop meningitis, endocarditis, pericarditis or osteomyelitis.

- **Oculoglandular tularemia** is rare (<2% of cases) and is characterized by a primary conjunctival papule, which forms a pustule and ulcerates. Lymphadenopathy develops in the head and neck. Severe ulceration may cause blindness if infection penetrates the sclera and reaches the optic nerve.
- **Typhoidal tularemia** is diagnosed when fever, hepatosplenomegaly and toxemia are the presenting signs and symptoms.
- **Pneumonic tularemia,** in which pneumonia is a major feature, may complicate any of the other types.

Tularemia lasts 1 week to 3 months, but this may be shortened by prompt treatment with streptomycin.

Anthrax is Rapidly Fatal When It Disseminates

Anthrax is a necrotizing disease caused by *Bacillus anthracis,* which is a large spore-forming, gram-positive rod.

EPIDEMIOLOGY: Anthrax has been recognized for centuries, and descriptions of disease consistent with anthrax were reported in early Hebrew, Roman and Greek records. The major reservoirs are goats, sheep, cattle, horses, pigs and dogs. Spores form in the soil and dead animals, resisting heat, desiccation and chemical disinfection for years. Humans are infected when spores enter the body through breaks in the skin, by inhalation or by ingestion. Human disease may also result from exposure to contaminated animal byproducts, such as hides, wool, brushes or bone meal.

Anthrax has been a persistent problem in Iran, Turkey, Pakistan and Sudan. One of the largest recorded naturally occurring outbreaks of anthrax occurred in Zimbabwe, when an estimated 10,000 persons became infected in 1978–1980. In North America, human infection is extremely rare (one case per year for the past few years) and usually results from exposure to imported animal products. However, increased vigilance for anthrax has emerged following a recent bioterrorism episode involving transport of organisms by the postal system (see below).

PATHOPHYSIOLOGY: The spores of *B. anthracis* germinate in the human body to yield vegetative bacteria that multiply and release a potent necrotizing toxin. In 80% of cases of cutaneous anthrax, infection remains localized and host immune responses eventually eliminate the organism. If the infection disseminates, as occurs when the organisms are inhaled or ingested, the resulting widespread tissue destruction is usually fatal.

PATHOLOGY: *B. anthracis* produces extensive tissue necrosis at the sites of infection, with only a mild infiltrate of neutrophils. Cutaneous lesions are ulcerated, contain numerous organisms and are covered by a black scab. Pulmonary infection produces a necrotizing, hemorrhagic pneumonia, associated with hemorrhagic necrosis of mediastinal lymph nodes and widespread dissemination of the organism.

CLINICAL FEATURES: The mode of presentation of anthrax depends on the site of inoculation.

- **Malignant pustule,** the cutaneous form, accounts for 95% of all anthrax. The patient presents with an elevated skin papule that enlarges and erodes into an ulcer. Bloody purulent exudate accumulates and gradually darkens to purple or black. The ulcer is often surrounded by a zone of brawny edema, which is disproportionately large for the size of the ulcer. Regional lymphadenitis portends a poor prognosis, since lymphatic invasion precedes septicemia. If infection does not disseminate, cutaneous lesions heal without sequelae.
- **Pulmonary, or inhalational, anthrax,** sometimes called "woolsorters' disease," is a hazard of handling raw wool and develops after inhaling the spores of *B. anthracis.* It begins as a flu-like illness that rapidly progresses to respiratory failure and shock. Death often ensues within 24–48 hours. Inhalational anthrax is very rare in the United States. During a bioterror attack in the United States in 2001, 11 cases of inhalational anthrax occurred. The only hope is early antibiotic therapy.
- **Septicemic anthrax** more commonly follows pulmonary anthrax than malignant pustule. Disseminated intravascular coagulation is a common complication. Moreover, a bacterial toxin depresses the respiratory center, which explains why death can occur even when antibiotic therapy has cured the infection.
- **Gastrointestinal anthrax** is rare and is acquired by eating contaminated meat. Stomach or bowel ulceration and invasion of regional lymphatics are common. Death is caused by fulminant diarrhea and massive ascites.

Listeriosis Is a Systemic Multiorgan Infection with a High Mortality

Listeriosis is caused by *Listeria monocytogenes,* a small, motile, gram-positive coccobacillus. It is particularly important as a cause of perinatal disease in newborn babies.

EPIDEMIOLOGY: Listeriosis is usually sporadic but may be epidemic. The organism has been isolated worldwide from surface water, soil, vegetation, feces of healthy persons, many species of wild and domestic mammals and several species of birds. However, spread of infection from animals to humans is rare. Most human infections occur in urban rather than rural environments, usually in the summer. *L. monocytogenes* grows at refrigerator temperatures, and outbreaks have been traced to unpasteurized milk, cheese and dairy products.

MOLECULAR PATHOGENESIS: *L. monocytogenes* has an unusual life cycle, which accounts for its ability to evade intracellular and extracellular

host antibacterial defenses. After phagocytosis by host cells, the organisms enter phagolysosomes, where acidic pH activates *listeriolysin O,* an exotoxin that disrupts the vesicular membrane and allows bacteria to escape into the cytoplasm. After replicating, bacteria usurp host cytoskeleton contractile elements to form elongated protrusions that are engulfed by adjacent cells. Thus, *Listeria* spread from one cell to another without exposure to the extracellular environment.

PATHOLOGY AND CLINICAL FEATURES: Listeriosis of pregnancy includes prenatal and postnatal infections. Listeriosis of the adult population is characterized by meningoencephalitis and septicemia but may be localized to the skin, eyes, lymph nodes, endocardium or bone.

Maternal infection early in pregnancy may lead to abortion or premature delivery. Infected infants rapidly develop respiratory distress, hepatosplenomegaly, cutaneous and mucosal papules, leukopenia and thrombocytopenia. Intrauterine infections involve many organs and tissues, including amniotic fluid, the placenta and the umbilical cord. Abscesses are found in many organs. Foci of necrosis and suppuration contain many bacteria. Older lesions tend to be granulomatous. Neurologic sequelae are common, and the mortality of neonatal listeriosis is high even with prompt antibiotic therapy. Neonatal listeriosis may also be acquired during delivery, in which case the onset of clinical disease is 3 days to 2 weeks after birth.

Chronic alcoholics, patients with cancer or receiving immunosuppressive therapy and those with AIDS are far more susceptible to infection than is the general population. Meningitis is the most common form of the disease in adults and resembles other bacterial meningitides.

Septicemic listeriosis is a severe febrile illness most common in immunodeficient patients. It may lead to shock and disseminated intravascular coagulation, accounting for misdiagnosis as gram-negative sepsis. Prolonged treatment with antimicrobials is usually required because patients tend to experience relapse if therapy is administered for less than 3 weeks. The mortality from systemic listeriosis remains at 25%.

Bartonella henselae Causes Cat-Scratch Disease

Cat-scratch disease is a self-limited infection usually caused by *Bartonella* strain *Bartonella henselae* and, more rarely, *Bartonella quintana.* The bacteria are small (0.2–0.6 µm) gram-negative rods. They are difficult to culture but are easily seen in tissue sections of the skin, lymph nodes and conjunctiva when stained with a silver impregnation technique (Fig. 9-30).

EPIDEMIOLOGY: The animal reservoir is thought to be cats; surveys have shown that up to 30% of cats are bacteremic. Infection begins when the bacillus is inoculated into the skin by the claws of cats (or rarely other animals) or by thorns or splinters. Sometimes the conjunctiva is contaminated by close contact with a cat, possibly by licking around the eye. Infections are more common in children (80%) than in adults.

PATHOLOGY AND CLINICAL FEATURES: Bacteria multiply in the walls of small vessels and about collagen fibers at the site of inoculation. The organisms are then carried to regional lymph nodes, where they cause a **suppurative** and **granulomatous lymphadenitis**. In early lesions, clusters of bacteria fill and expand lumina of small blood vessels. However, bacteria are rare in late lesions. A papule develops at the site of inoculation, followed by tenderness and enlargement of regional lymph nodes. Nodes remain enlarged for 3–4 months and may drain through the skin. About half of patients have other symptoms, including fever and malaise, rash, a brief encephalitis and erythema nodosum. There are other clinical presentations. **Parinaud oculoglandular syndrome** (preauricular adenopathy secondary to conjunctival infection) is common. **Bacillary angiomatosis** is a vascular skin disease that can extend to other organs—it is most commonly seen in immunocompromised persons. **Bacillary peliosis** affects the liver and spleen, causing blood-filled cystic spaces; it affects patients with severe immunologic compromise. Antibiotics are not known to help.

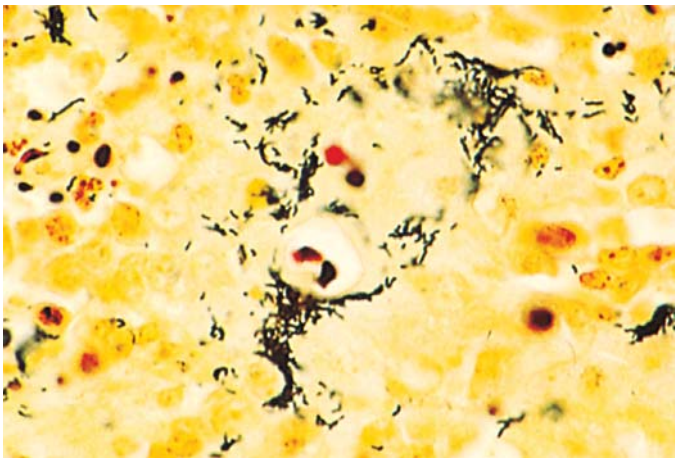

FIGURE 9-30. Cat-scratch disease. Section of a lymph node shows the bacilli, which are gram negative but difficult to visualize with tissue Gram stains. They are blackened by the Warthin-Starry silver impregnation technique.

Glanders Is a Granulomatous Infection Acquired from Horses

Glanders is an infection of equine species (horses, mules, donkeys) that is only rarely transmitted to humans, in whom it causes acute or chronic granulomatous disease. It is caused by *Pseudomonas mallei,* a small gram-negative, nonmotile bacillus. Although uncommon, the infection remains endemic in South America, Asia and Africa. People acquire the disease by contact with infected equines through broken skin or inhalation of contaminated aerosols.

- **Acute glanders** is characterized by bacteremia, severe prostration and fever. Granulomatous abscesses may form in subcutaneous tissues and many other organs, including the lung, liver, spleen, muscles and joints. Acute glanders is almost always fatal.
- **Chronic glanders** features low-grade fever, draining abscesses of the skin, lymphadenopathy and hepatosplenomegaly. Granulomas in many organs mimic tuberculosis. The mortality in chronic glanders exceeds 50%.

Bartonellosis Causes Acute Anemia and Skin Disease

Bartonellosis is an infection by *Bartonella bacilliformis*, a small, multiflagellated, gram-negative coccobacillus.

EPIDEMIOLOGY: Bartonellosis occurs only in Peru, Ecuador and Colombia, in river valleys of the Andes, and is transmitted by sandflies. Humans are the only reservoir and acquire the infection at sunrise and sunset, when sandflies are most active. In endemic areas, 10%–15% of the population have latent infections. Newcomers are susceptible, whereas the indigenous population tends to be resistant.

PATHOLOGY AND CLINICAL FEATURES: Bartonellosis presents a biphasic pattern, with acute hemolytic anemia **(Oroya fever)** first, followed some months later by a chronic dermal phase **(verruga peruana)**. Either phase may occur by itself.

The most severe consequence of bartonellosis is hemolytic anemia. After *B. bacilliformis* is inoculated into the skin by a sandfly, bacteria proliferate in the vascular endothelium and then invade erythrocytes, leading to profound hemolysis.

The **acute anemic phase** follows 3 weeks of incubation and is characterized by abrupt onset of fever, skeletal pains and severe, hemolytic anemia. If untreated, 40% of patients in the anemic phase die. Secondary *Salmonella* sepsis is common and contributes to the high mortality.

The **dermal eruptive phase** may coexist with the anemic phase but usually appears 3–6 months later. Many small hemangioma-like lesions stud the dermis, and bacteria may be identified in endothelial cells. Nodular lesions may be prominent on extensor surfaces of the arms and legs. Large deep-seated lesions, which tend to ulcerate, develop near joints and limit motion. The dermal eruptive phase is often prolonged but eventually heals spontaneously. The mortality in this phase is less than 5%.

INFECTIONS CAUSED BY BRANCHING FILAMENTOUS ORGANISMS

Actinomycosis Features Abscesses and Sinus Tracts

Actinomycosis is a slowly progressive, suppurative, fibrosing infection involving the jaw, thorax or abdomen. It is caused by a number of anaerobic and microaerophilic bacteria termed *Actinomyces.* These are branching, filamentous, gram-positive rods that normally reside in the oropharynx, gastrointestinal tract and vagina. Several *Actinomyces* species cause human disease, the most common being *Actinomyces israelii.*

PATHOPHYSIOLOGY: *Actinomyces* is not ordinarily virulent; the organisms reside as saprophytes in the body without producing disease. Two uncommon conditions must occur for *Actinomyces* to cause disease. First, it must be inoculated into deeper tissues, since it cannot invade. Second, an anaerobic atmosphere is necessary for bacterial proliferation. Trauma can produce tissue necrosis, providing an excellent anaerobic medium for growth of *Actinomyces* and inoculating the organism into normally sterile tissue. Actinomycosis occurs at four distinct sites:

- **Cervicofacial actinomycosis** results from jaw injury, dental extraction or dental manipulation.
- **Thoracic actinomycosis** is due to aspiration of organisms contaminating dental debris.
- **Abdominal actinomycosis** follows traumatic or surgical disruption of the bowel, especially the appendix.
- **Pelvic actinomycosis** is associated with the prolonged use of intrauterine devices (IUDs).

Actinomycosis begins as a nidus of proliferating organisms that attract an acute inflammatory infiltrate. The small abscess grows slowly, becoming a series of abscesses connected by sinus tracts. Tracts burrow, characteristically, across normal tissue boundaries and into adjacent organs. Eventually, a tract may reach an external surface or mucosal membrane and produce a draining sinus. The walls of abscesses and tracts are granulation tissue, often thick, densely fibrotic and chronically inflamed. Within abscesses and sinuses are pus and colonies of organisms.

Actinomyces colonies can grow to several millimeters and be visible to the naked eye. They appear as hard, yellow grains called **sulfur granules,** because they resemble elemental sulfur. These are tangled masses of narrow, branching filaments in a polysaccharide–protein matrix. Histologically, colonies are rounded, basophilic grains with scalloped eosinophilic borders (Fig. 9-31A). Individual filaments of *Actinomyces* cannot be discerned with hematoxylin and eosin stain but are readily visible on Gram staining or silver impregnation (Fig. 9-31B).

CLINICAL FEATURES: The presentation of actinomycosis depends on the site of infection. If infection originates in a tooth socket or the tonsils, it is characterized by swelling of the jaw ("lumpy jaw"), face and neck, at first painless and fluctuant but later painful. In pulmonary infections, sinus tracts may penetrate from lobe to lobe, through the pleura and into ribs and vertebrae. Abdominal or pelvic disease may present as an expanding mass, suggesting an enlarging tumor. Actinomycosis responds to prolonged antibiotic therapy; penicillin is highly effective.

Nocardiosis Is a Suppurative Respiratory Infection in Immunocompromised Hosts

Nocardia are aerobic, gram-positive filamentous, branching bacteria. They are weakly acid-fast, as distinguished from the morphologically similar actinomycetes. From the lungs, infection often spreads to the brain and skin.

EPIDEMIOLOGY: *Nocardia* species are widely distributed in soil, and human disease is caused by inhaling or inoculating soil-borne organisms. It is not transmitted from person to person. *Nocardia asteroides* is the species most often involved in human disease. Nocardiosis is most common in patients with impaired immunity, particularly cell-mediated immunity. Organ transplantation,

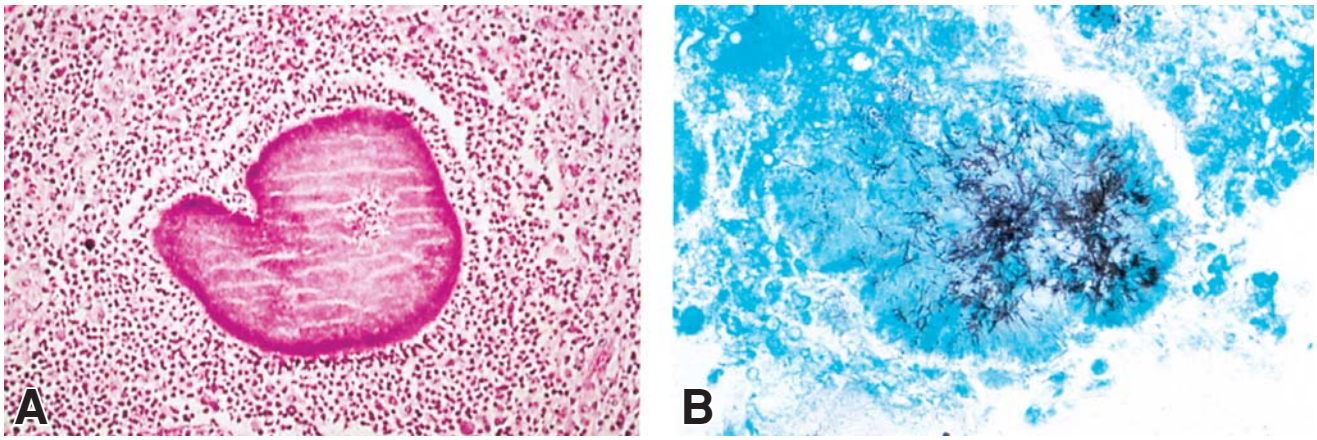

FIGURE 9-31. Actinomycosis. A. A typical sulfur granule lies within an abscess. **B.** The individual filaments of *Actinomyces israeli* are readily visible with the silver impregnation technique.

long-term corticosteroid therapy, lymphomas, leukemias and other debilitating diseases are predisposing factors.

Two other pathogenic species of *Nocardia, Nocardia brasiliensis* and *Nocardia caviae,* may cause pulmonary nocardiosis resembling that produced by *N. asteroides.* They are usually encountered in underdeveloped countries as a cause of mycetomas.

PATHOLOGY AND CLINICAL FEATURES: The respiratory tract is the usual portal of entry. The organism elicits a brisk infiltrate of neutrophils, and disease begins as a slowly progressive, pyogenic pneumonia. If an infected person mounts a vigorous cell-mediated immune response, the infection may be eliminated. In immunocompromised people, however, *Nocardia* produces pulmonary abscesses, which are frequently multiple and confluent. Direct extension to the pleura, trachea and heart and blood-borne metastases to the brain or skin carry a grave prognosis. Nocardial abscesses are filled with neutrophils, necrotic debris and scattered organisms. Bacteria can be demonstrated by silver impregnation (Fig. 9-32). With the Gram stain, they appear as beaded, filamentous, gram-positive rods. Untreated nocardiosis is usually fatal. Sulfonamides or related antibiotics for several months are often effective therapy.

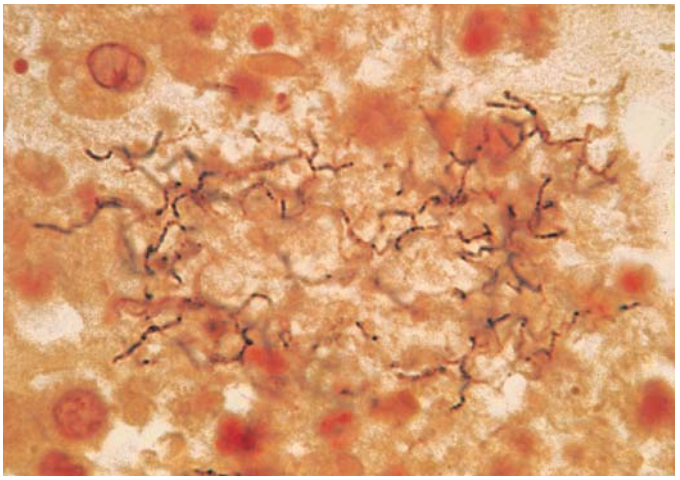

FIGURE 9-32. Nocardiosis. A silver stain of a necrotic exudate reveals the branching, filamentous rods of *Nocardia asteroides.*

Spirochetal Infections

Spirochetes are long, slender, helical bacteria with specialized cell envelopes that permit them to move by flexion and rotation. The thinner organisms are below the resolving power of routine light microscopy. Specialized techniques, such as darkfield microscopy or silver impregnation, are needed to visualize them. They have the basic cell wall structure of gram-negative bacteria but stain poorly with the Gram stain.

Three genera of spirochetes, *Treponema, Borrelia* and *Leptospira,* cause human disease (Table 9-5). They are adept at evading host inflammatory and immunologic defenses, and diseases caused by these organisms are all chronic or relapsing.

SYPHILIS

Syphilis (lues) is a chronic, sexually transmitted, systemic infection caused by *Treponema pallidum,* a thin, long spirochete (Fig. 9-33) that cannot be grown in artificial media. The disease was first recognized in Europe in the 1490s and has been related to Columbus's return from the New World. Urbanization and mass movements of people caused by war contributed to its rapid spread. Originally, syphilis was an acute disease that caused destructive skin lesions and early death, but it has become milder, with a more protracted and insidious clinical course.

EPIDEMIOLOGY: Syphilis is a worldwide disease that is transmitted almost exclusively by sexual contact. Infection may also spread from an infected mother to her fetus **(congenital syphilis)**. The incidence of primary and secondary syphilis has declined since the introduction of penicillin therapy at the end of World War II.

TABLE 9-5
SPIROCHETE INFECTIONS

Disease	Organism	Clinical Manifestation	Distribution	Mode of Transmission
Treponemes				
Syphilis	*Treponema pallidum*	See text	Common worldwide	Sexual contact, congenital
Bejel	*Treponema endemicum (Treponema pallidum,* subspecies *endemicum*)	Mucosal, skin and bone lesions	Middle East	Mouth-to-mouth contact
Yaws	*Treponema pertenue (Treponema pallidum* subspecies *pertenue*)	Skin and bone	Tropics	Skin-to-skin contact
Pinta	*Treponema carateum*	Skin lesions	Latin America	Skin-to-skin contact
Borrelia				
Lyme disease	*Borrelia burgdorferi*	See text	North America, Europe, Russia, Asia, Africa, Australia	Tick bite
Relapsing fever	*Borrelia recurrentis*	Relapsing flu-like illness	Worldwide	Tick bite, louse bite and related species
Leptospira				
Leptospirosis	*Leptospira interrogans*	Flu-like illness, meningitis	Worldwide	Contact with animal urine

ETIOLOGIC FACTORS AND PATHOPHYSIOLOGY: *T. pallidum* is very fragile and is killed by soap, antiseptics, drying and cold. Person-to-person transmission requires direct contact between a rich source of spirochetes (e.g., an open lesion) and mucous membranes or abraded skin of the genital organs, rectum, mouth, fingers or nipples. The organisms reproduce at the site of inoculation, pass to regional lymph nodes, gain access to systemic circulation and disseminate throughout the body. Although *T. pallidum* induces an inflammatory response and is taken up by phagocytic cells, it persists and proliferates. Chronic infection and inflammation cause tissue destruction, sometimes for decades. The course of syphilis is classically divided into three stages (Fig. 9-34).

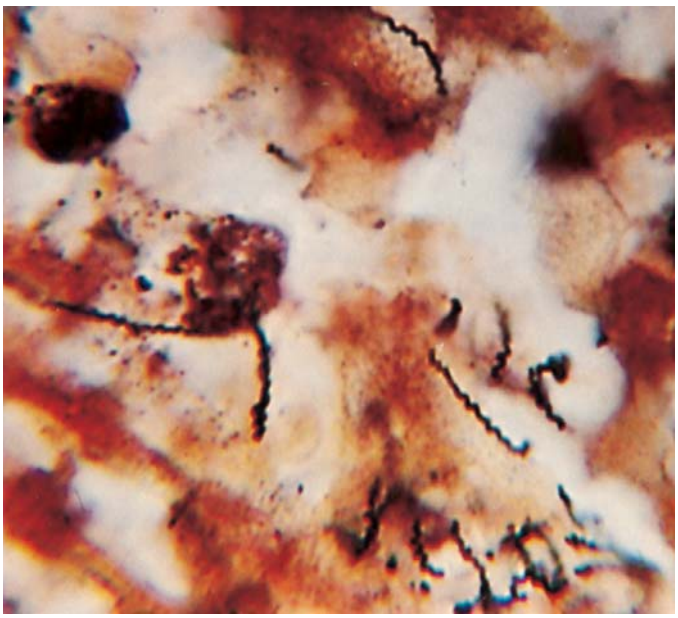

FIGURE 9-33. Syphilis. Spirochetes of *Treponema pallidum,* visualized by silver impregnation, in the eye of a child with congenital syphilis.

The Classical Lesion of Primary Syphilis Is the Chancre

Chancres (Fig. 9-35) are characteristic ulcers at sites of *T. pallidum* entry, usually the penis, vulva, anus or mouth. They appear 1 week to 3 months after exposure, with an average of 3 weeks, and tend to be solitary, with firm raised borders. Spirochetes concentrate in vessel walls and in the epidermis around the ulcer. Chancres, as well as the lesions of the other stages of syphilis, show a characteristic **"luetic vasculitis,"** with endothelial cell proliferation and swelling and vessel walls thickened by lymphocytes and fibrosis.

Chancres quickly erode to characteristic ulcers. They are painless and may go unnoticed especially in the uterine cervix, anal canal and mouth. Chancres last 3–12 weeks, are frequently accompanied by inguinal lymphadenopathy and heal without scarring.

Secondary Syphilis Reflects Dissemination of Spirochetes

In secondary syphilis, *T. pallidum* spreads systemically and proliferates to cause lesions in the skin, mucous membranes, lymph nodes, meninges, stomach and liver. Lesions show

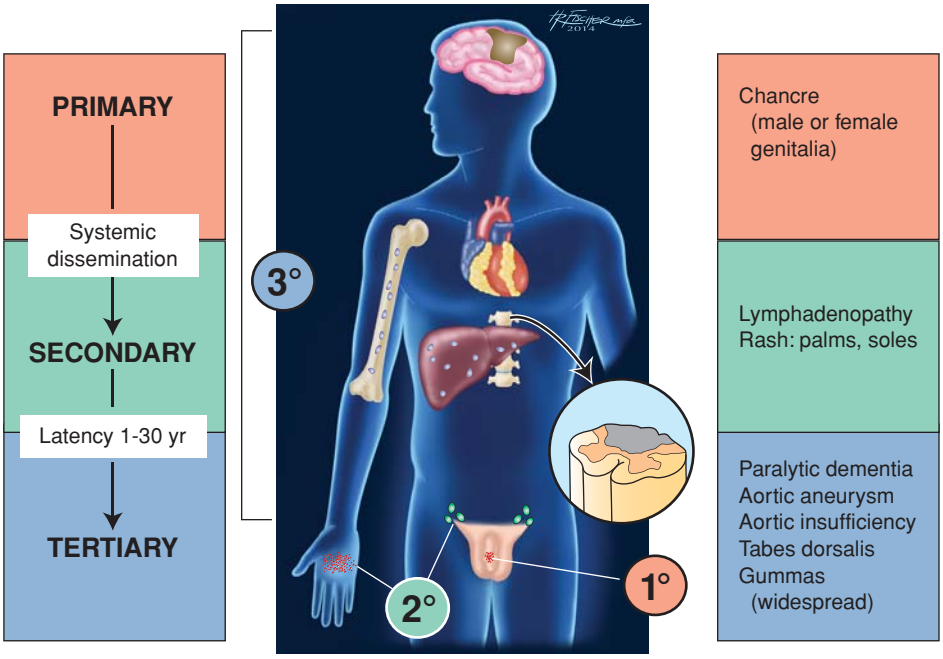

FIGURE 9-34. Clinical characteristics of the various stages of syphilis.

perivascular lymphocytic infiltration and obliterative endarteritis.

- **Skin:** Secondary syphilis most often appears as an erythematous and maculopapular rash of the trunk and extremities, often including the palms (Fig. 9-36) and soles. The rash appears 2 weeks to 3 months after the chancre heals. Other skin lesions in secondary syphilis include **condylomata lata** (exudative plaques in the perineum, vulva or scrotum, which abound in spirochetes) (Fig. 9-37), **follicular syphilids** (small papular lesions around hair follicles that cause loss of hair) and **nummular syphilids** (coin-like lesions of the face and perineum).
- **Mucous membranes:** Lesions on mucosal surfaces of the mouth and genital organs, called **mucous patches,** teem with organisms and are highly infectious.
- **Lymph nodes:** Characteristic changes in lymph nodes, especially epitrochlear nodes, include a thickened capsule, follicular hyperplasia, increased plasma cells and macrophages and luetic vasculitis. Spirochetes are numerous in the lymph nodes of secondary syphilis.
- **Meninges:** Although the meninges are commonly seeded with *T. pallidum,* the condition is frequently asymptomatic.

FIGURE 9-35. Syphilitic chancre. A patient with primary syphilis displays a raised, erythematous penile lesion.

FIGURE 9-36. Secondary syphilis. A maculopapular rash is present on the palm.

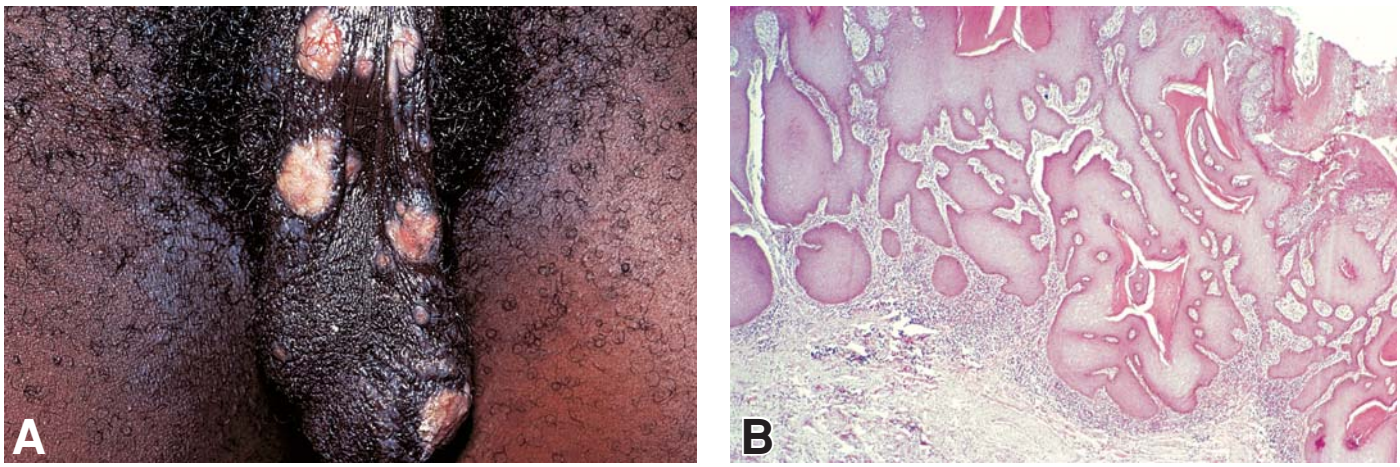

FIGURE 9-37. Condylomata lata in secondary syphilis. A. Whitish plaques are seen on the vulva and perineum. **B.** A photomicrograph shows papillomatous hyperplasia of the epidermis with underlying chronic inflammation.

Tertiary Syphilis Causes Neurologic and Vascular Diseases

After lesions of secondary syphilis subside, an asymptomatic period of years to decades follows. During this time, spirochetes continue to multiply, and the deep-seated lesions of tertiary syphilis gradually develop in one third of untreated patients. ***Focal ischemic necrosis secondary to obliterative endarteritis is the underlying mechanism for many of the processes associated with tertiary syphilis***. *T. pallidum* elicits mononuclear inflammation, mainly of lymphocytes and plasma cells. These cells infiltrate small arteries and arterioles, producing a characteristic obstructive vascular lesion **(endarteritis obliterans)**. Small arteries are inflamed and their endothelial cells are swollen. They are surrounded by concentric layers of proliferating fibroblasts, giving the vascular lesions an "onion skin" appearance.

- **Syphilitic aortitis:** This disorder results from a slowly progressive endarteritis obliterans of vasa vasorum that eventually leads to necrosis of the aortic media, gradual weakening and stretching of the aortic wall and aortic aneurysm. Syphilitic aneurysms are saccular and involve the ascending aorta, which is an unusual site for the much more common atherosclerotic aneurysms. On gross examination, the aortic intima is rough and pitted **(tree-bark appearance;** Fig. 9-38) (see Chapter 16). The aortic media is gradually replaced by scar tissue, after which the aorta loses strength and resilience. The aorta stretches, becoming progressively thinner to the point of rupture, massive hemorrhage and sudden death. ***Damage to, and scarring of, the ascending aorta also commonly leads to dilation of the aortic ring, separation of the valve cusps and regurgitation of blood through the aortic valve (aortic insufficiency).*** Luetic vasculitis may narrow or occlude the coronary arteries and cause myocardial infarction.
- **Neurosyphilis:** The slowly progressive infection damages the meninges, cerebral cortex, spinal cord, cranial nerves or eyes. Tertiary syphilis of the CNS is subclassified according to the predominant tissue affected. Thus, there are **meningovascular syphilis** (meninges), **tabes dorsalis** (spinal cord) and **general paresis** (cerebral cortex) (see Chapter 32).
- **Benign tertiary syphilis:** The appearance of a gumma (Fig. 9-39) in any organ or tissue is the hallmark of benign

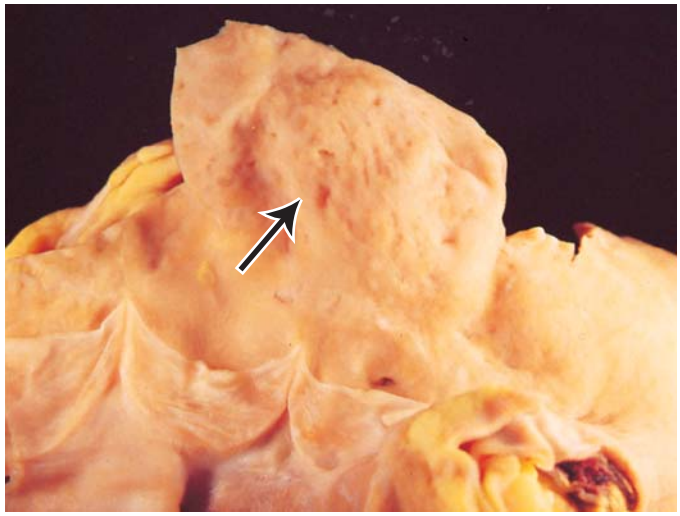

FIGURE 9-38. Syphilitic aortitis. The ascending aorta exhibits a roughened intima (*arrow,* "tree bark" appearance), owing to destruction of the media.

FIGURE 9-39. Syphilitic gumma. A patient with tertiary syphilis shows a sharply circumscribed gumma in the testis, characterized by a fibrogranulomatous wall and a necrotic center.

tertiary syphilis. Gummas are most common in the skin, bone and joints but can occur anywhere. These granulomatous lesions have a central area of coagulative necrosis, epithelioid macrophages, occasional giant cells and peripheral fibrous tissue. Gummas are usually localized lesions that do not significantly damage the patient.

Congenital Syphilis Is Transmitted from an Infected Mother to the Fetus

In this setting, the treponeme disseminates in fetal tissues, which are injured by the proliferating organisms and accompanying inflammatory response. Fetal infection produces stillbirth, neonatal illness or death or progressive postnatal disease.

PATHOLOGY: Lesions of congenital syphilis are identical to those of adult disease. Infected tissues show a chronic inflammatory infiltrate of lymphocytes and plasma cells and endarteritis obliterans. Virtually any tissue can be affected, but the skin, bones, teeth, joints, liver and CNS are characteristically involved (see Chapter 6).

CLINICAL FEATURES: Congenital syphilis presents variably. Infected newborns are often asymptomatic. Early signs of infection include rhinitis **(snuffles)** and a desquamative rash. Infections of periosteum, bone, cartilage and dental pulp produce deformities of bones and teeth, including **saddle nose,** anterior bowing of the legs **(saber shins)** and peg-shaped upper incisor teeth **(Hutchinson teeth)**. Disease progression can be arrested by penicillin.

NONVENEREAL TREPONEMATOSES

In tropical and subtropical climes, there are nonvenereal, chronic diseases caused by treponemes indistinguishable from *T. pallidum.* Like syphilis, they result from inoculation of the organism into mucocutaneous surfaces. They also pass through clearly defined clinical and pathologic stages, including a primary lesion at the site of inoculation, secondary skin eruptions, a latent period and a tertiary late stage.

Yaws Is a Tropical Disease Caused by *Treponema pertenue*

Yaws occurs among poor rural populations in warm, humid areas of tropical Africa, South America, Southeast Asia and Oceania. Children and adolescents in tropical regions are at risk. Transmission is by skin-to-skin contact and is facilitated by breaks or abrasions. Two to 5 weeks after exposure, a single "mother yaw" appears at the site of inoculation, usually on an exposed part. It evolves from a papule to a 2–5-cm "raspberry-like" papilloma. The secondary or disseminated stage begins with the eruption of similar, but smaller, yaws on other parts of the skin. The mother yaw and secondary lesions show hyperkeratosis, papillary acanthosis and an intense neutrophilic infiltrate of the epidermis. The epidermis at the apex of the papilloma lyses to form a shallow ulcer, and plasma cells invade the upper dermis. Spirochetes are numerous in the dermal papillae.

Painful papillomas on the soles of the feet lead patients to walk on the side of their feet like a crab, a condition called **"crab yaw."** Treponemes are borne by the blood to bones, lymph nodes and skin, where they grow during a latent period of 5 or more years. The lesions in the late stage include cutaneous gummas, which are destructive to the face and upper airway. Periostitis of the tibia causes "saber shins" or "boomerang legs." One dose of long-acting penicillin cures yaws.

Bejel Is Characterized by Gummas of the Skin, Airways and Bone

Bejel (also known as "endemic syphilis") has a focal distribution in Africa, western Asia and Australia. It is transmitted from an infected infant to the breast of the mother, from mouth to mouth or from utensils to the mouth. The causative agent, *T. pallidum* subspecies *endemicum,* is morphologically and serologically indistinguishable from the agent of syphilis. Other than on the nursing breast, primary lesions are rare. Secondary lesions in the mouth are identical to the mucosal lesions of syphilis and may spread from the upper airway to the larynx. Lesions of the perineum and bone are encountered, and gummas of the breast occur.

Pinta Is a Tropical Skin Disease

Pinta (from the Spanish for "painted" or "blemish") is a treponematosis (*Treponema carateum*) characterized by variably colored spots on the skin. It was first described in the 16th century in Aztec and Caribbean Amerindians. It is prevalent in remote, arid, inland regions and river valleys of the American tropics. The lesions of the three stages of pinta are limited to the skin and tend to merge. Transmission is by skin-to-skin inoculation, usually after long intimate contact with an infected person. Currently, there are only a few hundred new cases reported each year from endemic areas, but this is probably an underestimate.

LYME DISEASE

Lyme disease is a chronic systemic infection that begins with a characteristic skin lesion and later manifests as cardiac, neurologic or joint disturbances. The causative agents are large, microaerophilic spirochetes belonging to the genus *Borrelia.*

EPIDEMIOLOGY: Lyme disease was first described in patients from Lyme, Connecticut, but has since been recognized in many other areas. *Borrelia burgdorferi* is the major cause of Lyme disease in the United States, while *Borrelia afzelii* and *Borrelia garinii* cause most cases in Europe. The spirochete is transmitted from its animal reservoir to humans by the bite of the minute *Ixodes* tick. This pinhead-sized insect is found in wooded areas, where it usually feeds on mice and deer. Transmission to humans is most likely from May through July, when nymph forms of the tick feed.

In the United States, Lyme disease is the most common tick-borne illness, causing an estimated 15,000–20,000 cases annually. It is concentrated along the eastern seaboard from Maryland to Massachusetts, in the Midwest in Minnesota

and Wisconsin and in the West in California and Oregon. It also occurs in Europe, Australia and Asia.

PATHOLOGY AND CLINICAL FEATURES: *B. burgdorferi* reproduces locally at the site of inoculation, spreads to regional lymph nodes and disseminates throughout the body via the bloodstream. Like other spirochetal diseases, Lyme disease is chronic, occurring in stages, with remissions and exacerbations. In patients who die of the disease, organisms are seen at autopsy in virtually every organ affected, including the skin, myocardium, liver, CNS and musculoskeletal system.

Three clinical stages are described:

- **Stage 1:** The characteristic skin lesion, **erythema chronicum migrans,** appears at the site of the tick bite. It begins 3–35 days after the bite as an erythematous macule or papule, which grows into an erythematous patch 3–7 cm in diameter. It often is intensely red at its periphery, with some central clearing, imparting an annular appearance. Studies of skin and synovium have shown that *B. burgdorferi* elicits a chronic inflammatory infiltrate, composed of lymphocytes and plasma cells. It is accompanied by fever, fatigue, headache, arthralgias and regional lymphadenopathy. Secondary annular skin lesions develop in about half of patients and may persist for long periods. During this phase, patients experience constant malaise and fatigue, headache and fever. Intermittent manifestations may also include meningeal irritation, migratory myalgia, cough, generalized lymphadenopathy and testicular swelling.
- **Stage 2:** The second stage begins weeks to months after the skin lesion and is characterized by exacerbation of migratory musculoskeletal pains and cardiac and neurologic abnormalities. In 10% of cases, conduction abnormalities, particularly atrioventricular block, result from myocarditis. Neurologic abnormalities, most commonly meningitis and facial nerve palsies, occur in 15% of patients.
- **Stage 3:** The third stage of Lyme disease begins months to years afterward, with joint, skin and neurologic abnormalities. Over half of these patients have arthralgia and severe arthritis of the large joints, especially the knee. The histopathology of affected joints is virtually indistinguishable from that of rheumatoid arthritis, including villous hypertrophy and a conspicuous mononuclear infiltrate in the subsynovial lining area.

Neurologic manifestations may begin months to years after disease begins. They range from intermittent tingling paresthesias without demonstrable neurologic deficits to slowly progressive encephalomyelitis, transverse myelitis, organic brain syndromes and dementia.

Distinctive late skin manifestations of Lyme disease include acrodermatitis chronica atrophicans. This occurs years after erythema chronicum migrans and presents as patchy atrophy and sclerosis of the skin.

Antibody titers (initially IgM, later IgG) against the organism are the most practical way to establish the diagnosis. Treatment with tetracycline or erythromycin is effective in eliminating early Lyme disease. In later stages, and when there are extensive extracutaneous manifestations, high doses of intravenous penicillin or other combinations of antibiotic regimens for long periods are necessary.

Leptospirosis

Leptospirosis is an infection with spirochetes of the genus *Leptospira.* Usually (90% of patients) leptospirosis is a mild, self-limited, febrile disease. More severe infections may entail hepatic and renal failure, which may prove fatal.

EPIDEMIOLOGY: Leptospirosis is a worldwide zoonosis. Leptospires penetrate abraded skin or mucous membranes following contact with infected rats, contaminated water or mud. Since warm, moist environments favor survival of the spirochetes, the incidence is higher in the tropics. Between 30 and 100 cases are reported annually in the United States, some of them in slaughterhouse workers and trappers, but recently some cases occurred among destitute people in urban areas.

PATHOLOGY AND CLINICAL FEATURES: The symptoms of leptospirosis begin 4 days to 3 weeks after exposure to *Leptospira interrogans.* In most cases, the disease resolves within a week without sequelae. In more severe infections, leptospirosis is a biphasic disease.

- In the **leptospiremic phase,** leptospires are present in the blood and cerebrospinal fluid. There is an abrupt onset of fever, shaking chills, headache and myalgias. Symptoms abate after 1–2 weeks, as the leptospires disappear from the blood and bodily fluids.
- The **immune phase** begins within 3 days of the end of the leptospiremic phase and is accompanied by the production of IgM antibodies. The earlier symptoms recur, and signs of meningeal irritation become apparent. At this time, the cerebrospinal fluid shows a prominent pleocytosis. In severe cases, jaundice appears and may be followed by hepatic and renal failure and the appearance of widespread hemorrhages and shock. This severe form of leptospirosis has historically been referred to as **Weil disease**.

Untreated Weil disease has a mortality rate of 5%–30%. At autopsy tissues are bile stained, and hemorrhages are seen in many organs. The principal lesion is a diffuse vasculitis with capillary injury. Livers show dissociation of liver cell plates, erythrophagocytosis by Kupffer cells, minimal necrosis of hepatocytes, neutrophils in the sinusoids and a mixed inflammatory cell infiltrate in portal tracts. Renal tubules are swollen and necrotic. Spirochetes are numerous in tubular lumina, and particularly in bile-stained casts (Fig. 9-40).

RELAPSING FEVER

Relapsing fever is an acute, febrile, septicemic illness caused by spirochetes of the genus *Borrelia.* There are two main types of relapsing fever:

- **Epidemic relapsing fever** is caused by *Borrelia recurrentis* and is transmitted by the bite of an infected louse. Humans are the only reservoir.
- **Endemic relapsing fever** is produced by a number of *Borrelia* species and is transferred from rodents and other animals by the bite of an infected tick.

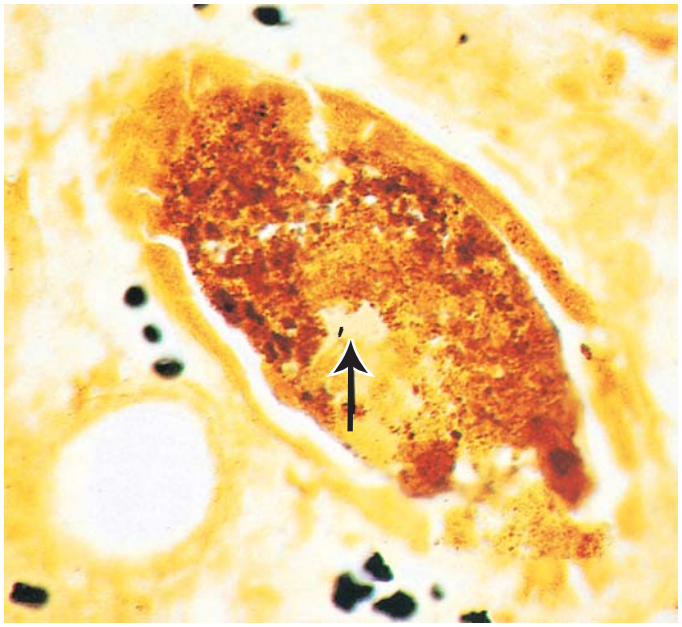

FIGURE 9-40. Leptospirosis. A distal renal tubule is obstructed by a bile-stained mass of hemoglobin and cellular debris. A leptospire (*arrow*) is in the center of this mass.

EPIDEMIOLOGY: The human body louse, *Pediculus humanus humanus,* becomes infected with *B. recurrentis* when it feeds on an infected person. The spirochetes only enter a subsequent person if the louse is crushed when feeding. War, crowded migrant worker camps and heavy clothing during cold weather all favor mobilization of lice and the spread of relapsing fever. Lice also dislike the higher temperatures of feverish victims and seek new hosts, another factor in the rapid spread of relapsing fever during epidemics. Louse-borne relapsing fever is currently seen in several African countries, especially Ethiopia and Sudan, and also in the South American Andes.

In endemic, tick-borne relapsing fever, the insects are infected while biting rats and other hosts. Humans are infected by saliva or coxal fluid of the tick. Ticks live much longer than lice and may harbor spirochetes for 12–15 years without a blood meal. Tick-borne relapsing fever occurs sporadically worldwide.

PATHOLOGY: In fatal infections, the spleen is enlarged and contains miliary microabscesses. Spirochetes form tangled aggregates around the necrotic centers. Lymphocytes and neutrophils infiltrate central and midzonal areas of the liver, where spirochetes lie free in the sinusoids. Focal hemorrhages involve many organs.

CLINICAL FEATURES: Arthralgias, lethargy, fever, headache and myalgias appear within 1–2 weeks of a bite of an infected arthropod. The liver and spleen enlarge, and there are petechiae of the skin, conjunctival hemorrhages and abdominal tenderness. The fever ends abruptly within 3–9 days, only to begin anew 7–10 days later. During the afebrile period, spirochetes disappear from the blood and change their antigenic coats. With each relapse, symptoms are milder and the illness shorter. In severe cases, the initial episode may be characterized by a rash, meningitis, myocarditis, liver failure and coma. Tetracycline is an effective treatment for both types of relapsing fever.

FUSOSPIROCHETAL INFECTIONS

Tropical Phagedenic Ulcer Is a Painful Lesion of the Leg

Tropical phagedenic (rapid spreading and sloughing) ulcer, also known as **tropical foot,** is a painful, necrotizing lesion of the skin and subcutaneous tissues of the leg that afflicts people in tropical climates. *Bacillus fusiformis* and *Treponema vincentii* are two causes. Malnutrition may predispose to infection.

CLINICAL FEATURES: The lesion usually starts on the skin at a point of trauma and develops rapidly. The surface sloughs to form an ulcer with raised borders and a cup-shaped crater, which contains a gray, putrid exudate (Fig. 9-41). The ulcer may be so deep that the underlying bone and tendons are exposed. The margin becomes fibrotic, but complete healing may be delayed for years. In addition to secondary infection, tibial osteomyelitis and squamous cell carcinoma may be late complications. Antibiotics may be effective, but reconstructive plastic surgery is often necessary to close the defect.

Noma Is a Destructive Lesion of the Face

Noma (gangrenous stomatitis, cancrum oris) is a rapidly progressive necrosis of soft tissues and bones of the mouth and face. Less commonly, it involves other sites, such as the chest, limbs and genitalia. It afflicts malnourished children in the tropics, many of whom are further debilitated by recent infections (e.g., measles, malaria, leishmaniasis). *T. vincentii, B. fusiformis, Bacteroides* spp. and *Corynebacterium* spp. tend to predominate in these lesions.

CLINICAL FEATURES: The ulcer is destructive, disfiguring and usually unilateral (Fig. 9-42). Initially it is a small papule, often on the cheek opposite the molars or premolars. Large malodorous defects quickly develop. The lesions are painful and advanced ulcers

FIGURE 9-41. Tropical phagedenic ulcer caused by infection by fusospirochetal organisms, following penetrating trauma.

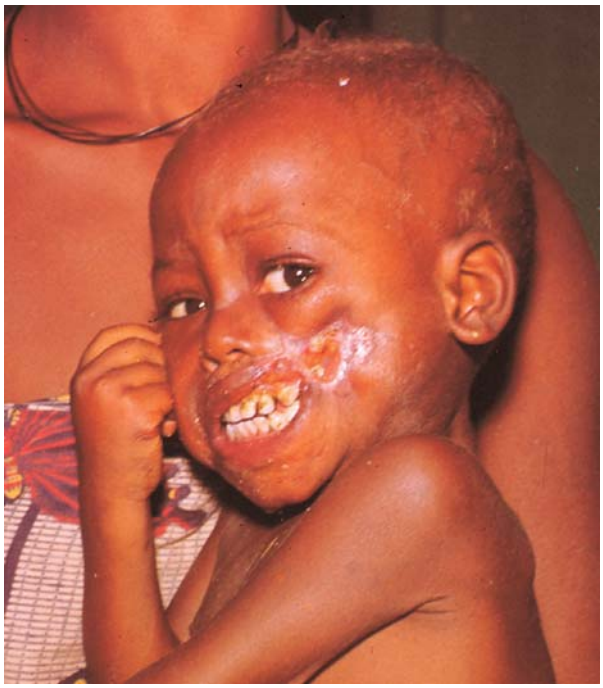

FIGURE 9-42. Noma. There is massive destruction of the soft tissues and bones of the mouth and cheek.

reveal necrosis of skin, muscle and adipose tissue, with exposure of underlying bone. Without treatment, patients usually die. Antibiotics are helpful, but reconstructive surgery is often required.

Chlamydial Infections

Chlamydiae are obligate intracellular parasites that are smaller than most other bacteria. They cannot make adenosine triphosphate (ATP), and so must parasitize the metabolic machinery of a host cell to reproduce. The life cycle involves two morphologic forms. The **elementary body** is the smaller, metabolically inactive form, which survives extracellularly. It attaches to the appropriate host cell and induces endocytosis, forming a vacuole. It then transforms into the larger, metabolically active form, the **reticulate body,** which commandeers host cell metabolism to fuel chlamydial replication. The reticulate body divides repeatedly, forming daughter elementary bodies and destroying the host cell. Necrotic debris elicits inflammatory and immunologic responses that further damage infected tissue.

Chlamydial infections are widespread among birds and mammals, and as many as 20% of humans are infected. Three species of chlamydiae (*Chlamydia trachomatis, Chlamydia psittaci* and *Chlamydia pneumoniae*) cause human infection.

CHLAMYDIA TRACHOMATIS INFECTION

C. trachomatis contains a variety of strains (serovars), which cause three distinct types of disease: (1) genital and neonatal disease, (2) lymphogranuloma venereum and (3) trachoma.

Infections with *Chlamydia trachomatis* Are among the Most Common Sexually Transmitted Diseases

C. trachomatis serovars D through K cause genital epithelial infections that are the most common sexually contracted disease in North America. In men, they produce urethritis and sometimes epididymitis or proctitis. In women, infection usually begins with cervicitis, which can progress to endometritis, salpingitis and generalized infection of the pelvic adnexal organs (pelvic inflammatory disease). Repeated episodes of salpingitis are associated with scarring, which can lead to infertility or ectopic pregnancy. Perinatal transmission of *C. trachomatis* causes neonatal conjunctivitis and pneumonia.

EPIDEMIOLOGY: The organism spreads in genital secretions. Infection is chronic and frequently asymptomatic, providing an enormous reservoir for transmission. As with all sexually transmitted diseases, people with the largest number of sexual partners are at greatest risk of infection. Newborns acquire the organism by contact with infected endocervical secretions on passage through the birth canal. Two thirds of exposed newborns develop *C. trachomatis* conjunctivitis.

PATHOLOGY: Chlamydial infection elicits an infiltrate of neutrophils and lymphocytes. Lymphoid aggregates, with or without germinal centers, may appear at the site of infection. In newborns, the conjunctival epithelium often contains characteristic vacuolar cytoplasmic inclusions and the disease is frequently called **inclusion conjunctivitis**.

CLINICAL FEATURES: Most genital infections are asymptomatic. In men, clinically apparent infection presents as a purulent penile discharge, with dysuria and urinary urgency. Chlamydial cervicitis causes a mucopurulent drainage from the cervical os. Chlamydial disease in the newborn presents as reddened conjunctivae with a watery or purulent discharge. Untreated neonatal conjunctivitis is potentially serious, although it may resolve without sequelae. Chlamydial pneumonia manifests in the second or third month with tachypnea and paroxysmal cough, usually without fever. Inclusion conjunctivitis is treated with systemic or topical antibiotics.

Lymphogranuloma Venereum Is a Sexually Transmitted Disease That Causes Necrotizing Lymphadenitis

Lymphogranuloma venereum (LGV) begins as a genital ulcer, spreads to lymph nodes (Fig. 9-43A) and may cause local scarring. It is caused by *C. trachomatis* serovars L1 to L3.

EPIDEMIOLOGY: LGV is uncommon in developed countries but is endemic in the tropics and subtropics. It accounts for 5% of sexually transmitted disease in Africa, India, parts of southeast Asia, South America and the Caribbean. Since 2003, LGV has been increasingly reported from developed countries. Large outbreaks, primarily in men who have sex with men, have occurred, especially in New York City and the United Kingdom. In these outbreaks the disease has presented

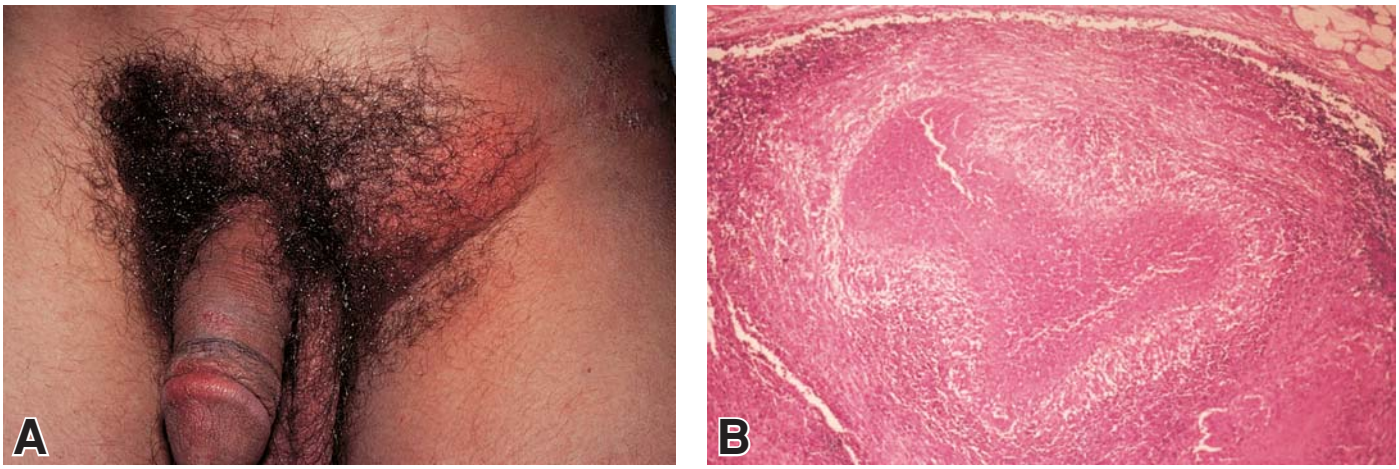

FIGURE 9-43. Lymphogranuloma venereum. A. Painful inguinal lymphadenopathy in a man infected with *Chlamydia trachomatis.* **B.** Microscopic section of a lymph node shows a necrotic central area surrounded by a granulomatous zone.

mostly as proctitis, and the majority of men were HIV coinfected (up to 75%).

PATHOLOGY: The organism is introduced through a break in the skin. After incubation for 4–21 days, an ulcer appears, usually on the penis, vagina or cervix, although the lips, tongue and fingers may also be primary sites. The organisms are transported by lymphatics to regional lymph nodes, where a **necrotizing lymphadenitis** with abscesses erupts 1–3 weeks after the primary lesion. The nodes become tender and fluctuant and frequently ulcerate and discharge pus. The intense inflammation can cause severe scarring, leading to chronic lymphatic obstruction, ischemic necrosis of overlying structures or strictures and adhesions. Enlarged and matted lymph nodes result, containing multiple, coalescing abscesses, which often develop a stellate shape (Fig. 9-43B). Abscesses have neutrophils and necrotic debris in the center, surrounded by palisading epithelioid cells, macrophages and occasional giant cells. There is a rim of lymphocytes, plasma cells and fibrous tissue.

CLINICAL FEATURES: Patients with lymphogranuloma venereum present with lymphadenopathy. Most infections resolve completely, even without antimicrobial therapy. However, progressive ulceration of the penis, urethra or scrotum, with fistulas and urethral stricture, develops in 5% of men. Women and men who have sex with men often present with hemorrhagic proctitis, and most late complications, such as rectal stricture, rectovaginal fistulas and genital elephantiasis, occur in women.

Trachoma Is a Leading Cause of Blindness in Many Developing Countries

Trachoma is a chronic infection that causes progressive scars of the conjunctiva and cornea. *C. trachomatis* serovars A, B, Ba and C cause the disease.

EPIDEMIOLOGY: Trachoma is worldwide, associated with poverty and most prevalent in dry or sandy regions. Only humans are naturally infected, and poor personal hygiene and inadequate public sanitation are common factors. Trachoma remains a major problem in parts of Africa, India and the Middle East. It is spread mostly by direct contact but may also be transmitted by fomites, contaminated water and probably flies. Subclinical infections are an important reservoir. In endemic areas, infection is acquired early in childhood, becomes chronic and eventually progresses to blindness.

PATHOLOGY: When *C. trachomatis* is inoculated into the eye, it reproduces in the conjunctival epithelium, inciting a mixed acute and chronic inflammatory infiltrate. Histologic examination of early lesions shows chronic inflammation, lymphoid aggregates, focal degeneration and chlamydial inclusions in the conjunctiva. As trachoma progresses, lymphoid aggregates enlarge, and the conjunctiva becomes scarred and focally hypertrophic. The cornea is invaded by blood vessels and fibroblasts, forming a scar reminiscent of a cloth (*pannus* in Latin) and is eventually opacified (see Chapter 33).

CLINICAL FEATURES: Early trachoma is characterized by the abrupt onset of palpebral and conjunctival inflammation, leading to tearing, purulent conjunctivitis and photophobia. The lymphoid aggregates appear as small yellow grains beneath the palpebral conjunctivae within 3–4 weeks. After months or years, eyelid deformities eventually interfere with normal ocular function, and secondary bacterial infections and corneal ulcers are common. Blindness is a common endpoint.

PSITTACOSIS (ORNITHOSIS)

Psittacosis is a self-limited pneumonia transmitted to humans from birds. The causative agent, *C. psittaci*, is spread by infected birds. The resulting disease is known as both psittacosis (association with parrots) and ornithosis (contact with birds in general).

EPIDEMIOLOGY: *C. psittaci* is present in the blood, tissues, excreta and feathers of infected birds. Humans inhale infectious excreta or dust from feathers. Infection is endemic in tropical birds, but *C. psittaci* can

infect almost any species and can spread to humans from any bird. Use of tetracycline-containing bird feeds and quarantine of imported tropical birds limit the spread of disease, and fewer than 50 cases are reported annually in the United States.

PATHOLOGY: *C. psittaci* first infects pulmonary macrophages, which carry the organism to the phagocytes of the liver and spleen, where it reproduces. It then spreads via the bloodstream, producing systemic infection, with particularly diffuse involvement of the lungs. *C. psittaci* reproduces in alveolar lining cells, whose destruction elicits an inflammatory response. The pneumonia is predominantly interstitial, with an interstitial lymphocytic inflammatory infiltrate. Dissemination of the infection is characterized by foci of necrosis in the liver and spleen and diffuse mononuclear cell infiltrates in the heart, kidneys and brain.

CLINICAL FEATURES: The spectrum of clinical illness varies widely. There is usually a persistent dry cough, with constitutional symptoms of high fever, headache, malaise, myalgias and arthralgias. Untreated, fever persists for 2–3 weeks, then subsides as pulmonary disease regresses. With tetracycline therapy, the disease is rarely fatal.

CHLAMYDIA PNEUMONIAE

C. pneumoniae is a cause of acute, self-limited, usually mild respiratory tract infections, including pneumonia. It is transmitted from person to person, and infection appears to be very common. In the developed world, half of all adults show evidence of past exposure, but only 10% of infections cause clinical pneumonia. Symptoms include fever, sore throat and cough. Severe pneumonia occurs only if there is an underlying pulmonary condition. Untreated disease usually resolves in 2–4 weeks.

Rickettsial Infections

The rickettsiae are small, gram-negative coccobacillary bacteria that are obligate intracellular pathogens and cannot replicate outside a host. Unlike chlamydiae, rickettsiae replicate by binary fission. They synthesize their own ATP and can obtain ATP from the host. The organisms induce endocytosis by target cells and replicate in their cytoplasm. Rickettsiae have cell wall structures like gram-negative bacteria, but do not stain well with the Gram stain. They are best demonstrated by the Gimenez method or with acridine orange.

Humans are accidental hosts for most species of *Rickettsia*. The organisms reside in animals and insects and do not require humans for perpetuation. Human infections result from insect bites. Several species of *Rickettsia* cause different human diseases (Table 9-6) that share many common features. ***In humans, the target cells for all rickettsiae are capillary and small vessel endothelial cells.*** The organisms reproduce within these cells, killing them in the process and producing a necrotizing vasculitis. Human rickettsial infections are traditionally divided into the **"spotted fever group"** and the **"typhus group."**

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever is an acute, potentially fatal, systemic vasculitis that is usually attended by headache, fever and rash. The causative organism, *Rickettsia rickettsii*, is transmitted to humans by tick bites.

TABLE 9-6
RICKETTSIAL INFECTIONS

Disease	Organism	Distribution	Transmission
Spotted-Fever Group (genus *Rickettsia*)			
Rocky Mountain spotted fever	*R. rickettsii*	Americas	Ticks
Queensland tick fever	*R. australis*	Australia	Ticks
Boutonneuse fever, Kenya tick fever	*R. conorii*	Mediterranean, Africa, India	Ticks
Siberian tick fever	*R. sibirica*	Siberia, Mongolia	Ticks
Rickettsialpox	*R. akari*	United States, Russia, Central Asia, Korea, Africa	Mites
Flea-borne spotted fever	*R. felis*	North and South America, Europe, Australia	Ticks
Typhus Group			
Louse-borne typhus (epidemic typhus)	*R. prowazekii*	Latin America, Africa, Asia	Lice
Murine typhus (endemic typhus)	*R. typhi*	Worldwide	Fleas
Scrub typhus	*Orientia tsutsugamushi*	South Pacific, Asia	Mites
Q fever	*Coxiella brunetti*	Worldwide	Inhalation

EPIDEMIOLOGY: Rocky Mountain spotted fever is acquired by bites of infected ticks, which are the vectors for *R. rickettsii.* The organism is transmitted from mother to progeny ticks, thereby maintaining a natural reservoir for human infection. Rocky Mountain spotted fever occurs in various areas throughout North, Central and South America. About 500 cases occur annually in the eastern United States. Its name derives from its discovery in Idaho, but the disease is uncommon in the Rocky Mountain region.

PATHOPHYSIOLOGY: *R. rickettsii* in salivary glands of ticks are introduced into the skin as the ticks feed. Organisms spread via lymphatics and small blood vessels to the systemic and pulmonary circulation. They enter vascular endothelial cells, reproduce in the cytoplasm and are then shed into the vascular and lymphatic systems. Further infection and destruction of vascular endothelium causes a systemic vasculitis. The rash, produced by inflammatory damage to cutaneous vessels, is the most visible manifestation of the generalized vascular injury. Other rickettsiae infect only capillary endothelial cells, but *R. rickettsii* spreads to vascular smooth muscle and endothelium of larger vessels. Extensive damage to blood vessel walls causes loss of vascular integrity, fluid exudation and disseminated intravascular coagulation. Fluid loss can be so extensive as to lead to shock. Damage to pulmonary capillaries can produce pulmonary edema and acute alveolar injury.

PATHOLOGY: The vascular lesions of Rocky Mountain spotted fever are seen throughout the body, affecting capillaries, venules, arterioles and sometimes larger vessels. Necrosis and reactive hyperplasia of vascular endothelium are often associated with thrombosis of small-caliber vessels. Vessel walls are infiltrated, initially with neutrophils and macrophages and later by lymphocytes and plasma cells. Microscopic infarcts and extravasation of blood into surrounding tissues are common. The orientation of the intracellular bacilli in parallel rows and in an end-to-end pattern gives them the appearance of a "flotilla at anchor facing the wind."

CLINICAL FEATURES: Rocky Mountain spotted fever manifests with fever, headache and myalgias, followed by a rash. Skin lesions begin as a maculopapular eruption but rapidly become petechial, spreading centripetally from the distal extremities to the trunk (Fig. 9-44). Cutaneous lesions usually appear on the palms and soles, a distinctive feature of the disease. If untreated, more than 20%–50% of infected people die within 8–15 days. Prompt diagnosis and antibiotic treatment (chloramphenicol and tetracycline) is life saving; mortality in the United States is less than 5%.

FIGURE 9-44. Rocky mountain spotted fever. A severe petechial and purpuric eruption is noted on the arm in this fatal case.

EPIDEMIC (LOUSE-BORNE) TYPHUS

Epidemic typhus is a severe systemic vasculitis transmitted by bites of infected lice. It is caused by *Rickettsia prowazekii,* an organism that has a human–louse–human life cycle (Fig. 9-45).

EPIDEMIOLOGY: The disease is widely distributed in some regions of Africa, Asia, Europe and the Western Hemisphere. Devastating epidemics of typhus were associated with cold climates, poor sanitation and crowding during natural disasters, famine or war. Infrequent bathing and lack of changes of clothing lead to louse infestation of human populations and consequently epidemics of typhus. Mass displacements of populations in Eastern Europe in World War I led to epidemic typhus, which affected 30 million people and killed 3 million. Epidemic louse-borne typhus last occurred in the United States in 1921.

PATHOPHYSIOLOGY: After a louse takes blood from someone infected with *R. prowazekii,* large numbers of rickettsiae contaminate louse feces. These are deposited on the skin or clothing of a second host and may remain infectious for more than 3 months. Human infection begins when contaminated louse feces penetrate an abrasion or scratch, or when the person inhales airborne rickettsiae from clothing containing louse feces. Epidemic typhus begins as a localized infection of capillary endothelium and progresses to a systemic vasculitis. Louse-borne typhus differs from other rickettsial diseases in that *R. prowazekii* can establish latent infection and produce recrudescent disease (Brill-Zinsser disease) many years after primary infection.

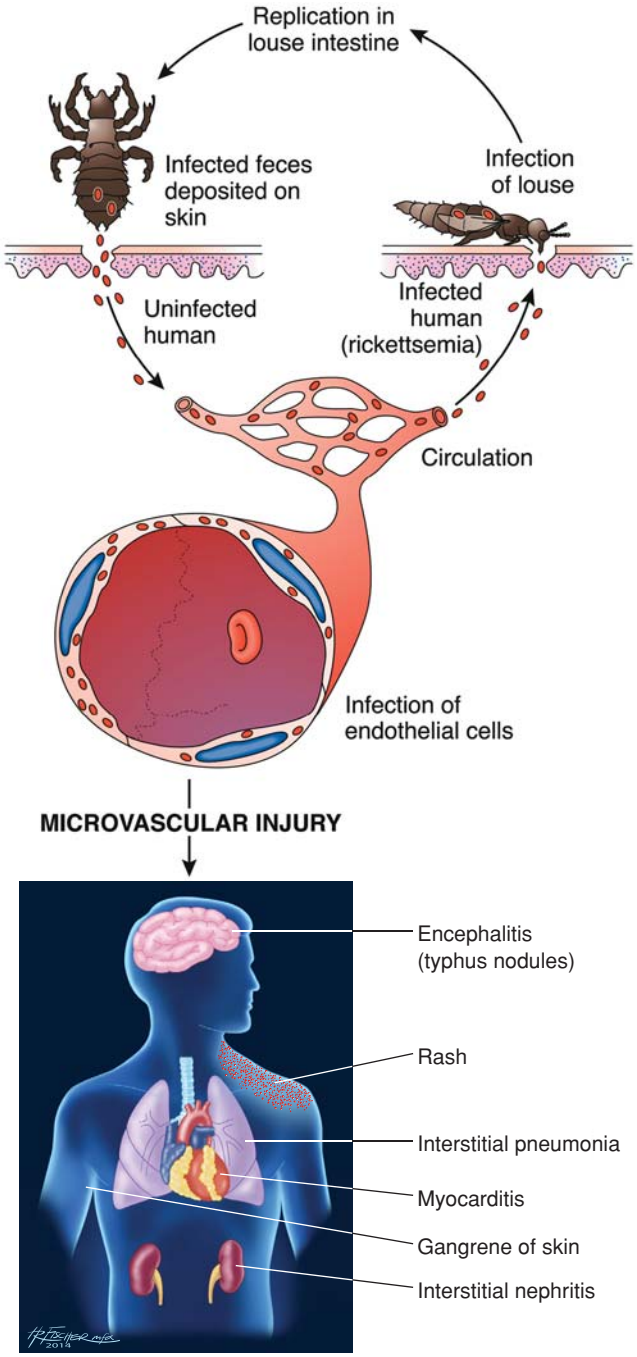

FIGURE 9-45. Epidemic typhus (louse-borne typhus). *Rickettsia prowazekii* has a man–louse–man life cycle. The organism multiplies in endothelial cells, which detach, rupture and release organisms into the circulation (rickettsemia). A louse taking a blood meal becomes infected with rickettsiae, which enter the epithelial cells of its midgut, multiply and rupture the cells, thereby releasing rickettsiae into the lumen of the louse intestine. Contaminated feces are deposited on the skin or clothing of a second host, penetrate an abrasion or are inhaled. The rickettsiae then enter endothelial cells, multiply and rupture the cells, thus completing the cycle.

PATHOLOGY: The pathologic findings produced by *R. prowazekii* are similar to those in Rocky Mountain spotted fever and other rickettsial diseases. At autopsy, there are few gross findings except for splenomegaly and occasional areas of necrosis. Collections of mononuclear cells are found in various organs (e.g., skin, brain and heart). The infiltrate includes mast cells, lymphocytes, plasma cells and macrophages, frequently arranged as **typhus nodules** around arterioles and capillaries. Throughout the body, the endothelium of small blood vessels is focally necrotic and hyperplastic, and the walls contain inflammatory cells. Rickettsiae can be demonstrated within the endothelial cells.

CLINICAL FEATURES: Symptoms of louse-borne typhus are fever, headache and myalgias, followed by a rash. Macular lesions, which become petechial, appear on the upper trunk and axillary folds and spread centrifugally to the extremities. In fatal cases, the rash commonly becomes confluent and purpuric. Mild rickettsial pneumonia may precede a bacterial pneumonia. Dying patients may exhibit the symptoms of encephalitis, myocarditis, interstitial pneumonia, interstitial nephritis and shock. Fatalities usually occur during the second or third week of illness. In patients who recover, the symptoms abate after about 3 weeks.

Epidemic typhus can be controlled by large-scale delousing of the population, steam sterilization of clothing and use of insecticides. Prompt treatment with azithromycin or other broad-spectrum antibiotics is curative.

ENDEMIC (MURINE) TYPHUS

Endemic typhus is similar to epidemic typhus but tends to be milder. Humans are infected with *Rickettsia typhi,* interrupting the rat–flea–rat cycle of transmission. Contaminated flea feces on the skin may enter the body via the small wound made by the bite. *R. typhi* may also contaminate clothes and become airborne. If inhaled, they cause pulmonary infection. Outbreaks of murine typhus are associated with an exploding population of rats, although sporadic infections occur in the southwestern United States. These are associated with rat-infested dwellings and with occupations that bring humans into contact with rats, such as the handling and storage of grain.

SCRUB TYPHUS

Scrub typhus **(Tsutsugamushi fever)** is an acute, febrile illness of humans caused by *Orientia tsutsugamushi,* the only member of its genus. It was previously designated *Rickettsia tsutsugamushi.* Rodents are the natural mammalian reservoir, from which the organism is passed to trombiculid mites known as chiggers. These insects transmit infection to their larvae, which crawl to the tips of vegetation and attach to passersby. While feeding, mites inoculate the organisms into the skin. Rickettsemia and lymphadenopathy follow shortly. Scrub typhus is widely distributed in eastern and southern Asia and the islands of the southern and western Pacific, including Japan. Endemic infection is unknown in the Western world.

A multiloculated vesicle forms at the inoculation site and ulcerates, followed by an eschar. As the lesion heals, headache and fever appear suddenly, followed by pneumonia, a macular rash, lymphadenopathy and hepatosplenomegaly. Severe infections are complicated by myocarditis, meningoencephalitis and shock. Mortality rates in untreated patients have ranged up to 30%.

Q FEVER

Q fever is a self-limited, systemic infection, usually manifesting as headache, fever and myalgias. The disease is caused by *Coxiella burnetii*, a small pleomorphic coccobacillus with a gram-negative cell wall. Unlike true rickettsiae, *C. burnetii* enters cells passively upon phagocytosis by macrophages. It does not produce a vasculitis, so there is no associated rash.

EPIDEMIOLOGY: Humans acquire Q fever by exposure to infected animals or animal products. Infection is endemic in many wild and domesticated animals, but cattle, sheep and goats are the usual sources of human infection. These animals shed large numbers of organisms in urine, feces, milk, bodily fluids and birth products. Q fever is most often seen in herders, slaughterhouse workers, veterinarians, dairy workers and others with occupational exposure to infected domesticated animals. Aerosol droplets may spread infection from person to person. Q fever is rare in the United States.

PATHOLOGY: Q fever begins with inhalation of organisms, which are phagocytosed by alveolar macrophages and replicate in phagolysosomes. Recruitment of neutrophils and macrophages produces a focal bronchopneumonia. The nonactivated phagocytes fail to kill *C. burnetii*, and the organism disseminates through the body, primarily infecting monocytes/macrophages. Most infections resolve with the onset of specific cell-mediated immunity, but occasional cases persist as chronic infections.

The lungs and liver are most prominently involved in Q fever. The lungs show single or multiple irregular areas of consolidation, in which the pulmonary parenchyma is infiltrated by neutrophils and macrophages. Organisms may be demonstrated in macrophages by the Giemsa stain. In the liver, Q fever is usually characterized by multiple microscopic granulomas with a distinctive "fibrin ring." In these granulomas epithelioid macrophages encircle a ring of fibrin, sometimes containing a lipid vacuole.

CLINICAL FEATURES: Q fever is usually a self-limited mildly symptomatic febrile disease. More-severe cases may present with headache, fever, fatigue and myalgias, with no rash. Pulmonary infection is virtually always present, but it may appear as an atypical pneumonia with dry cough, a rapidly progressive pneumonia or chest roentgenographic abnormalities without significant respiratory symptoms. Many patients have some hepatosplenomegaly. Q fever usually resolves spontaneously in 2–14 days.

Mycoplasmal Infections

At less than 0.3 µm in greatest dimension, mycoplasmas are the smallest free-living **prokaryotes**. They lack the rigid cell walls of more complex bacteria. Mycoplasmas are widespread, geographically and ecologically, as saprophytes and as parasites of many animals and plants. Many *Mycoplasma* species inhabit the human body, but only three are pathogenic: *Mycoplasma pneumoniae*, *Mycoplasma hominis* and *Ureaplasma urealyticum*. The diseases associated with these organisms are shown in Table 9-7.

TABLE 9-7
MYCOPLASMAL INFECTIONS

Organism	Disease
Mycoplasma pneumoniae	Tracheobronchitis Pneumonia Pharyngitis Otitis media
Ureaplasma urealyticum	Urethritis Chorioamnionitis Postpartum fever
Mycoplasma hominis	Postpartum fever

M. pneumoniae *produces acute, self-limited lower respiratory tract infections, affecting mostly children and young adults.* It can also cause pharyngitis and otitis media.

EPIDEMIOLOGY: Most infections occur in small groups of people who have frequent close contact (e.g., families, college fraternities, military units). The organism is spread by aerosol from person to person over several months, with an attack rate exceeding 50% within the group. *M. pneumoniae* infection occurs worldwide, and in developed countries, the organism causes 15%–20% of all pneumonias.

PATHOPHYSIOLOGY: *M. pneumoniae* initiates infection by attaching to a glycolipid on the surface of the respiratory epithelium. The agent remains outside the cells, where it reproduces and causes progressive dysfunction and eventual death of host cells. Because *M. pneumoniae* infection rarely produces symptomatic disease in children younger than the age of 5 years, it is thought that the host immune response plays a role in tissue injury.

PATHOLOGY: Pneumonia caused by *M. pneumoniae* usually shows patchy consolidation of a single segment of a lower lung lobe, although the process can be more widespread. The mucosa of affected airways is edematous and infiltrated by a mostly mononuclear inflammatory infiltrate. Alveoli show a largely interstitial process, with reactive alveolar lining cells and mononuclear infiltration. Pulmonary changes are often complicated by bacterial superinfection. The organism itself is too small to be seen by routine light microscopy.

CLINICAL FEATURES: *Mycoplasma* pneumonia tends to be milder than other bacterial pneumonias and is sometimes called "walking pneumonia." Fever rarely lasts more than 2 weeks, although cough may linger for 6 weeks or more. Death from *M. pneumoniae*

infection is rare. However, life-threatening cases of Stevens-Johnson syndrome have been linked to mycoplasma infection.

Mycobacterial Infections

Mycobacteria are distinctive organisms, 2–10 μm in length, with cell wall architecture like that of gram-positive bacteria, but also containing large amounts of lipid. The high lipid content interferes with staining by aniline dyes, including crystal violet used in the Gram stain. Thus, although mycobacteria are structurally gram-positive, this property is difficult to demonstrate by routine staining. ***The waxy lipids of the cell wall make the mycobacteria "acid fast" (i.e., they retain carbolfuchsin after rinsing with acid alcohol).***

Mycobacteria grow more slowly than other pathogenic bacteria, and their diseases are chronic, slowly progressive illnesses. They produce no known toxins but damage human tissues by inducing inflammatory and immune responses. Most mycobacterial pathogens replicate within cells of the monocyte/macrophage lineage and elicit granulomatous inflammation. The outcome of mycobacterial infection is largely determined by the host's capacity to contain the organism through cell-mediated immune responses.

The two main mycobacterial pathogens, *Mycobacterium tuberculosis* and *Mycobacterium leprae,* only infect humans and have no environmental reservoir. Other pathogenic mycobacteria are environmental organisms that only occasionally cause human disease.

TUBERCULOSIS

Tuberculosis is a chronic, communicable disease in which the lungs are the prime target, although any organ may be infected. Disease is mainly caused by* M. tuberculosis hominis *(Koch bacillus) but also occasionally by* M. tuberculosis bovis. *The characteristic lesion is a spherical granuloma with central caseous necrosis.

M. tuberculosis is a slender, beaded, nonmotile, acid-fast bacillus, which is an obligate aerobe (Fig. 9-46). It grows slowly in culture, with a doubling time of 24 hours, and 3–6 weeks are commonly required to produce visible growth in culture.

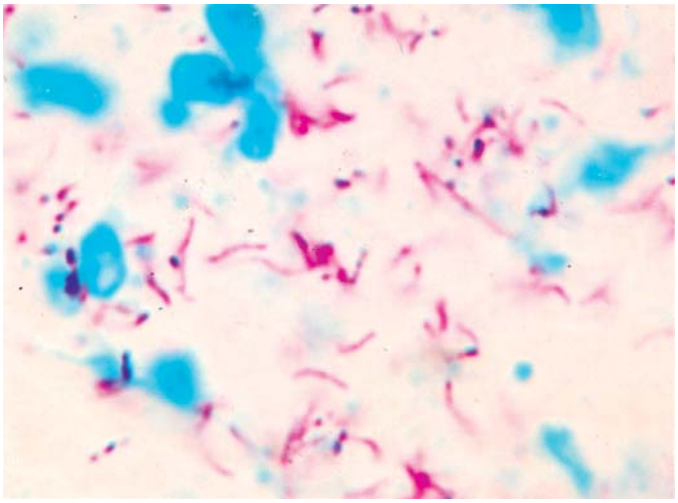

FIGURE 9-46. *Mycobacterium tuberculosis.* A smear of a pulmonary lesion shows slender, beaded, acid-fast bacilli.

EPIDEMIOLOGY: Tuberculosis is one of the most important human bacterial diseases worldwide. Rates of infection are now low in developed countries. HIV-infected, homeless and malnourished people are highly susceptible, as are immigrants from areas where the disease is endemic. In the United States, the annual incidence is 12 per 100,000 and mortality is 1–2 per 100,000. In some developing countries, the incidence reaches 450 per 100,000, with a high fatality rate. There are also racial and ethnic differences—Africans, Native Americans and Eskimos are more susceptible than are white people. In the United States, tuberculosis is most common among the elderly, possibly reflecting reactivation of infections acquired early in life before the decline in the prevalence of the disease.

M. tuberculosis is transmitted from person to person by aerosol. Coughing, sneezing and talking all create aerosolized respiratory droplets. Droplets usually evaporate, leaving an organism (droplet nucleus) that is readily carried in the air. Tuberculosis can also be caused by the closely related *M. tuberculosis bovis,* which is acquired by drinking nonpasteurized milk from infected cows.

CLINICAL FEATURES: The course of tuberculosis depends on age and immune competence, as well as total burden of organisms. Some patients have only an indolent, asymptomatic infection, while in others, tuberculosis is a destructive, disseminated disease. Many more people are infected with *M. tuberculosis* than develop clinical symptoms. Thus, one must distinguish between infection and active tuberculosis. **Tuberculous infection** means that the organism is growing in a person, whether or not there is symptomatic disease. **Active tuberculosis** denotes the subset of tuberculous infections manifested by destructive, symptomatic disease.

Primary tuberculosis occurs on first exposure to the organism and can pursue either an indolent or aggressive course (Fig. 9-47). **Secondary tuberculosis** develops long after a primary infection, mostly due to reactivation of a primary infection. Secondary tuberculosis can also be produced by exposure to exogenous organisms and is always an active disease.

Primary Tuberculosis Occurs upon First Exposure to the Tubercle Bacillus

PATHOPHYSIOLOGY: Inhaled *M. tuberculosis* is deposited in alveoli, usually in the lower segments of lower and middle lobes and anterior segments of upper lobes. The organisms are phagocytosed by alveolar macrophages but resist killing; cell wall lipids of *M. tuberculosis* block fusion of phagosomes and lysosomes and allow the bacilli to proliferate within macrophages. As bacilli multiply, the macrophages degrade some organisms and present antigens to T lymphocytes. Some macrophages carry bacilli from the lung to regional (hilar and mediastinal) lymph nodes, from which they may disseminate by the bloodstream. Tubercle bacilli

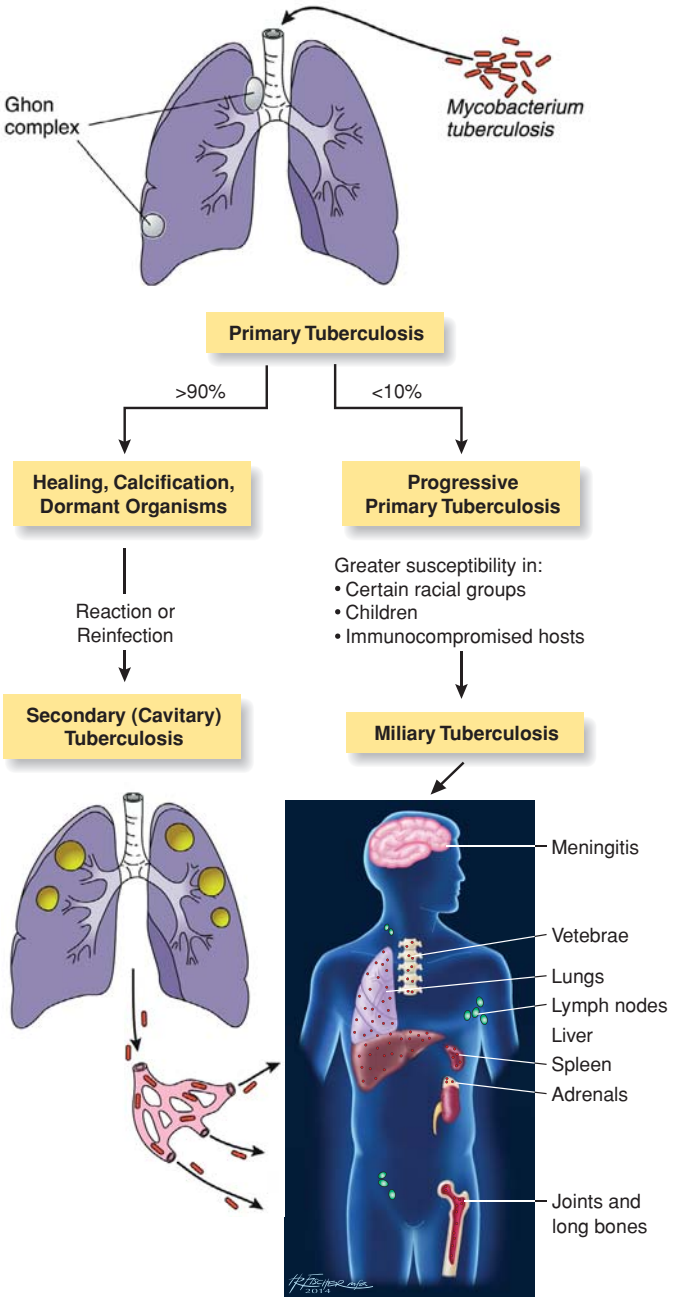

FIGURE 9-47. Stages of tuberculosis. Primary tuberculosis develops in a person lacking previous contact or immune responsiveness. **Progressive primary** tuberculosis develops in less than 10% of infected normal adults, but more frequently in children and immunosuppressed patients. **Secondary** (cavitary) tuberculosis results from reactivation of dormant endogenous bacilli or reinfection with exogenous bacilli. **Miliary** tuberculosis is caused by dissemination of tubercle bacilli to produce numerous, minute, yellow-white lesions (resembling millet seeds) in distant organs.

continue to proliferate at the primary site in the lungs and elsewhere, including lymph nodes, kidneys, meninges, epiphyseal plates of long bones and vertebrae and apical areas of the lungs.

Although the macrophages that first ingest *M. tuberculosis* cannot kill it, hypersensitivity and cell-mediated immunologic responses eventually contain the infection. Infected macrophages present mycobacterial antigens to T cells. Clones of sensitized T cells proliferate, produce interferon-γ and activate macrophages, thereby increasing their concentrations of lytic enzymes and augmenting their capacity to kill mycobacteria. The lytic enzymes of these activated macrophages may, if released, also damage host tissues.

Development of activated lymphocytes responsive to *M. tuberculosis* antigen is the hypersensitivity response to the organism. The emergence of activated macrophages that can ingest and destroy the bacilli accounts for the cell-mediated immune response. These responses together combat the organisms, a process that requires 3–6 weeks to come into play.

If an infected person is immunologically competent and the burden of organisms is small, a vigorous granulomatous reaction is produced. Tubercle bacilli are ingested and killed by activated macrophages, surrounded by fibrous tissue and successfully contained. When the number of organisms is high, the hypersensitivity reaction produces significant tissue necrosis, which has a characteristic cheese-like (caseous) consistency. Although not invariably caused by *M. tuberculosis*, caseous necrosis is so strongly associated with tuberculosis that its discovery in tissue inevitably raises suspicion of this disease.

In immunologically immature or compromised subjects (young children or immunosuppressed patients), granulomas are poorly formed or not formed at all, and infection may progress at the primary site in the lung, in the regional lymph nodes or in multiple sites of dissemination. This process produces **progressive primary tuberculosis**.

PATHOLOGY: The lung lesion of primary tuberculosis is known as a **Ghon focus**. It is found in the subpleural area of the upper segments of the lower lobes or in the lower segments of the upper lobes. Initially, it is a small, ill-defined area of inflammatory consolidation, which then drains to hilar lymph nodes. The combination of a peripheral Ghon focus and involved mediastinal or hilar lymph nodes is called the **Ghon complex**.

The classic lesion of tuberculosis is a caseous granuloma (Fig. 9-48), which has a soft, semisolid core surrounded by

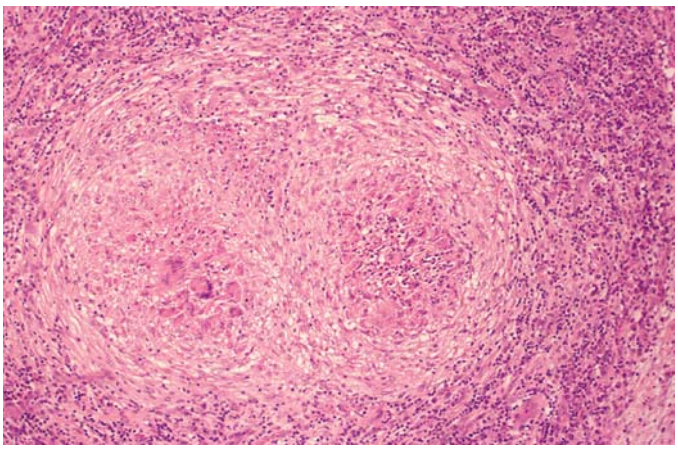

FIGURE 9-48. Primary tuberculosis. Photomicrograph of a hilar lymph node shows a tuberculous granuloma with central caseation.

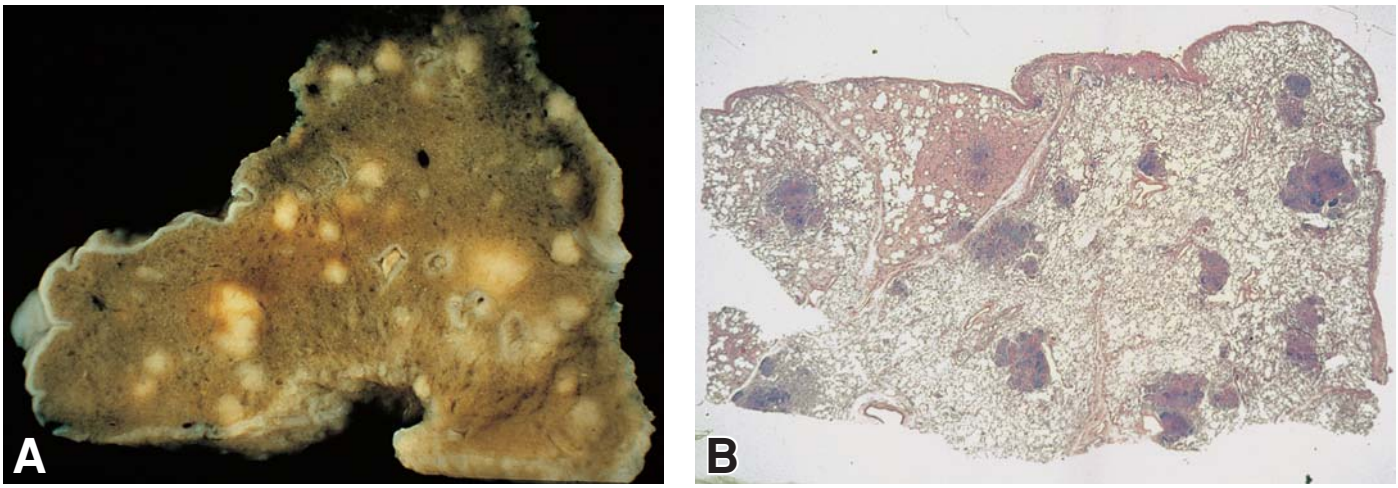

FIGURE 9-49. Miliary tuberculosis. A. The cut surface of the lung reveals numerous uniform, white nodules. **B.** A low-power photomicrograph discloses many foci of granulomatous inflammation.

epithelioid macrophages, Langhans giant cells, lymphocytes and peripheral fibrous tissue. If the host is immunocompromised, the granulomas elicited by *M. tuberculosis* may be less organized and consist of only aggregates of macrophages, without the architecture or Langhans giant cells of the classic granuloma.

In over 90% of normal adults, tuberculous infection is self-limited. In both lungs and lymph nodes, the Ghon complex heals, undergoing shrinkage, fibrous scarring and calcification, the latter visible radiographically. Small numbers of organisms may remain viable for years. Later, if immune mechanisms wane or fail, resting bacilli may proliferate and break out, causing serious secondary tuberculosis.

In **progressive primary tuberculosis,** the host immune response fails to control the tubercle bacilli. This happens in less than 10% of normal adults, but it is common in children younger than 5 years and in patients with suppressed or defective immunity. The Ghon focus enlarges and may even erode into the bronchial tree. Affected hilar and mediastinal lymph nodes also enlarge, sometimes compressing the bronchi to produce atelectasis of the distal lung; collapse of the middle lobe **(middle lobe syndrome)** is a common result of this compression. In some instances, the infected lymph nodes erode into an airway to spread organisms throughout the lungs.

Miliary tuberculosis occurs when infection disseminates to produce multiple, small, yellow, nodular lesions in several organs (Fig. 9-49). The term "miliary" refers to the resemblance of these lesions to millet seeds. The lungs, lymph nodes, kidneys, adrenals, bone marrow, spleen and liver are common sites of miliary lesions. Progressive disease may involve the meninges and cause tuberculous meningitis.

CLINICAL FEATURES: Most people contain primary infection successfully, and primary tuberculosis is generally asymptomatic. In those who develop progressive primary disease, symptoms are usually insidious and nonspecific, with fever, weight loss, fatigue and night sweats. Sometimes the onset of symptoms is abrupt, with high fever, pleurisy, pleural effusion and lymphadenitis. Cough and hemoptysis develop only when active pulmonary disease is well established. In miliary tuberculosis, symptoms vary according to the organs affected and tend to occur late in the course of disease.

Secondary (Cavitary) Tuberculosis Follows a Previously Contained Infection

The mycobacteria in secondary tuberculosis may be either dormant organisms from old granulomas (which is usually the case) or newly acquired bacilli. Various conditions, including cancer, antineoplastic chemotherapy, immunosuppressive therapy, AIDS and old age, predispose to reemergence of dormant *M. tuberculosis*. Secondary tuberculosis may develop even decades after primary infection.

PATHOLOGY: Any location may be involved, but the lungs are by far the most common site for secondary tuberculosis. In the lungs, secondary tuberculosis usually begins in apical–posterior segments of the upper lobes, where organisms are commonly seeded during primary infection. There, the bacilli proliferate and elicit an inflammatory response, causing localized consolidation. ***Ensuing T-cell–mediated immune responses to the now familiar tuberculous antigens lead to tissue necrosis and production of tuberculous cavities*** (Fig. 9-50). Apical cavities are optimal sites for multiplication of *M. tuberculosis*,

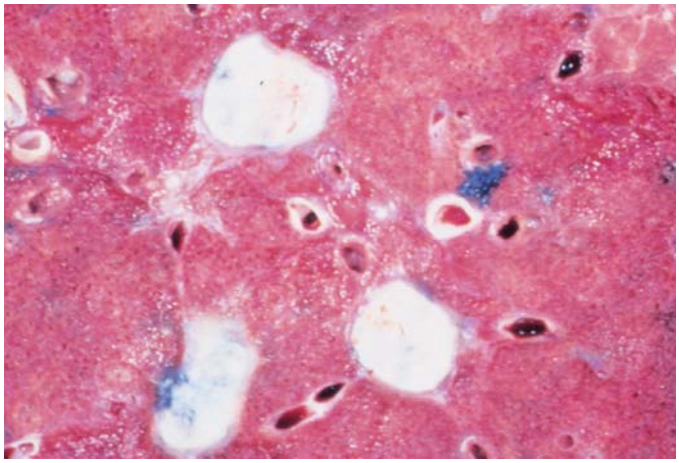

FIGURE 9-50. Secondary pulmonary tuberculosis. A cross-section of lung shows several tuberculous cavities filled with necrotic, caseous material.

and large numbers of organisms are produced in this environment. Cavities are typically 2–4 cm when first detected clinically but can exceed 10 cm. They contain necrotic material teeming with mycobacteria and are surrounded by a granulomatous response.

Lung lesions in secondary tuberculosis may be complicated by secondary effects:

- Scarring and calcification
- Spread to other areas
- Pleural fibrosis and adhesions
- Rupture of a caseous lesion, spilling bacilli into the pleural cavity
- Erosion into a bronchus, which seeds bronchioles, bronchi and trachea
- Implantation of bacilli in the larynx, causing hoarseness and pain on swallowing

Tubercle bacilli may also spread throughout the body through the lymphatics and bloodstream to cause miliary tuberculosis.

CLINICAL FEATURES: Cough (which may be mistakenly attributed to smoking or a cold), low-grade fever, general malaise, fatigue, anorexia, weight loss and often night sweats are the usual manifestations. Cavitation may be accompanied by hemoptysis, on occasion severe enough to cause exsanguination. Chest radiographs that show unilateral or bilateral apical cavities suggest the diagnosis of secondary tuberculosis. If disease is disseminated, the signs and symptoms reflect the particular organs involved.

Untreated secondary tuberculosis is a wasting disease that is eventually fatal, and at one time chronic cavitary tuberculosis was a common cause of secondary amyloidosis. Tuberculosis is now treated with prolonged courses of antituberculous antibiotics, including isoniazid, pyrazinamide, rifampin and ethambutol. Strains of *M. tuberculosis* resistant to these antibiotics have recently emerged, often as a consequence of poor compliance with the full regimen of antibiotic therapy.

LEPROSY

Leprosy (Hansen disease) is a chronic, slowly progressive, destructive process involving peripheral nerves, skin and mucous membranes, caused by *Mycobacterium leprae.* This agent is a slender, weakly acid-fast rod, which cannot be cultured on artificial media or in cell culture.

EPIDEMIOLOGY: Leprosy is one of the oldest recognized human diseases. Lepers were isolated from the community in the Old Testament. For centuries, leprosy was widespread in Europe, including England. In 1873, Hansen first documented the causative agent (leprosy is also called "Hansen disease").

Lepra bacilli multiply in experimental animals at sites with temperatures below that of the internal organs, such as foot pads of mice and ear lobes of hamsters, rats and other rodents. Naturally acquired leprosy has been recognized in armadillos in Louisiana and Texas. Lepra bacilli have been experimentally transmitted to armadillos, whose susceptibility is related, at least in part, to their low body temperature (32°C–35°C [89.6°F–95°F]).

Leprosy is transmitted from person to person, after years of intimate contact. *M. leprae* is present in nasal secretions or ulcerated lesions of infected persons. The mode of infection is unclear, but probably involves inoculation of bacilli into the respiratory tract or open wounds. Leprosy is now rare in developed countries, but worldwide 15 million people are infected, mainly in tropical areas such as India, Papua New Guinea, Southeast Asia and tropical Africa. Fewer than 400 cases are diagnosed yearly in the United States, mostly in immigrants from endemic areas. In total, there are approximately 6500 people with leprosy in the United States, of whom 3300 require active management.

PATHOPHYSIOLOGY: *M. leprae* multiplies best at temperatures below core human body temperature, and lesions tend to occur in cooler parts of the body (e.g., hands and face). Leprosy exhibits a bewildering variety of clinical and pathologic features. Lesions vary from the small, insignificant and self-healing macules of tuberculoid leprosy to the diffuse, disfiguring and sometimes fatal ones of lepromatous leprosy (Fig. 9-51). This extreme variation in disease presentation probably reflects differences in immune reactivity.

Most (95%) persons have a natural protective immunity to *M. leprae* and are not infected, despite intimate and prolonged exposure. Susceptible individuals (5%) span a broad spectrum of immune function, from anergy to hyperergy, and may develop symptomatic infection. At one end of the spectrum, anergic patients have little or no resistance and develop **lepromatous leprosy,** whereas hyperergic patients with high resistance manifest **tuberculoid leprosy**. Most patients, in between these extremes, have **borderline leprosy**.

TUBERCULOID LEPROSY: This condition is characterized by a single lesion or very few lesions of the skin, usually on the face, extremities or trunk. Microscopically, lesions show well-formed, circumscribed dermal granulomas, with epithelioid macrophages, Langhans giant cells and lymphocytes. Nerve fibers are almost invariably swollen and infiltrated with lymphocytes. Destruction of small dermal nerve twigs accounts for the sensory deficit associated with tuberculoid leprosy. Bacilli are rare and often not found with acid-fast stains. The term "tuberculoid leprosy" is used because the granulomas vaguely resemble those of tuberculosis. However, leprous granulomas lack caseation. The lesions of tuberculoid leprosy cause minimal disfigurement and are not infectious.

LEPROMATOUS LEPROSY: This form exhibits multiple, tumor-like lesions of the skin, eyes, testes, nerves, lymph nodes and spleen. Nodular or diffuse infiltrates of foamy macrophages contain myriad bacilli (Fig. 9-52). The epidermis is stretched thinly over the nodules, and beneath it is a narrow, uninvolved "clear zone" of the dermis. Rather than destroying the bacilli, macrophages seem to act as microincubators. When subjected to acid-fast stains, the numerous organisms within the foamy macrophages appear as aggregates of acid-fast material, called "globi." The dermal infiltrates expand slowly to distort and disfigure the face, ears and upper airway and to destroy the eyes, eyebrows and eyelashes, nerves

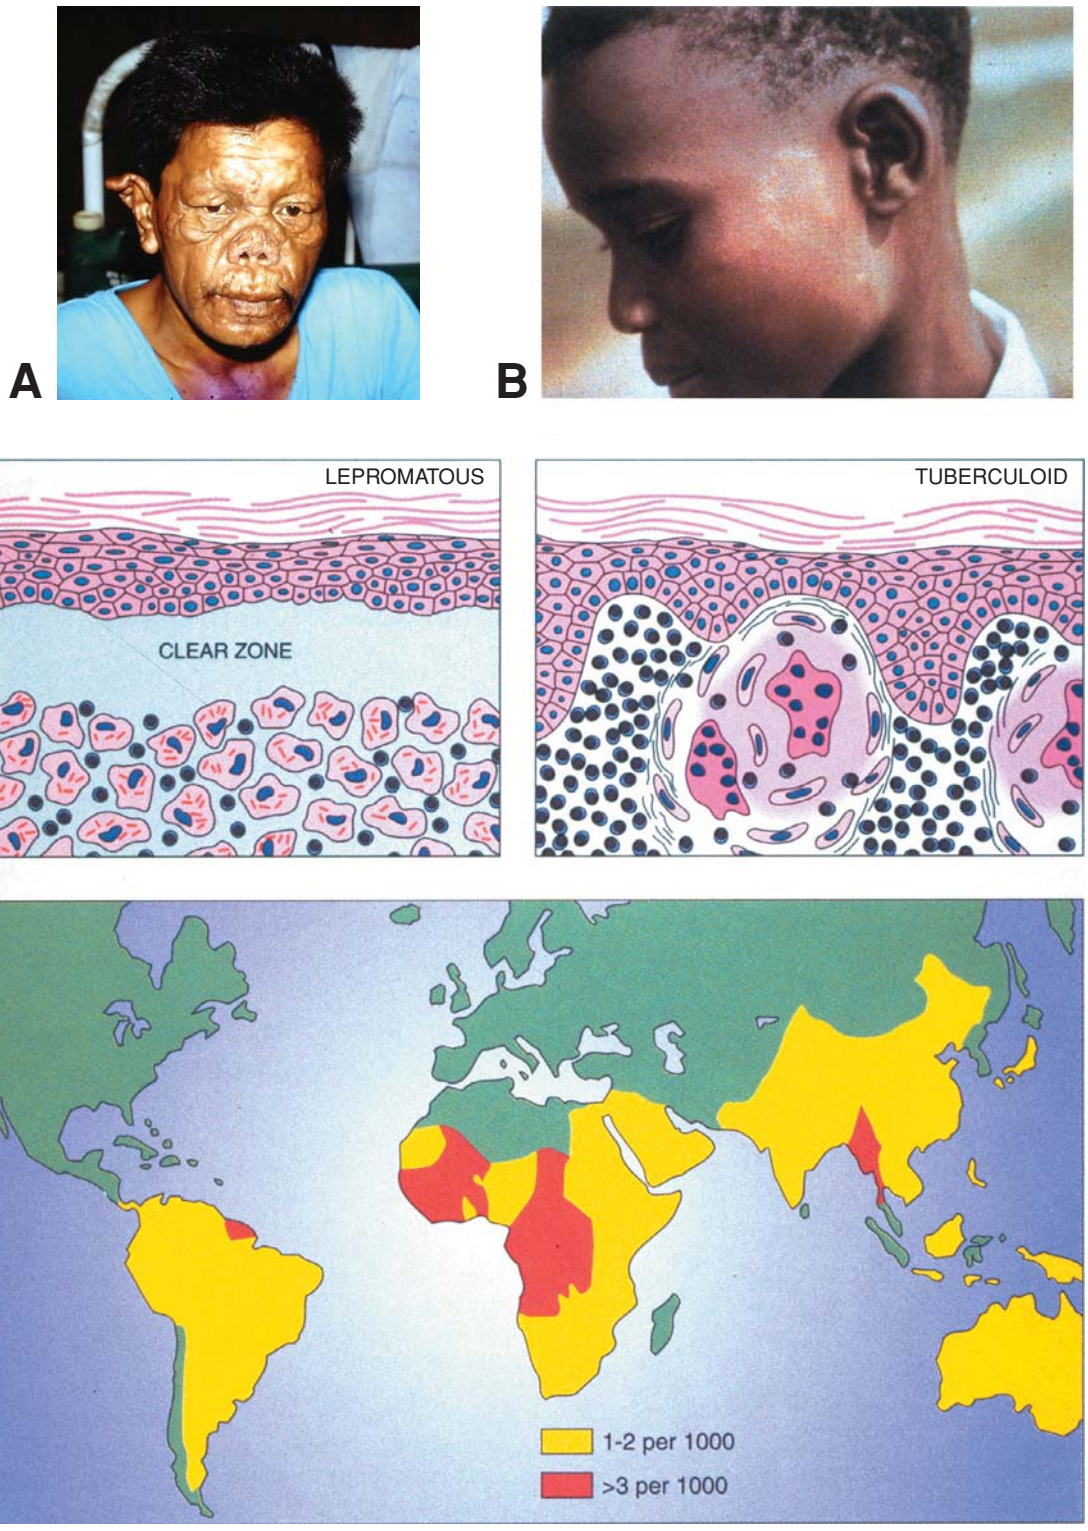

FIGURE 9-51. A. (*Top*) **Leonine facies of lepromatous leprosy.** There is diffuse involvement, including a loss of eyebrows and eyelashes and nodular distortions of the face and ears, the exposed (cool) parts of the body. The septum and bone of the nose are damaged, producing "saddle nose" deformity. This Filipino patient also had deformities of the hands and feet. (*Bottom*) The nodular skin lesions of advanced lepromatous leprosy. Swelling has flattened the epidermis (loss of rete ridges). A characteristic "clear zone" of uninvolved dermis separates the epidermis from tumor-like accumulations of macrophages, each containing numerous lepra bacilli *(Mycobacterium leprae).* **B.** (*Top*) **Tuberculoid leprosy** on the cheek, showing a hypopigmented macule with a raised, infiltrated border. The central portion may be hypesthetic or anesthetic. (*Bottom*) Macular skin lesion of tuberculoid leprosy. Skin from the raised "infiltrated" margin of the plaque contains discrete granulomas that extend to the basal layer of the epidermis (without a clear zone). The granulomas are composed of epithelioid cells and Langhans giant cells and are associated with lymphocytes and plasma cells. Lepra bacilli are rare. **C. Distribution of leprosy.** Prevalence is greatest in tropical regions of Africa, Asia and Latin America.

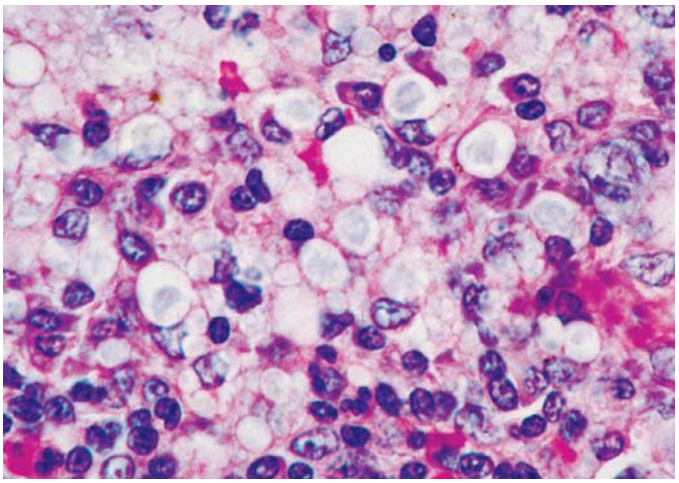

FIGURE 9-52. Lepromatous leprosy. A section of skin shows a tumor-like mass of foamy macrophages. The faint masses within the vacuolated macrophages are enormous numbers of lepra bacilli.

and testes. The nodular skin lesions of lepromatous leprosy may ulcerate. Claw-shaped hands, hammer toes, saddle nose and pendulous ear lobes are common. Nodular lesions of the face may coalesce to produce a lion-like appearance ("leonine facies"). Involvement of the upper airways leads to chronic nasal discharge and voice change. Infection of the eyes may cause blindness.

MYCOBACTERIUM AVIUM-INTRACELLULARE COMPLEX

Mycobacterium avium and *Mycobacterium intracellulare* are similar species, which cause identical diseases and are grouped as *M. avium-intracellulare* (MAI) complex, or simply MAI. The agents cause two types of disease: (1) a rare, slowly progressive granulomatous pulmonary disease in immunocompetent persons, and (2) a progressive systemic disease in patients with AIDS. ***MAI infection is the third most common opportunistic infection in AIDS patients in the United States.***

MAI is found in soil, water and foodstuffs worldwide. Humans probably acquire it from the environment by inhaling aerosols from infected water sources. Colonization by the organisms is common. As much as 70% of the population shows immunologic responsiveness to MAI, indicating prior exposure.

Granulomatous MAI Disease Affects Some Immunocompetent Persons

Most immunocompetent persons with granulomatous pulmonary disease caused by MAI are older (50–70 years), and many suffer from preexisting pulmonary disease. ***Clinically and pathologically, MAI disease resembles tuberculosis but progresses much more slowly. It causes pulmonary nodules and cavities and caseating granulomas.***

CLINICAL FEATURES: The most common antecedent illnesses predisposing to pulmonary MAI infection in people with a normal immune system are chronic obstructive pulmonary disease, treated tuberculosis, pneumoconioses and bronchiectasis. Cough is a common symptom, but most symptoms that characterize tuberculosis are lacking. MAI lung disease is indolent or only slowly progressive, causing lung function to decline gradually over years or decades. The organism is resistant to first-line antituberculous drugs, and combination therapies often yield disappointing results.

M. Avium-Intracellulare Causes Disseminated Infection in AIDS

One third of AIDS patients in the United States develop overt MAI infection; as many as one half have evidence of infection at autopsy.

PATHOPHYSIOLOGY: In patients with AIDS, progressive depletion of helper T cells cripples immune responses that normally prevent MAI disease. Although macrophages phagocytose the organisms, they cannot kill them. The bacilli replicate, fill the cells and spread first to other macrophages and then throughout the body via the lymphatics and bloodstream.

PATHOLOGY: Infected macrophages are found in many organs, and proliferation of the organisms leads to recruitment of additional macrophages. As a result, expanding nodular lesions range from structured epithelioid granulomas with few organisms to loose aggregates of foamy macrophages packed with acid-fast bacilli (Fig. 9-53). Eventually, lymph nodes, spleen and bone marrow may be almost completely replaced by aggregates of macrophages, and lesions in the bowel erode into the lumen of the gut.

CLINICAL FEATURES: Early, constitutional symptoms of MAI disease in AIDS resemble those of tuberculosis: fever, night sweats, fatigue and weight loss. Progressive small bowel involvement produces

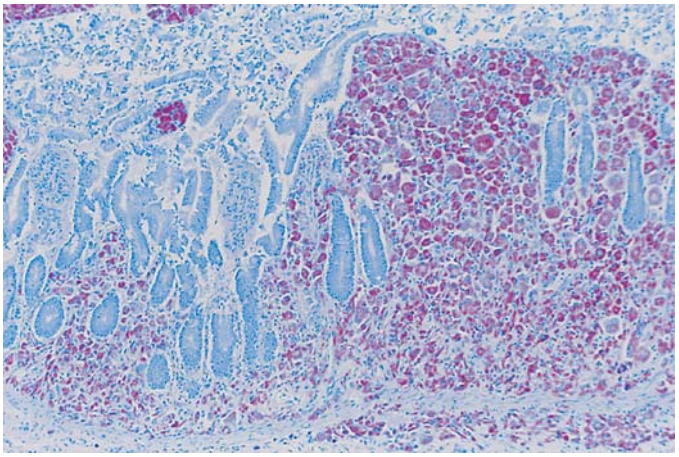

FIGURE 9-53. *Mycobacterium avium-intracellulare* (MAI). A section of small bowel from a patient with acquired immunodeficiency syndrome (AIDS) reveals the presence of numerous macrophages stuffed with acid-fast bacilli in the lamina propria.

malabsorption and diarrhea, often with abdominal pain. Pulmonary involvement is common but does not usually produce symptoms. Combinations of five or more different antibiotics, including clarithromycin, may control, but rarely cure, widespread MAI infection in AIDS patients.

ATYPICAL MYCOBACTERIA

Several other species of environmental mycobacteria occasionally produce human disease. These organisms are also present in surface waters, dust and dirt, and people acquire infection by inhalation, inoculation or ingestion of environmental material.

These bacteria, including MAI, are often lumped together as the "atypical mycobacteria" (in contrast to *M. tuberculosis*, regarded as the "typical" mycobacterium). The atypical mycobacteria are biologically diverse and the uncommon diseases that they produce in humans differ in circumstances of acquisition, pathology, clinical presentations and therapies. The features of these diseases are compared in Table 9-8.

- ***Mycobacterium kansasii*** causes a chronic, slowly progressive, granulomatous pulmonary disease in people over 50 years, similar to that produced by MAI in immunocompetent patients.
- ***Mycobacterium scrofulaceum***, a common soil inhabitant, produces a draining, granulomatous, cervical lymphadenitis in young children (aged 1–5 years). The infection affects the submandibular lymph nodes and probably results from inoculation or ingestion of organisms by toddlers playing in soil. The disease is localized, and surgical excision of affected lymph nodes is curative.
- ***Mycobacterium marinum***, commonly found on underwater surfaces, leads to a localized nodular skin lesion ("swimming pool granuloma"), sometimes with lymphatic involvement. Infection is acquired by traumatic inoculation, such as abrading an elbow on a swimming pool ladder or cutting a finger on a fish spine. Tissue reactions may be pyogenic or granulomatous.
- ***Mycobacterium ulcerans*** is associated with severe ulcerating skin disease in Australia, Africa and New Guinea. Infection presents as a solitary, undermining, deep ulcer of the skin and subcutaneous fat of the extremities.
- ***Mycobacterium chelonae*** and ***Mycobacterium fortuitum*** are closely related organisms that are ubiquitous in the environment. Infection follows traumatic or iatrogenic inoculation of material contaminated with organisms. Painless, fluctuant abscesses appear at the site of inoculation, ulcerate and gradually heal spontaneously. The tissue reaction can be pyogenic or granulomatous.

Fungal Infections

Of more than 100,000 known fungi, only a few cause human disease. Of these, most are "opportunists"; they only infect people with impaired defenses. ***Thus, corticosteroid administration, antineoplastic therapy and congenital or acquired T-cell deficiencies all predispose to mycotic infections.***

Fungi are larger and more complex than bacteria. They vary in size from 2 to 100 µm and are eukaryotes. Thus, they possess nuclear membranes and cytoplasmic organelles, such as mitochondria and endoplasmic reticulum.

There are two morphologic types of fungi: yeasts and molds.

- **Yeasts** are unicellular forms of fungi. They are round or oval cells that reproduce by budding, a process by which daughter organisms pinch off from a parent. Some yeasts produce buds that do not detach but instead create

TABLE 9-8
ATYPICAL MYCOBACTERIAL INFECTIONS

Organism	Disease	Ages Affected	Pathology	Source	Distribution
Mycobacterium kansasii	Chronic granulomatous pulmonary disease (similar to that caused by *Mycobacterium avium-intracellulare*)	50–70	Granulomatous inflammation	Inhaled organisms from soil, dust or water	Worldwide
Mycobacterium scrofulaceum	Cervical lymphadenitis	1–5	Granulomatous inflammation	Probably ingested organisms from soil or dust	Worldwide
Mycobacterium marinum	Localized skin lesions	All	Granulomatous inflammation	Direct inoculation of organisms from fish or underwater surfaces (swimming pools, fish tanks)	Worldwide
Mycobacterium ulcerans	Large, solitary, severe ulcer of skin and subcutaneous tissue	Usually 5–25	Coagulative necrosis	Probably inoculation of environmental organisms	Australia, Africa
Mycobacterium fortuitum and *Mycobacterium chelonae*	Infections associated with traumatic or iatrogenic inoculations	All	Pyogenic inflammation	Inoculation of environmental organisms	Worldwide

pseudohyphae (i.e., chains of elongated yeast cells that resemble hyphae).

- **Molds** are multicellular filamentous fungal colonies with branching tubules, or **hyphae,** 2–10 µm in diameter. The mass of tangled hyphae in the mold form is called a **mycelium.** Some hyphae are separated by septa that are located at regular intervals; others are nonseptate.
- **Dimorphic fungi** may grow as yeasts or molds, depending on their environment.

Most fungi are visible on tissue sections stained with hematoxylin and eosin. The periodic acid–Schiff (PAS) and Gomori methenamine silver (GMS) stains outline fungal cell walls and are commonly used to detect fungal infection in tissues.

PNEUMOCYSTIS JIROVECI PNEUMONIA

Pneumocystis jiroveci (*formerly,* carinii) ***causes progressive, often fatal, pneumonia in people with impaired cell-mediated immunity. It is a common opportunistic pathogen in AIDS.*** The organism has recently been reclassified with the fungi.

EPIDEMIOLOGY: *P. jiroveci* is distributed worldwide. Since 75% of the population have antibodies by 5 years of age, it is likely that the organisms are inhaled by all. If cell-mediated immunity is intact, infection is rapidly contained without producing symptoms.

In the 1960s and 1970s, 100–200 cases of active *Pneumocystis* disease were reported annually in the United States, mainly in people with hematologic malignancies, transplant recipients or those treated with corticosteroids or cytotoxic therapy. Pneumocystis became a common pathogen with the AIDS pandemic. Before the use of highly active antiretroviral therapy (see Chapter 4), 80% of AIDS patients developed *Pneumocystis* pneumonia.

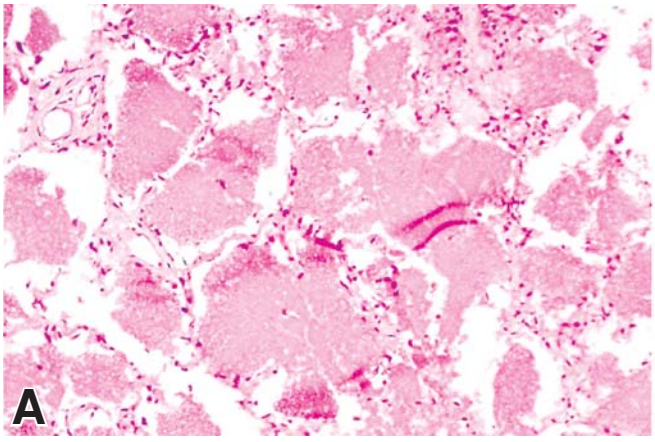
PATHOPHYSIOLOGY: *P. jiroveci* reproduces in association with alveolar type 1 lining cells, and active disease is confined to the lungs. Infection begins with attachment of *Pneumocystis* trophozoites to alveolar lining cells. Trophozoites feed on host cells and enlarge and transform into the cyst form, which contains daughter organisms. The cyst ruptures to release new trophozoites, which attach to additional alveolar lining cells. If the process is not checked by the host immune system or antibiotics, infected alveoli eventually fill with organisms and proteinaceous fluid. The progressive filling of alveoli prevents adequate gas exchange and the patient slowly suffocates.

It is assumed, but not proved, that most cases of pneumocystosis derive from latent endogenous infection. Outbreaks of *Pneumocystis* pneumonia have also occurred among severely malnourished (and thus immunosuppressed) infants in nurseries; these represent primary infection with the organism.

PATHOLOGY: *P. jiroveci* causes progressive consolidation of the lungs. Microscopically, alveoli contain a frothy eosinophilic material, composed of alveolar macrophages and cysts and *P. jiroveci* trophozoites (Fig. 9-54). Hyaline membranes and type 2 pneumocytes are prominent. In newborns, alveolar septa are thickened by lymphoid cells and macrophages. The prominent plasma cells in the infantile disease led to the now obsolete term *plasma cell pneumonia.*

The various forms of *P. jiroveci* are best visualized with methenamine silver stains. The cyst form measures about 60 µm in diameter (Fig. 9-54B); extracellular trophozoites and intracystic forms of the organism appear as irregularly shaped cells, 1–3 µm across, with punctate violet nuclei by Giemsa staining.

CLINICAL FEATURES: *P. jiroveci* pneumonia features fever and progressive shortness of breath, often exacerbated by exertion and accompanied by a nonproductive cough. Dyspnea may be subtle in onset and slowly progressive over many weeks. Chest radiographs show a diffuse pulmonary process. The diagnosis requires recovery of alveolar material (by bronchoscopy, endobronchial washing or sputum induction) for staining. The disease



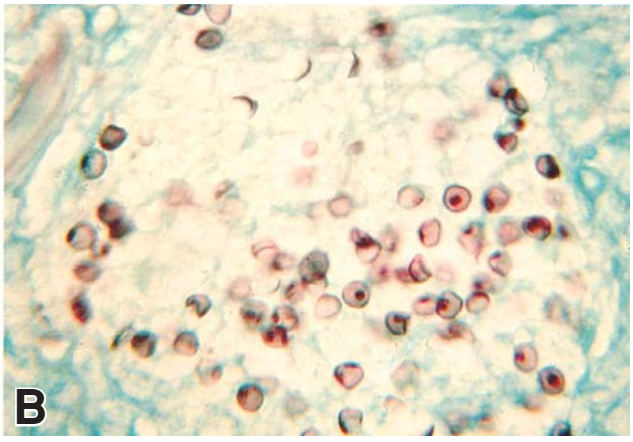


FIGURE 9-54. ***Pneumocystis jiroveci*** **pneumonia. A.** The alveoli contain a frothy eosinophilic material that is composed of alveolar macrophages and cysts and trophozoites of *P. jiroveci.* **B.** A silver stain shows crescent-shaped organisms, which are collapsed and degenerated. Some have a characteristic dark spot in their walls.

is fatal if untreated. Therapy is with trimethoprim-sulfamethoxazole or pentamidine.

CANDIDA

The genus *Candida*, comprising over 20 species of yeasts, includes the most common opportunistic pathogens. Many are endogenous human flora, well adapted to life on or in the human body. However, they can cause disease when host defenses are compromised. Although the various forms of candidiasis vary in clinical severity, most are localized, superficial diseases, limited to a particular mucocutaneous site, including:

- **Intertrigo:** infection of opposed skin surfaces
- **Paronychia:** infection of the nail bed
- **Diaper rash**
- **Vulvovaginitis**
- **Thrush:** oral infection
- **Esophagitis**

Candidal infections of deep tissues are much less common than superficial infections but can be life-threatening. The most common deep sites affected are the brain, eye, kidney and heart. Deep infections, with candidal sepsis and disseminated candidiasis, occur only in immunologically compromised people and are often fatal.

Most candidal infections derive from endogenous flora. *Candida albicans* resides in small numbers in the oropharynx, gastrointestinal tract and vagina and accounts for more than 95% of these infections.

PATHOPHYSIOLOGY: Mechanical barriers, inflammatory cells, humoral immunity and cell-mediated immunity relegate *Candida* to superficial, nonsterile sites. In turn, the resident bacterial flora normally limit the number of fungal organisms. Bacteria (1) block candidal attachment to epithelial cells, (2) compete with them for nutrients and (3) prevent conversion of the fungus to tissue-invasive forms. When any of these defenses is compromised, candidal infections can occur (Table 9-9). ***Antibiotic use suppresses competing bacterial flora and is the most common precipitating factor for candidiasis***. Under conditions of unopposed growth, the yeast converts to its invasive form (hyphae or pseudohyphae), invades superficially and elicits an inflammatory or immunologic response.

Although *Candida* inhabits skin surfaces, it does not cause cutaneous disease without a predisposing skin lesion. The most common such factor is maceration, or softening and destruction of the skin. Chronically warm and moist areas, such as between fingers and toes, between skinfolds and under diapers, are prone to maceration and superficial candidal disease.

The incidence of invasive candidal infections is increasing. Frequent use of potent broad-spectrum antibiotics eliminates bacteria that otherwise limit *Candida* colonization. Expanded use of medical devices, such as intravascular catheters, monitoring devices, endotracheal tubes and urinary catheters, provides access to sterile sites. AIDS and iatrogenic neutropenias render individuals susceptible to even weak pathogens, such as *Candida*. Finally, intravenous drug users develop deep candidal infections because of inoculation of the fungi into the bloodstream.

TABLE 9-9
CANDIDAL INFECTIONS

Disease	Predisposing Conditions
Superficial Infections	
Intertrigo (opposed skin surfaces)	Maceration
Paronychia (nail beds)	Maceration
Diaper rash	Maceration
Vulvovaginitis	Alteration in normal flora
Thrush (oral)	Decreased cell-mediated immunity
Esophagitis	Decreased cell-mediated immunity
Deep Infections	
Urinary tract infections	Indwelling urinary catheters
Sepsis and disseminated infection	Neutropenia, indwelling vascular catheters and change in normal flora

PATHOLOGY AND CLINICAL FEATURES: Superficial infections of the skin, oropharynx (Fig. 9-55A) and esophagus feature invasive organisms in the most superficial epithelial layers and are associated with acute inflammatory infiltrates. Yeast, pseudohyphae and hyphae are present (Fig. 9-55B). The yeasts are round, are 3–4 µm in diameter and display septate hyphae. Candidal vaginitis is characterized by superficial invasion of the squamous epithelium, but inflammation is usually scanty. Deep infections consist of multiple microscopic abscesses, which contain yeast, hyphae, necrotic debris and neutrophils. Rarely, *Candida* elicit granulomatous responses.

The various superficial cutaneous infections manifest as tender, erythematous papules, which expand to form confluent erythematous areas:

- **Thrush:** This disorder involves the tongue and mucous membranes of the mouth. Early in life, it is the most common form of mucocutaneous candidiasis. Candidal vaginitis during pregnancy predisposes newborns to infection. Friable, white, curd-like membranes are adherent to affected surfaces. These patches contain fungi, necrotic debris, neutrophils and bacteria, and can be dislodged by scraping. Removal of the membranes leaves a painful, bleeding surface.
- **Candidal vulvovaginitis:** This condition causes a thick, white vaginal discharge, with vaginal and vulvar itching. Involved areas of the vulva are erythematous and tender. Candidal vaginitis is most intense when vaginal pH is low. Antibiotics, pregnancy, diabetes and corticosteroids predispose to this form of vaginitis.
- **Candidal sepsis and disseminated candidiasis:** Systemic candidiasis is rare and is ordinarily a terminal event in someone with altered immunity or neutropenia. Several candidal species can produce invasive disease in this context. Organisms may enter through ulcerated skin or

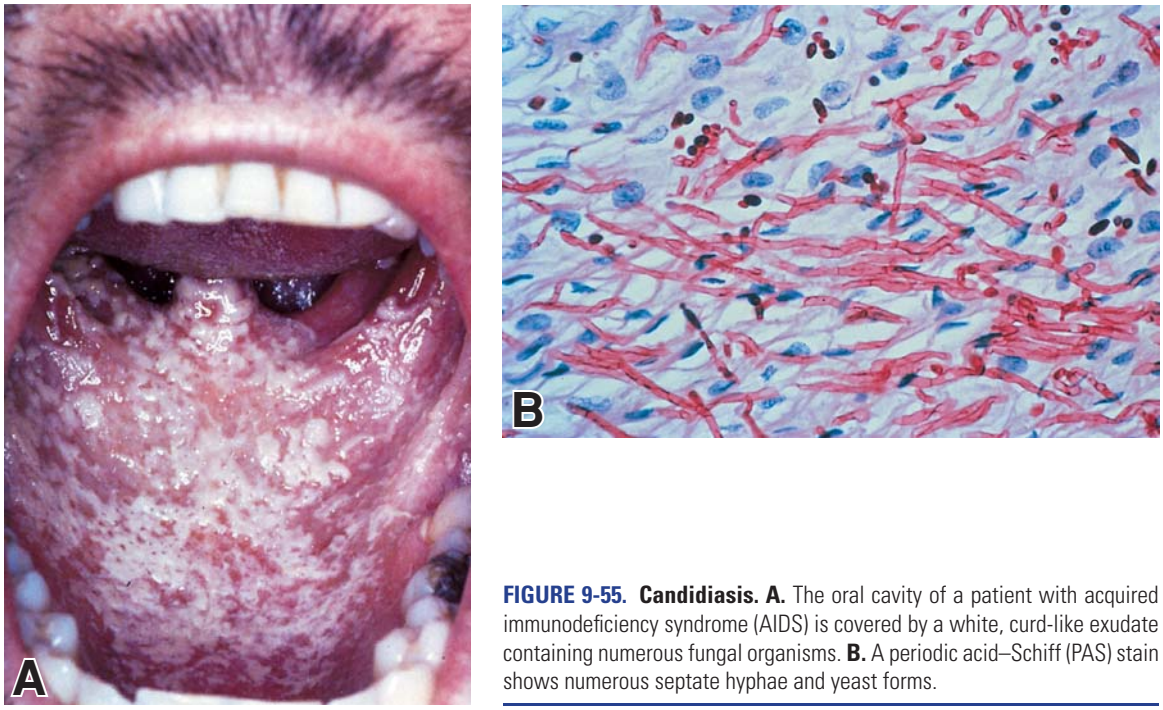

FIGURE 9-55. Candidiasis. A. The oral cavity of a patient with acquired immunodeficiency syndrome (AIDS) is covered by a white, curd-like exudate containing numerous fungal organisms. **B.** A periodic acid–Schiff (PAS) stain shows numerous septate hyphae and yeast forms.

mucous membrane lesions or may be introduced iatrogenically (e.g., peritoneal dialysis, intravenous lines or urinary catheters). The urinary tract is most commonly involved, and the incidence in women is four times that in men. Renal lesions may be blood-borne or may arise from an ascending pyelonephritis.

- **Candidal endocarditis:** This infection is characterized by large vegetations on the heart valves and a high incidence of embolization to large arteries. In most patients with candidal endocarditis, the cause is not immunosuppression but unusual vulnerability. Drug addicts who use unsterilized needles and persons with preexisting valvular disease who have had prolonged antibacterial therapy or indwelling vascular catheters are at risk for endocarditis. One of the most serious complications of invasive candidiasis is septic embolism to the brain.

ASPERGILLOSIS

Aspergillus species are common environmental fungi that cause opportunistic infections, usually involving the lungs. There are three types of pulmonary aspergillosis: (1) **allergic bronchopulmonary aspergillosis,** (2) **colonization of a preexisting pulmonary cavity** (**aspergilloma** or **fungus ball**) and (3) **invasive aspergillosis** (see Chapter 18). Of the over 200 identified species of *Aspergillus,* approximately 20 cause human disease. *Aspergillus fumigatus* is by far the most frequent human pathogen.

EPIDEMIOLOGY: *Aspergillus* is a saprophyte found worldwide in soil, decaying plant matter and dung. Pulmonary aspergillosis is acquired by inhaling small (2–3 µm) spores, termed **conidia,** that are in the air in almost every human environment. The spores are small enough to reach the alveoli when inhaled. Exposure is greatest when the habitat of the fungus is disturbed, as during soil excavations or handling decaying organic matter.

In tissues, *Aspergillus* spp. show septate hyphae, 2–7 µm in diameter, branching progressively at acute angles. The multiple dichotomous branching led to the name *Aspergillus,* which is derived from a fancied resemblance to the aspergillum, a device used to sprinkle holy water during Catholic religious ceremonies.

Allergic Bronchopulmonary Aspergillosis Complicates Asthma

Inhalation of *Aspergillus* spores delivers fungal antigens to airways and alveoli; contact subsequently initiates an allergic response in susceptible people. The situation is aggravated if spores can germinate and grow in the airways, thereby causing long-term exposure to the antigen. Allergic bronchopulmonary aspergillosis is virtually restricted to asthmatics, 20% of whom eventually develop this disorder (see Chapter 18).

Bronchi and bronchioles show infiltrates of lymphocytes, plasma cells and variable numbers of eosinophils. Sometimes airways are impacted with mucus and fungal hyphae. Patients experience exacerbations of asthma, often accompanied by pulmonary infiltrates and eosinophilia.

Aspergillomas Reside in Pulmonary Cavities or Bronchiectasis

Inhaled spores germinate in the warm humid atmosphere provided by these hollows and fill them with masses of hyphae (see Chapter 18).

PATHOLOGY: An aspergilloma is a dense, roundish mass of tangled hyphae, 1–7 cm in diameter, within a fibrous cavity. The cavity wall is collagenous connective tissue, with lymphocytes and plasma cells. The hyphae do not invade adjacent tissues.

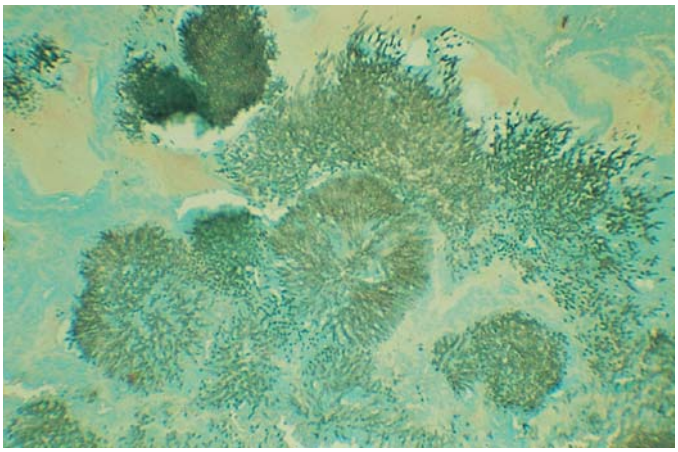

FIGURE 9-56. Invasive aspergillosis. A section of lung impregnated with silver shows branching fungal hyphae surrounding blood vessels and invading the adjacent parenchyma.

CLINICAL FEATURES: Aspergillomas occur most commonly in old tuberculous cavities. Symptoms reflect the underlying disease. The radiologic appearance of a dense round ball in a cavity is characteristic. Aspergillomas are usually best left untreated, although surgical excision may be indicated in some cases.

Invasive Aspergillosis Generally Affects Neutropenic Patients

Whenever neutrophil number or activity is compromised, invasive aspergillosis may occur. The most common settings are high-dose steroid or cytotoxic therapy or acute leukemia. In profoundly neutropenic patients, inhaled spores germinate to produce hyphae, which invade through bronchi into the lung parenchyma, from where the fungi may spread widely.

PATHOLOGY: *Aspergillus* readily invades blood vessels and produces thrombosis (Fig. 9-56). As a result, multiple nodular infarcts are seen throughout both lungs. Involvement of larger pulmonary arteries results in large, wedge-shaped, pleural-based infarcts. Vascular invasion also leads to fungus dissemination to other organs. *Aspergillus* hyphae are arranged radially around blood vessels and extend through their walls. Acute aspergillosis may also start in a nasal sinus and spread to the face, orbit and brain.

CLINICAL FEATURES: Invasive aspergillosis presents as fever and multifocal pulmonary infiltrates in a compromised patient. Because of frequent thrombosis and bloodstream dissemination, the disease is often fatal. Antifungal therapy with amphotericin B may be successful but must be initiated early and given in high doses.

MUCORMYCOSIS (ZYGOMYCOSIS)

Several related environmental fungi, members of the class Zygomycetes (*Rhizopus, Mucor, Rhizomucor, Absidia*) produce severe, necrotizing, invasive, opportunistic infections that begin in the nasal sinuses or lungs. The infections they produce are usually called **mucormycoses** or **zygomycoses**.

In tissues, zygomycetes have large (8–15 µm across) hyphae that branch at right angles, have thin walls and lack septa. In tissue sections, they appear as hollow tubes. Since they lack cross-walls, their liquid contents flow, leaving long empty segments. They also may resemble "twisted ribbons," which represent collapsed hyphae.

EPIDEMIOLOGY: Zygomycetes are ubiquitous, inhabiting soil, food and decaying vegetable matter. Their spores are inhaled, and in susceptible people, disease begins in the lungs. Mucormycosis occurs almost exclusively in the setting of compromised defenses. Common causes include severe neutropenia (e.g., after treatment for leukemia), high-dose glucocorticoid therapy and, particularly, severe diabetes.

PATHOLOGY AND CLINICAL FEATURES: The three predominant forms of mucormycosis are rhinocerebral, pulmonary and subcutaneous.

- **Rhinocerebral mucormycosis:** Fungi proliferate in nasal sinuses, invade surrounding tissues and extend into facial soft tissues, nerves, blood vessels and the brain. The palate or nasal turbinates are covered by a black crust, and underlying tissue is friable and hemorrhagic. Fungal hyphae grow into the arteries and cause devastating, rapidly progressive, septic infarction of affected tissues. Extension into the brain leads to fatal, necrotizing, hemorrhagic encephalitis. Therapy requires surgical excision of involved tissues, amphotericin B and correction of the predisposing abnormality.
- **Pulmonary mucormycosis:** This infection resembles invasive pulmonary aspergillosis, including vascular invasion and multiple areas of septic infarction (Fig. 9-57). Both rhinocerebral and pulmonary mucormycosis are usually fatal.
- **Subcutaneous zygomycosis:** This infection is limited to the tropics and is caused by *Basidiobolus haptosporus.* The fungus grows slowly in the panniculus, producing a gradually enlarging, hard inflammatory mass, usually on the shoulder, trunk, buttock or thigh.

CRYPTOCOCCOSIS

Cryptococcosis is a systemic mycosis caused by *Cryptococcus neoformans,* which principally affects the meninges and lungs (Fig. 9-58). *C. neoformans* has a worldwide distribution. Its main reservoir is pigeon droppings, which are alkaline and hyperosmolar. These conditions keep cryptococci small, allowing inhaled organisms to reach the terminal bronchioles. *C. neoformans* is unique among pathogenic fungi in having a proteoglycan capsule, which is essential for pathogenicity. The organisms appear as faintly basophilic yeasts with a clear, 3–5-µm-thick, mucinous capsule.

PATHOPHYSIOLOGY: **Cryptococcus *almost exclusively affects people with impaired cell-mediated immunity*.** Although the organism is ubiquitous and exposure is common, cryptococcosis is rare in the absence of predisposing illness. Disease is

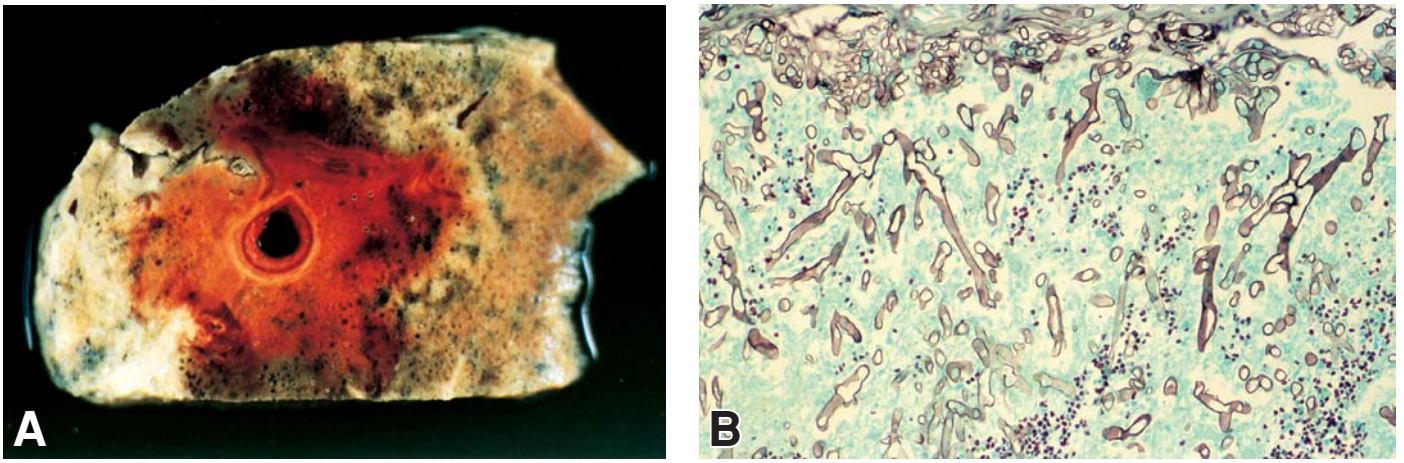

FIGURE 9-57. Pulmonary mucormycosis. A cross-section of the lung shows the vessel in the center of the field to be invaded by mucormycetes and occluded by a septic thrombus. The surrounding tissue is infarcted.

uncommon even among persons such as pigeon fanciers, who are exposed to high concentrations of the organism. Cryptococcosis occurs in patients with AIDS, lymphomas (particularly Hodgkin disease), leukemias and sarcoidosis, and in those treated with high doses of corticosteroids.

In immunologically intact individuals, neutrophils and alveolar macrophages kill *C. neoformans*, and no clinical disease develops. By contrast, in a patient with defective cell-mediated immunity, the cryptococci survive, reproduce locally and then disseminate. Although the lung is the portal of entry, the CNS is the most common site of disease, owing to the nourishing environment provided by the cerebrospinal fluid.

PATHOLOGY: Over 95% of cryptococcal infections involve the meninges and brain. Lesions in the lungs can be demonstrated in half of patients. In a small minority, skin, liver and other involvement occurs. In cryptococcal meningoencephalitis, the entire brain is swollen and soft, and leptomeninges are thickened and gelatinous from infiltration by the thickly encapsulated organisms. Inflammatory responses are variable but are often minimal, with large numbers of cryptococci infiltrating tissue. When present, inflammation may be neutrophilic, lymphocytic or granulomatous.

Cryptococcosis in the lung may appear as diffuse disease or as isolated areas of consolidation. Affected alveoli are distended by clusters of organisms, usually with minimal inflammation.

Because of its thick capsule, *C. neoformans* stains poorly with the routine hematoxylin and eosin stain and appears as bubbles or holes in tissue sections (Fig. 9-59A). Fungal stains (PAS and GMS) demonstrate the yeasts well but do not stain the polysaccharide capsule. The organism thus appears to be surrounded by a halo. The capsule can be highlighted by the mucicarmine stain (Fig. 9-59B).

CLINICAL FEATURES: Cryptococcal CNS disease often begins insidiously, with headache, dizziness, sleepiness and loss of coordination. Untreated cryptococcal meningitis is invariably fatal. Therapy requires prolonged systemic administration of antifungal agents. Cryptococcal pneumonia presents as diffuse progressive pulmonary disease.

HISTOPLASMOSIS

Histoplasmosis reflects an infection with *Histoplasma capsulatum.* ***The disease is usually self-limited but may lead to a systemic granulomatous disease.*** Most cases of histoplasmosis are asymptomatic, although progressive disseminated infections occur in people with impaired cell-mediated immunity. *H. capsulatum* is a dimorphic fungus of worldwide distribution, which grows as a mold at ambient temperatures and as a yeast in the body (37°C [98.6°F]). The yeast cell is round and has a central basophilic body surrounded by a clear zone or halo, which in turn is encircled by a rigid cell wall. In caseous lesions, silver impregnation identifies the remains of degenerating yeast forms.

EPIDEMIOLOGY: Histoplasmosis is acquired by inhalation of infectious spores of *H. capsulatum* (Fig. 9-55). The reservoir for the fungus is bird droppings and soil. In the Americas, hyperendemic areas are the eastern and central United States, western Mexico, Central America, the northern countries of South America and Argentina. In the tropics, bat nests, caves and soil beneath trees are foci of exposure.

PATHOPHYSIOLOGY: Histoplasmosis resembles tuberculosis in many ways. Primary infection begins with phagocytosis of microconidia by alveolar macrophages. Like *M. tuberculosis*, *H. capsulatum* reproduces in immunologically naive macrophages. As organisms grow, additional macrophages are recruited to the site of infection, producing an area of pulmonary consolidation. A few macrophages carry organisms first to hilar and mediastinal lymph nodes and then throughout the body, where fungi further infect monocytes/macrophages. The organisms proliferate within these cells

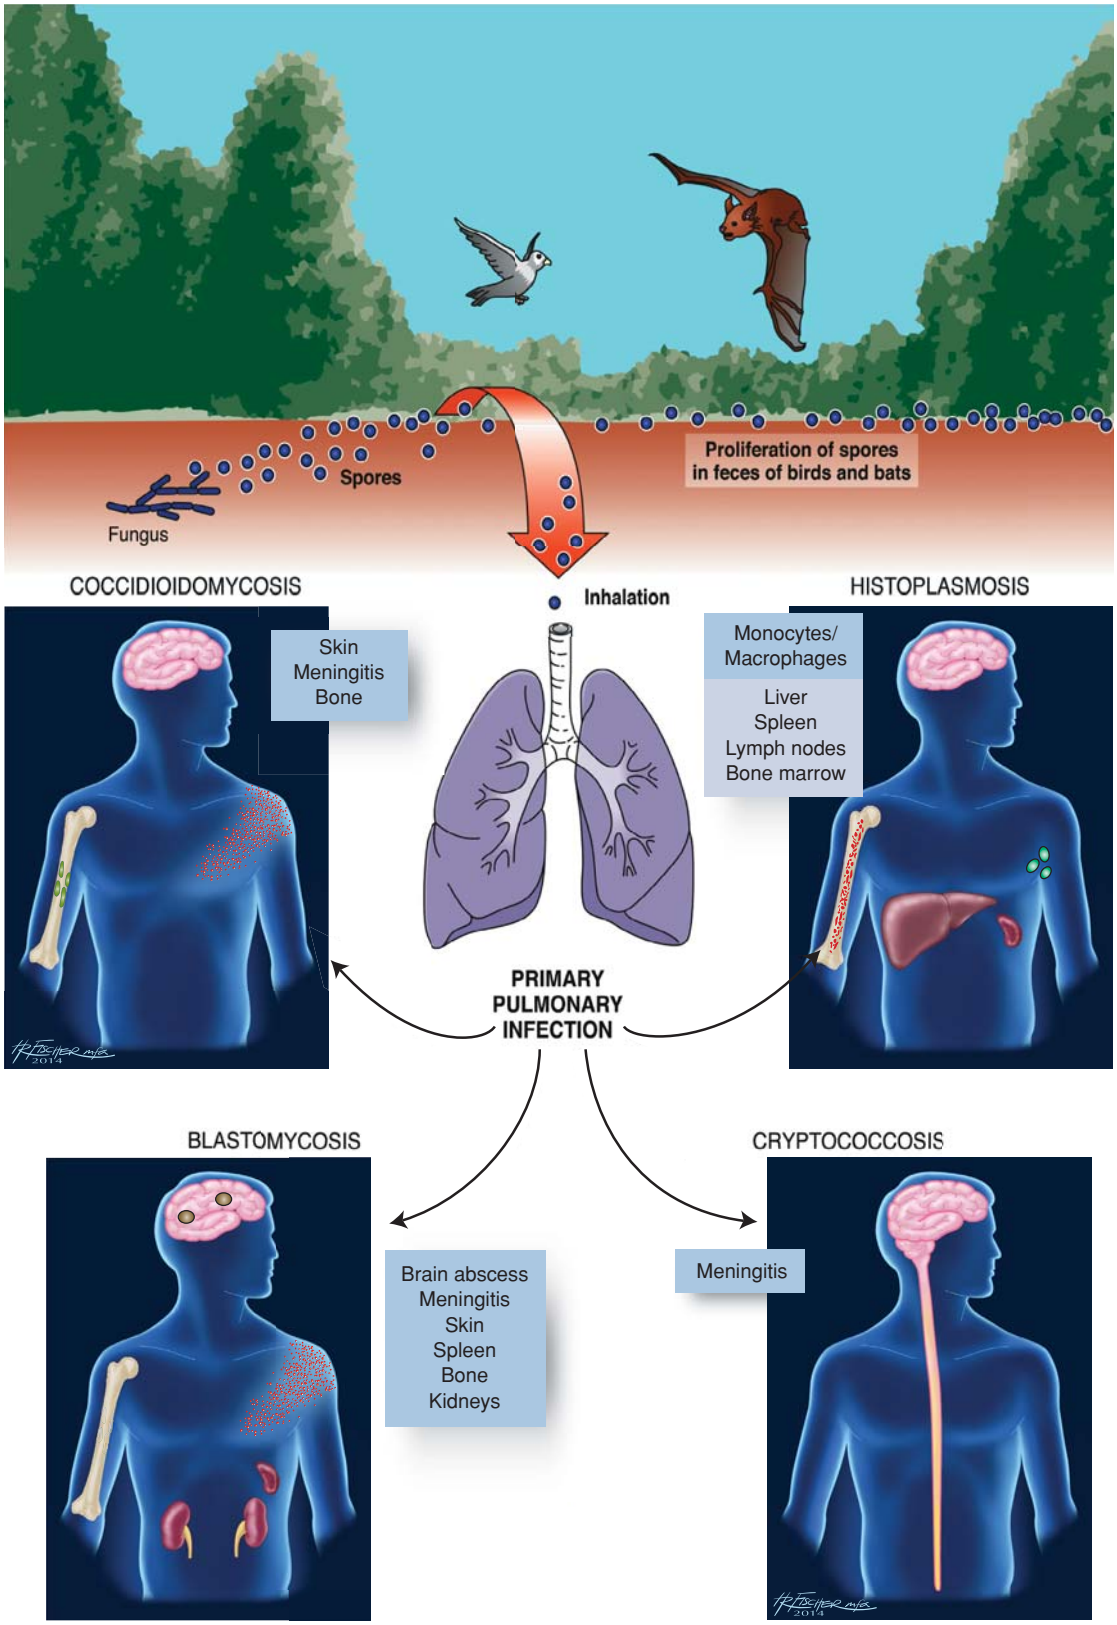

FIGURE 9-58. Pulmonary and disseminated fungal infection. Fungi grow in soil, air and the feces of birds and bats; they produce spores, some of which are infectious. When inhaled, spores cause primary pulmonary infection. In a few patients, the infection disseminates. **Histoplasmosis.** Primary infection is in the lung. In susceptible patients, the fungus disseminates to target organs, namely, the monocyte/macrophage system (liver, spleen, lymph nodes and bone marrow) and the tongue, mucous membranes of the mouth and the adrenals. **Cryptococcosis.** Primary infection of the lung disseminates to the meninges. **Blastomycosis.** Primary infection of the lung disseminates widely. The principal targets are the brain, meninges, skin, spleen, bone and kidney. **Coccidioidomycosis.** Primary infection of the lung may disseminate widely. The skin, meninges and bone are common targets.

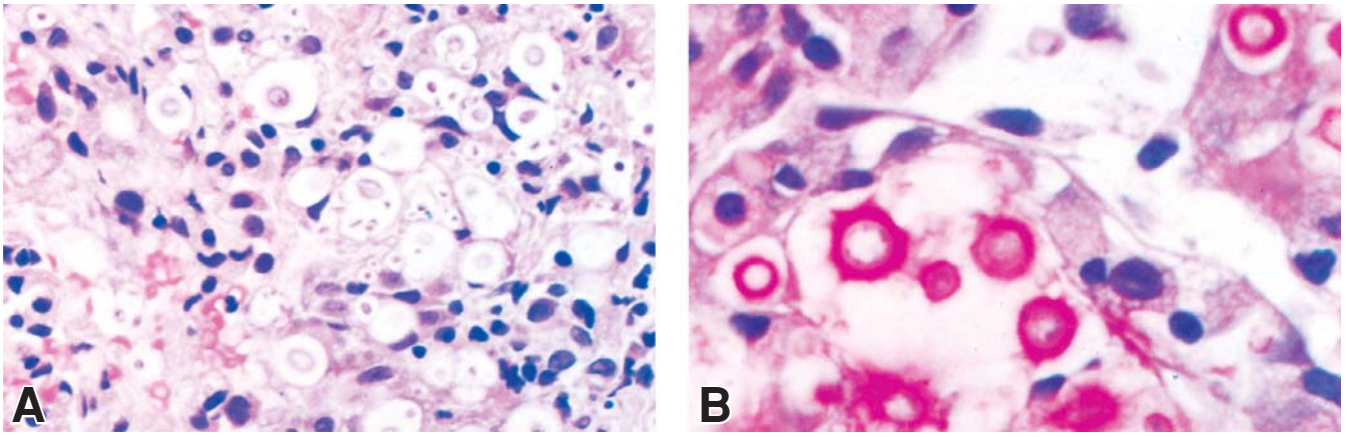

FIGURE 9-59. Cryptococcosis. A. In a section of the lung stained with hematoxylin and eosin, *Cryptococcus neoformans* appears as holes or bubbles. **B.** The same section stained with mucicarmine illustrates the capsule of the organism.

until the onset of hypersensitivity and cell-mediated immune responses, usually within 1–3 weeks. Normal immune responses usually limit the infection. Activated macrophages destroy the phagocytosed yeasts, forming necrotizing granulomas at sites of infection.

The course of infection varies with the size of the infecting inoculum and the immunologic competence of the host. Most infections (95%) involve small inocula of organisms in immunologically competent people. They affect small areas of the lung and regional lymph nodes and invariably remain unnoticed. On the other hand, exposure to a large inoculum, as occurs in an excavated bird roost, may lead to rapidly evolving pulmonary disease. Such cases feature large areas of pulmonary consolidation, prominent mediastinal and hilar nodal involvement and extension of the infection to the liver, spleen and bone marrow.

Disseminated histoplasmosis develops in people who do not mount an effective immune response to *H. capsulatum*. Infants, people with AIDS and patients treated with corticosteroids are at particular risk. In addition, on rare occasions individuals with no known underlying illness develop disseminated histoplasmosis.

PATHOLOGY: Acute self-limited histoplasmosis is characterized by necrotizing granulomas in the lung, mediastinal and hilar lymph nodes, spleen and liver. Early in infection, the caseous material is surrounded by macrophages, Langhans giant cells, lymphocytes and plasma cells. Yeast forms of *H. capsulatum* can be demonstrated within macrophages and in the caseous material. Eventually, the cellular components of the granuloma largely disappear and the caseous material calcifies, forming a "fibrocaseous nodule" (Fig. 9-60A).

Disseminated histoplasmosis is characterized by progressive organ infiltration with macrophages carrying *H. capsulatum* (Fig. 9-60B). In mild cases, immune responses can control the organism, but not eliminate it. For long periods, disease is largely confined to macrophages in infected organs. If the patient is immunocompromised, clusters of macrophages filled with *H. capsulatum* infiltrate the liver, spleen, lungs, intestine, adrenals and meninges.

CLINICAL FEATURES: Most infections are asymptomatic, but with extensive disease, patients present with fever, headache and cough. The symptoms persist for a few days to a few weeks, but the disease requires no therapy.

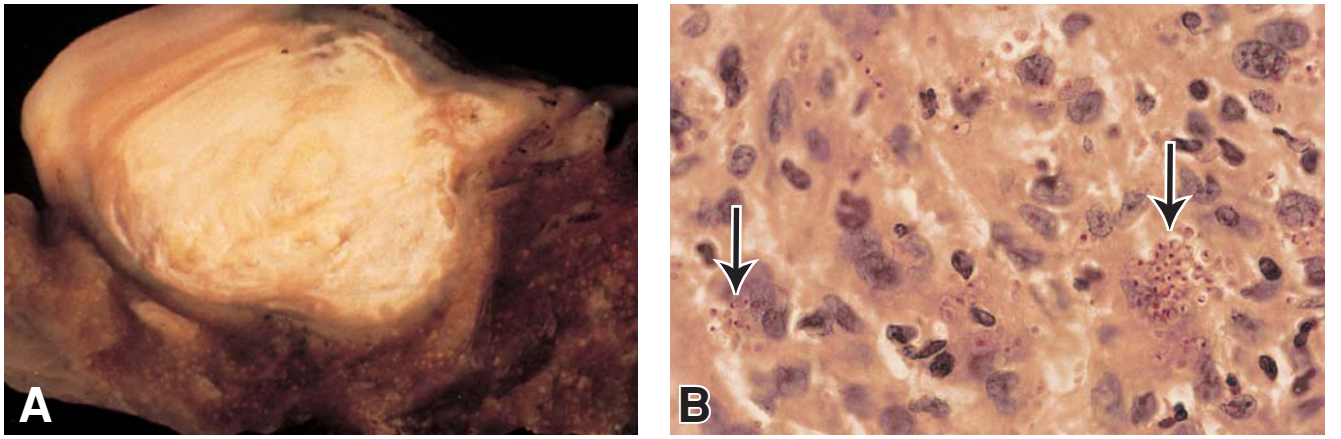

FIGURE 9-60. Histoplasmosis. A. A section of lung shows an encapsulated, subpleural, fibrocaseous nodule. **B.** A section of liver from a patient with disseminated histoplasmosis reveals Kupffer cells containing numerous yeasts of *Histoplasma capsulatum* (*arrows*) (periodic acid–Schiff [PAS] stain).

Disseminated histoplasmosis features weight loss, intermittent fever and weakness. In cases of subtle immunodeficiency, the disease may persist and progress for years, even decades. With more-profound immunodeficiency, dissemination progresses rapidly, often with high fever, cough, pancytopenia and changes in mental status. Disseminated histoplasmosis is treated with systemic antifungal agents.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is a chronic, necrotizing mycotic infection that clinically and pathologically resembles tuberculosis. The disease caused by *Coccidioides immitis* includes a spectrum of infections that begins as focal pneumonitis. Most cases are mild and asymptomatic and are limited to the lungs and regional lymph nodes. Occasionally, *C. immitis* infections spread outside the lungs to produce life-threatening disease.

EPIDEMIOLOGY AND ETIOLOGIC FACTORS: *C. immitis* is a dimorphic fungus that grows as a mold in the soil, where it forms spores. Inhaled spores reach the alveoli and terminal bronchioles, enlarge into spherules and then mature to form sporangia (30–60 µm across). These gradually fill with 1–5-µm endospores, which accumulate by endosporulation, a process unique among pathogenic fungi. The sporangia eventually rupture and release endospores, which then repeat the cycle.

C. immitis is found in the soil in restricted climatic regions, particularly the Lower Sonoran life zones of the Western Hemisphere. These are areas with sparse rainfall, hot summers and mild winters. In the United States, large portions of California, Arizona, New Mexico and Texas are natural habitats for *C. immitis.* The disease is particularly common in California's San Joaquin Valley, where it is called **"valley fever."** It also occurs in Mexico and parts of South America.

Long-term residents of endemic regions are almost always infected with *C. immitis.* Even brief visits to these areas can cause infection (usually asymptomatic). Dry, windy weather, which lifts spores into the air, favors infection. The disease is not contagious.

PATHOPHYSIOLOGY: Coccidioidomycosis begins with focal bronchopneumonia, where the spores are deposited. Mixed inflammatory infiltrates of neutrophils and macrophages follow, but the spores survive these immunologically naive inflammatory cells. As in tuberculosis and histoplasmosis, the host controls *C. immitis* infection only when inflammatory cells become immunologically activated. Necrotizing granulomas form with the onset of specific hypersensitivity and cell-mediated immune responses, which kills or contains the fungi.

The course of coccidioidomycosis varies from acute, self-limited disease to disseminated infection, depending on the size of the infecting dose and the immune status of the host. Coccidioidomycosis begins with focal bronchopneumonia. Most infections are produced by small inocula of organisms in immunologically competent hosts and are acute and self-limited. Extensive pulmonary involvement and fulminant disease may occur in persons from a nonendemic region exposed to large numbers of organisms.

Disseminated coccidioidomycosis occurs in immunocompromised people, from a primary infection or reactivation of old disease. Immunologically compromised patients are at greatest risk. Certain racial groups, including Filipinos, other Asians and blacks, are particularly susceptible to dissemination of coccidioidomycosis, probably because of a specific immunologic defect. For example, the risk of dissemination in Filipinos is 175 times that in whites. Pregnant women are also unusually susceptible to spread of the disease if they develop primary infection during the latter half of pregnancy.

PATHOLOGY: Acute self-limited coccidioidomycosis causes solitary lesions or patchy pulmonary consolidation, in which affected alveoli are infiltrated by neutrophils and macrophages. *C. immitis* spherules elicit an infiltrate of macrophages, whereas endospores predominantly attract neutrophils. Once an immune reaction begins, necrotizing, caseous granulomas develop. Successful immune responses cause the granuloma to heal, sometimes leaving a fibrocaseous nodule composed of caseous material and rimmed by residual macrophages and a thin capsule. In contrast to histoplasmosis, old granulomas of coccidioidomycosis rarely calcify.

The spherules and endospores of *C. immitis* stain with hematoxylin and eosin (Fig. 9-61). Spherules in various stages of development appear as basophilic rings. Mature spherules (sporangia) contain endospores that appear as smaller basophilic rings. As in other fungal infections, PAS and GMS stains can be used to enhance the staining of *C. immitis.*

Disseminated coccidioidomycosis may involve almost any body site and may manifest as a single extrathoracic site or as widespread disease, involving the skin (Fig. 9-62), bones, meninges, liver, spleen and genitourinary tract. Inflammatory responses at sites of dissemination are highly variable, ranging from infiltrates of neutrophils to granulomas.

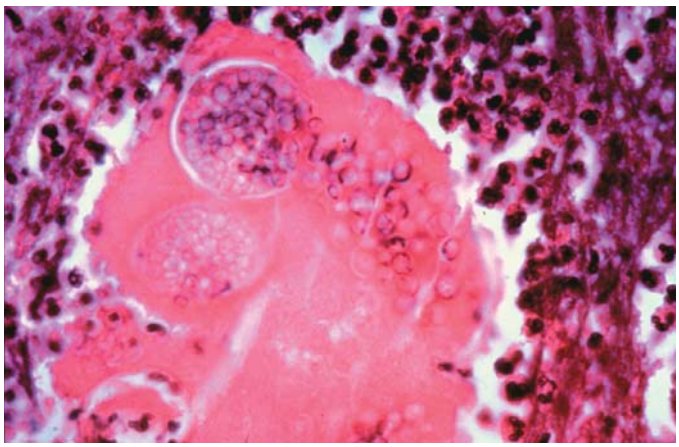

FIGURE 9-61. Coccidioidomycosis. A photomicrograph of the lung from a patient with acute coccidioidal pneumonia shows two spherules containing numerous endospores of *Coccidioides immitis.*

FIGURE 9-62. Disseminated coccidioidomycosis. A single raised, central ulcerated lesion is present on the face.

CLINICAL FEATURES: Coccidioidomycosis is a disease of protean manifestations, which vary from a subclinical respiratory infection to one that disseminates and is rapidly fatal. Like syphilis and typhoid fever, this disease is a great imitator; almost any complaint or syndrome may be its initial presentation.

Most people with coccidioidomycosis (>60%) are asymptomatic. The others develop a flu-like syndrome, with fever, cough, chest pain and malaise. Infection usually resolves spontaneously. Cavitation is the most frequent complication of pulmonary coccidioidomycosis, although it fortunately occurs in only few patients (<5%). The cavity, which may be mistaken for tuberculosis, is usually solitary and may persist for years. Progression or reactivation may lead to destructive lesions in the lungs or, more seriously, to disseminated lesions.

The signs and symptoms of disseminated coccidioidomycosis vary according to the site affected. Coccidioidal meningitis manifests with headache, fever, alteration in mental status or seizures and is fatal if untreated. Skin lesions in disseminated disease often have a warty appearance (Fig. 9-62). Even with prolonged amphotericin B therapy, the prognosis is poor in acute disseminated coccidioidomycosis, although the response rate has been improved with some of the newer azole antifungal agents.

BLASTOMYCOSIS

Blastomycosis is a chronic granulomatous and suppurative pulmonary disease, which is often followed by dissemination to other body sites, principally the skin and bone. The causative organism, *Blastomyces dermatitidis,* is a dimorphic fungus that grows as a mold in warm moist soil, rich in decaying vegetable matter.

EPIDEMIOLOGY: Blastomycosis is acquired by inhalation of infectious spores from the soil. The infection occurs within restricted geographic regions of the Americas, Africa and possibly the Middle East. In North America, the fungus is endemic along the distributions of the Mississippi and Ohio Rivers, the Great Lakes and the St. Lawrence River. Disturbance of the soil, either by construction or by leisure activities such as hunting or camping, leads to formation of aerosols containing fungal spores.

PATHOPHYSIOLOGY: Inhaled spores of *B. dermatitidis* germinate to form yeasts, which reproduce by budding. The host responds to the proliferating organisms with neutrophils and macrophages, producing a focal bronchopneumonia. However, organisms persist until the onset of specific hypersensitivity and cell-mediated immunity, when activated neutrophils and macrophages kill them.

PATHOLOGY: Blastomycosis is usually confined to the lungs, where infection mostly produces small areas of consolidation. *B. dermatitidis* incites a mixed suppurative and granulomatous inflammatory response and, even in the same patient, lesions range from neutrophilic abscesses to epithelioid granulomas. Pulmonary disease usually resolves by scarring, but some patients develop progressive miliary lesions or cavities. The skin (>50%) and bones (>10%) are the most common sites of extrapulmonary involvement. Skin infection often elicits marked pseudoepitheliomatous hyperplasia, imparting a warty appearance to the lesions.

Infected areas contain numerous yeasts of *B. dermatitidis,* which are spherical and 8–14 µm across, with broad-based buds and multiple nuclei in a central body (Fig. 9-63). With hematoxylin and eosin stains, the yeasts are rings with thick, sharply defined cell walls. They may be found in epithelioid cells, macrophages or giant cells, or they may lie free in microabscesses.

CLINICAL FEATURES: Pulmonary blastomycosis is self-limited in one third of cases. Symptomatic acute infection presents as a flu-like illness, with fever, arthralgias and myalgias. Progressive pulmonary disease is characterized by low-grade fever, weight loss, cough and predominantly upper lobe infiltrates on the chest radiograph. Skin lesions often resemble squamous cell carcinomas of the skin (Fig. 9-64) and are the most common signs of extrapulmonary dissemination. Although the lung infection may appear to resolve totally, in some patients blastomycosis may appear at distant sites months to years later.

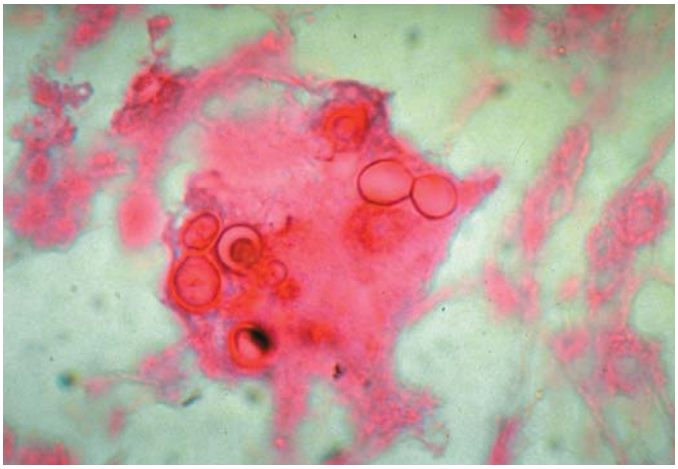

FIGURE 9-63. Blastomycosis. The yeasts of *Blastomyces dermatitidis* have a doubly contoured wall and nuclei in the central body. The buds have broad-based attachments.

FIGURE 9-64. Cutaneous blastomycosis with ulceration.

PARACOCCIDIOIDOMYCOSIS (SOUTH AMERICAN BLASTOMYCOSIS)

Paracoccidioidomycosis is a chronic granulomatous infection that begins with lung involvement and disseminates to involve skin, oropharynx, adrenals and the macrophages of the liver, spleen and lymph nodes. The causative organism is *Paracoccidioides brasiliensis*, a dimorphic fungus, whose mold form resides in the soil.

EPIDEMIOLOGY: Paracoccidioidomycosis is acquired by inhaling spores from the environment in restricted regions of Central and South America. Most infections are asymptomatic. Reactivation of latent infection occurs, and active disease can develop many years after someone leaves an endemic region. Interestingly, men develop symptomatic infections 15 times more often than women.

PATHOLOGY: Paracoccidioidomycosis can involve the lungs alone (Fig. 9-65) or multiple extrapulmonary sites, most commonly skin, mucosal surfaces and lymph nodes. *P. brasiliensis* elicits a mixed suppurative and granulomatous response, producing lesions similar to those seen in blastomycosis and coccidioidomycosis.

CLINICAL FEATURES: Paracoccidioidomycosis is usually an acute, self-limited and mild disease. Symptoms of progressive pulmonary involvement resemble those of tuberculosis. Chronic mucocutaneous ulcers are a frequent manifestation of extrapulmonary disease.

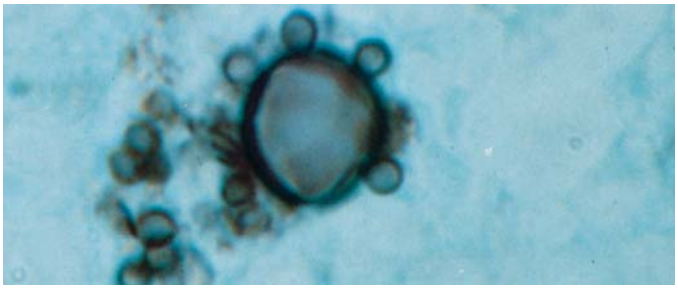

FIGURE 9-65. Paracoccidioidomycosis. The lung contains *Paracoccidioides braziliensis*, which displays many external buds arising circumferentially from the mother organism.

SPOROTRICHOSIS

Sporotrichosis is a chronic infection of the skin, subcutaneous tissues and regional lymph nodes caused by *Sporothrix schenckii*. This dimorphic fungus grows as a mold in soil and decaying plant matter and as yeast in the body.

EPIDEMIOLOGY: Sporotrichosis is endemic in parts of the Americas and southern Africa. Most cases are cutaneous, resulting from accidental inoculation of the fungus from thorns (especially rose thorns) or splinters, or by handling reeds or grasses. Cutaneous sporotrichosis is particularly common among gardeners, botanical nursery workers and others who suffer abrasions while working with soil, moss, hay or timbers. Infected animals, particularly cats, can also transmit the disease.

PATHOLOGY: On entry into the skin, *S. schenckii* proliferates locally, eliciting an inflammatory response that produces an ulceronodular lesion. The infection frequently spreads along subcutaneous lymphatic channels, resulting in a chain of similar nodular skin lesions (Fig. 9-66A). Extracutaneous disease is much less common than skin disease. Joint and bone involvement is the commonest form of extracutaneous disease, and infections of the wrist, elbow, ankle or knee account for most (80%) of the cases.

The lesions of cutaneous sporotrichosis are usually in the dermis or subcutaneous tissue. The periphery of the nodules is granulomatous and the center is suppurative. Surrounding skin shows exuberant pseudoepitheliomatous hyperplasia. Some yeasts are surrounded by an eosinophilic, spiculated zone and are termed "asteroid bodies" (Fig. 9-66B). The material surrounding the yeasts ("Splendore-Hoeppli substance") probably consists of antigen–antibody complexes.

CLINICAL FEATURES: Cutaneous sporotrichosis begins as a solitary nodular lesion at the site of inoculation, typically on a hand, arm or leg. Weeks afterward, additional nodules may appear along the lymphatic drainage of the primary lesion. Nodules often ulcerate and drain serosanguineous fluid. Joint involvement appears as pain and swelling of the affected joint, without involving overlying skin. Untreated cutaneous sporotrichosis continues to spread along the skin. The skin infection responds to systemic iodine therapy, but extracutaneous sporotrichosis requires systemic antifungal therapy.

CHROMOMYCOSIS

Chromomycosis is a chronic skin infection caused by several species of fungi that live as saprophytes in soil and decaying vegetable matter. The fungi are brown, round, thick walled and 8 μm across, and have been likened to "copper pennies" (Fig. 9-67). The infection is most common in barefooted agricultural workers in the tropics, in whom the fungus is implanted by trauma, usually below the knee. The lesions begin as papules and over the years become verrucous,

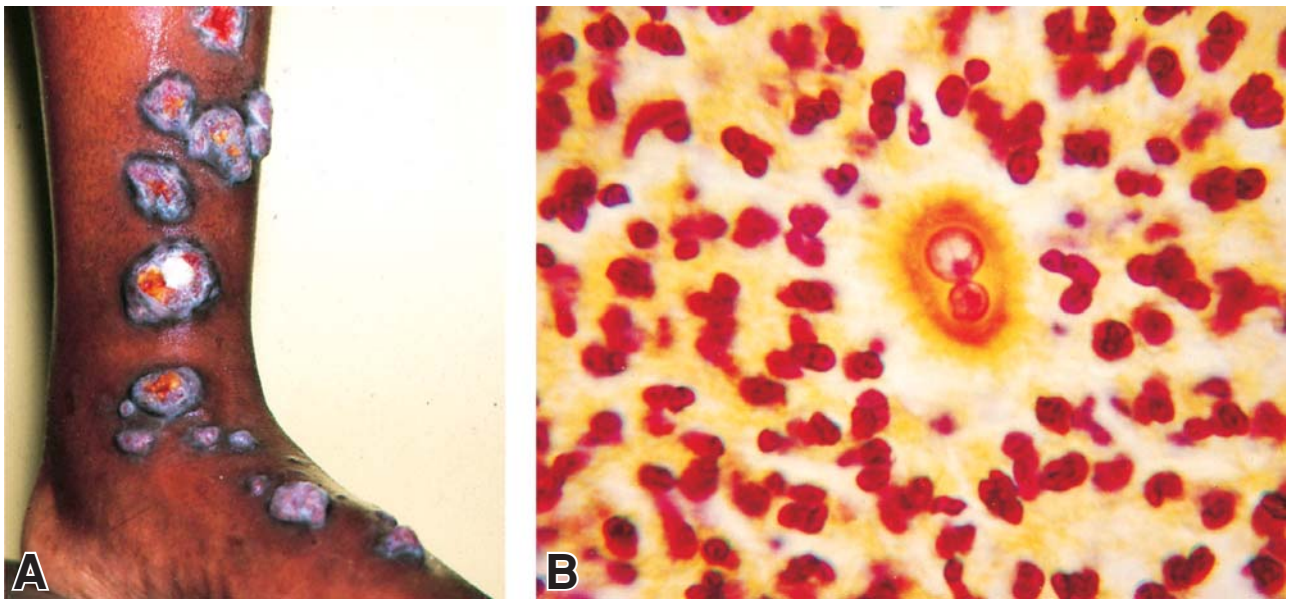

FIGURE 9-66. Sporotrichosis. A. The leg shows typical lymphocutaneous spread. **B.** A section of the lesion in **(A)** shows an asteroid body, composed of a pair of budding yeasts of *Sporothrix schenckii* surrounded by a layer of Splendore-Hoeppli substance, with radiating projections.

crusted and sometimes ulcerated. The infection spreads by contiguous growth and through lymphatics, and eventually may involve an entire limb.

DERMATOPHYTE INFECTIONS

Dermatophytes are fungi that cause localized superficial infections of keratinized tissues, including skin, hair and nails. There are about 40 species of dermatophytes in 3 genera: *Trichophyton, Microsporum* and *Epidermophyton*. ***Dermatophyte infections are minor illnesses, but are among the most common skin diseases for which medical help is sought.*** They are resident in soil, on animals and on humans. Most dermatophyte infections in temperate countries are acquired by direct contact with people who have infected hairs or skin scales.

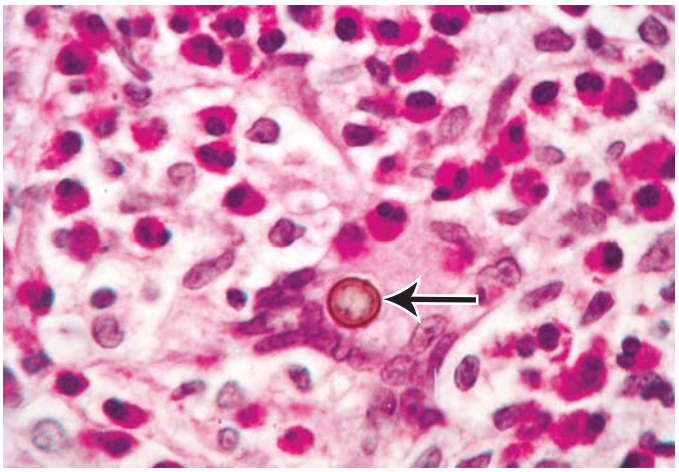

FIGURE 9-67. Chromomycosis. A section of skin shows a giant cell in the center, which contains a thick-walled, brown, sclerotic body (copper penny, *arrow*), representing the fungus.

PATHOLOGY: Dermatophytes proliferate within the superficial keratinized tissues. They spread centrifugally from the initial site, producing round, expanding lesions with sharp margins. The appearance once suggested that a worm was responsible for the disease, hence the names **ringworm** and **tinea** (from the Latin *tinea*, "worm").

Dermatophyte infections produce thickening of the squamous epithelium, with increased numbers of keratinized cells. Lesions severe enough to be biopsied show a mild lymphocytic inflammatory infiltrate in the dermis. Hyphae and spores of the infecting dermatophytes are confined to the nonviable portions of skin, hair and nails.

CLINICAL FEATURES: Dermatophyte infections are named according to the sites of involvement (e.g., scalp, tinea capitis; feet, tinea pedis, "athlete's foot"; nails, tinea unguium; intertriginous areas of the groin, tinea cruris, "jock itch"). These infections range from asymptomatic disease to chronic, fiercely pruritic eruptions and are treated with topical antifungal agents.

MYCETOMA

A mycetoma is a slowly progressive, localized and often disfiguring infection of the skin, soft tissues and bone produced by inoculation of various soil-dwelling fungi and filamentous bacteria. Responsible organisms include *Madurella mycetomatis, Petrilidium boydii, Actinomadura madurae* and *Nocardia brasiliensis*.

EPIDEMIOLOGY: Mycetoma usually occurs in the tropics among farmers and outdoor laborers whose skin is exposed to trauma. The foot is a common site of infection in locales where persons walk barefoot on soggy ground, and the disease is also known as **Madura foot**. Frequent immersion of the foot macerates the skin and facilitates deep inoculation with soil organisms.

FIGURE 9-68. Mycetoma of the foot. The foot is swollen and painful and drains through the skin. The extremity was amputated.

PATHOLOGY: The organisms proliferate in the subcutis and spread to adjacent tissues, including bone. This incites a mixed suppurative and granulomatous inflammatory infiltrate, which fails to eliminate the infecting organism. Surrounding granulation tissue and scarring produce progressive disfigurement of the affected sites.

A mycetoma begins as a solitary subcutaneous abscess and slowly expands to form multiple abscesses interconnected by sinus tracts (Fig. 9-68), which eventually drain to the skin surface. Abscesses contain colonies of compact bacteria or fungi, surrounded by neutrophils and an outer layer of granulomatous inflammation. The colonies of organisms, called "grains," resemble the "sulfur granules" of actinomycosis.

CLINICAL FEATURES: A mycetoma initially manifests as a painless, localized swelling at a site of penetrating injury. The lesion slowly expands and produces sinus tracts that tend to follow fascial planes in their lateral and deep spread through connective tissue, muscle and bone. Treatment is usually wide excision of the affected area.

Protozoal Infections

Protozoa are single-celled eukaryotes that fall into three general classes: **amebae, flagellates** and **sporozoites**. Amebae move by projection of cytoplasmic extensions termed **pseudopoda**. Flagellates move through thread-like structures, flagella, which extend out from the cell membrane. Sporozoites do not have organelles of locomotion and also differ from amebae and flagellates in their mode of replication.

Protozoa cause human disease by diverse mechanisms. Some, such as *Entamoeba histolytica,* are extracellular parasites that digest and invade human tissues. Others, such as plasmodia, are obligate intracellular parasites that replicate in, and kill, human cells. Still others, such as trypanosomes, damage human tissue largely by inflammatory and immunologic responses. Some protozoa (e.g., *Toxoplasma gondii*) can establish latent infections and cause reactivation disease in immunocompromised hosts.

MALARIA

Malaria is a mosquito-borne, hemolytic, febrile illness. It affects over 200 million people worldwide and kills more than 1 million yearly. Four *Plasmodium* species cause malaria: *Plasmodium falciparum, Plasmodium vivax, Plasmodium ovale* and *Plasmodium malariae.* All infect and destroy human erythrocytes, producing chills, fever, anemia and splenomegaly. *P. falciparum* causes more severe disease than the others and accounts for most malarial deaths.

EPIDEMIOLOGY: Although malaria has been eradicated in developed countries, it continues to afflict people in tropical and subtropical areas, especially Africa, South and Central America, India and Southeast Asia (Fig. 9-69). The rural poor, infants, children, malnourished people and pregnant women are especially susceptible to infection.

Malaria is transmitted by the bite of the female *Anopheles* mosquito. *P. falciparum* and *P. vivax* are the most common pathogens, but there is considerable geographic variation in species distribution. *P. vivax* is rare in Africa, where much of the black population lacks the erythrocyte cell surface receptors required for infection. *P. falciparum* and *P. ovale* are the predominant species in Africa. *P. malariae* is the least common and mildest form of malaria, although it has a broad geographic distribution.

ETIOLOGIC FACTORS: The life cycle of the *Plasmodium* species responsible for human malaria requires both human and mosquito hosts (Fig. 9-70). Infected humans produce forms of the organism (gametocytes) that mosquitoes acquire upon feeding. Within these insects, the organism reproduces sexually, producing plasmodial forms (sporozoites), which the mosquito transmits to humans when it feeds.

The anopheline mosquito inoculates the sporozoites into the human bloodstream. There, they undergo asexual division ("schizogony"). Circulating sporozoites rapidly invade hepatocytes and reproduce in the liver, yielding numerous daughter organisms, termed "merozoites" (exoerythrocytic phase). Within 2–3 weeks of hepatic infection, these agents rupture host hepatocytes, exit into the bloodstream and invade erythrocytes.

Merozoites feed on hemoglobin and grow and reproduce inside erythrocytes. Within 2–4 days, mature progeny merozoites are produced. These daughter merozoites burst from infected erythrocytes, invade naive red cells and so initiate another cycle of erythrocytic parasitism. This cycle is repeated many times. Eventually, subpopulations of merozoites differentiate into sexual forms called gametocytes, which are ingested when a mosquito feeds on an infected host, thus completing the parasite's life cycle.

The rupture of infected erythrocytes releases pyrogens and causes the chills and fever of malaria. Anemia results both from loss of circulating infected erythrocytes and sequestration of cells in the enlarging spleen. The fixed mononuclear phagocytes of the liver and spleen respond to the infestation by proliferating and causing enlargement of the liver and spleen.

FIGURE 9-69. The geographic distribution of malaria.

P. falciparum infestation produces **malignant malaria,** a much more aggressive disease than the other plasmodia. It is distinguished from other malarial parasites in four respects:

- It has no secondary exoerythrocytic (hepatic) stage.
- It parasitizes erythrocytes of any age, causing marked parasitemia and anemia. In other types of malaria, only subpopulations of erythrocytes (e.g., only young or old forms) are parasitized, leading to lower-level parasitemias and more modest anemias.
- There may be several parasites in a single red cell.
- *P. falciparum* alters flow characteristics and adhesive properties of infected erythrocytes, so that they adhere to endothelial cells of small blood vessels. Obstruction of small blood vessels frequently produces severe tissue ischemia, which is probably the most important factor in the organism's virulence.

PATHOLOGY: All forms of malaria show hepatosplenomegaly, as red blood cells are sequestered by fixed mononuclear phagocytes. The organs of this system (liver, spleen, lymph nodes) are darkened ("slate gray") by macrophages filled with hemosiderin and malarial pigment, the end-product of parasitic digestion of hemoglobin.

Adherence of infected red cells to microvascular endothelium in falciparum malaria has two consequences. First, parasitized erythrocytes attached to endothelial cells do not circulate, so patients with severe falciparum malaria have few circulating parasites. Second, capillaries of deep organs, especially the brain, become obstructed, leading to ischemia of the brain, kidneys and lungs. Brains of patients who die of cerebral malaria show congestion and thrombosis of small blood vessels in the white matter, which are rimmed with edema and hemorrhage ("ring hemorrhages") (Fig. 9-71). Obstruction of renal blood flow produces acute renal failure, while intravascular hemolysis results in hemoglobinuric nephrosis **(blackwater fever)**. In the lung, damage to alveolar capillaries generates pulmonary edema and acute alveolar damage.
